Chapter 15

This edition of the textbook is dedicated to the memory of Dr. Mary Amdur, who was a coeditor on editions two through four.

Mary Amdur received her B.S. in Chemistry from the University of Pittsburgh in 1943, and, in just three years, was awarded the Ph.D. in Biochemistry from Cornell. She spent her academic career at the Harvard School of Public Health (1949–1977), Massachusetts Institute of Technology (1977–1989), and the Institute of Environmental Medicine of New York University in Tuxedo Park, New York (1989–1996). She died in February 1998 while flying home from a vacation in Hawaii.

Dr. Amdur was a distinguished toxicologist in the area of air pollution. Her research accomplishments provided seminal contributions to our understanding of the effects of gases and particles on human and animal lungs. She contributed to our knowledge of the adverse effects of sulfuric acid mists and mixtures of gases and particles in the lung. This work had a major role in the establishment of national and international air pollution standards. Her career in toxicology was uniquely distinguished and profound in its impact on public policy and public health.

Dr. Amdur made these accomplishments at a time in which science was strongly male-dominated. Her research career was impaired by a number of barriers, because of this environment (Costa and Gordon, *Toxicol Sc*, 56: 5–7, 2000). In fact, she never was awarded a tenure position at any of the three academic positions where she did her outstanding research.

Dr. Amdur received a number of awards throughout her career. These included the 1974 Donald E. Cummings Memorial Award from the American Industrial Hygiene Association, the 1984 Henry F. Smyth Award from the American Academy of Industrial Hygiene, the 1986 Career Achievement Award from the Inhalation Section of the Society of Toxicology, and the 1989 Herbert E. Stockinger Award from the American Conference of Governmental Industrial Hygienists. In 1997, she became the first woman to receive the Merit Award from the Society of Toxicology.

For those of us who were fortunate to work with Mary Amdur, we will remember not only her scientific accomplishments but also her wit, demeanor, and absolute honesty.

EDITOR

Professor of Pharmacology and Toxicology
Department of Pharmacology, Toxicology, and Therapeutics
University of Kansas Medical Center
Kansas City, Kansas

NOTICE

PREFACE

The sixth edition of *Casarett and Doull's Toxicology: The Basic Science of Poisons* marks its silver anniversary. The sixth edition, as the previous five, is meant to serve primarily as a text for, or an adjunct to, graduate courses in toxicology. Because the five previous editions have been widely used in courses in environmental health and related areas, an attempt has been made to maintain those characteristics that make it useful to scientists from other disciplines. This edition will again provide information on the many facets of toxicology and especially on the principles, concepts, and modes of thought that are the foundation of the discipline. Mechanisms of toxicity are emphasized. Research toxicologists will find this book an excellent reference source to find updated material in areas of their special or peripheral interests.

The overall framework of the sixth edition is similar to the fifth edition. The seven units are "General Principles of Toxicology" (Unit 1), "Disposition of Toxicants" (Unit 2), "Non-Organ-Directed Toxicity" (carcinogenicity, mutagenicity, and teratogenicity) (Unit 3), "Target Organ Toxicity" (Unit 4), "Toxic Agents" (Unit 5), "Environmental Toxicology" (Unit 6), and "Applications of Toxicology" (Unit 7).

The sixth edition reflects the marked progress made in toxicology the last few years. For example, the importance of apoptosis, cytokines, growth factors, oncogenes, cell cycling, receptors, gene regulation, transcription factors, signaling pathways, transgenic animals, "knock-out" animals, polymorphisms, microarray technology, genomics, proteonomics, etc., in understanding the mechanisms of toxicity are included in this edition. More information on risk assessment is also included. References in this edition include not only traditional journal and review articles, but, for the first time, internet sites.

The editor is grateful to his colleagues in academia, industry, and government who have made useful suggestions for improving this edition, both as a book and as a reference source. The editor is especially thankful to all the contributors, whose combined expertise has made possible a volume of this breadth. I especially recognize John Doull, the original editor of this book, for his continued support.

PREFACE TO THE FIRST EDITION

This volume has been designed primarily as a textbook for, or adjunct to, courses in toxicology. However, it should also be of interest to those not directly involved in toxicologic education. For example, the research scientist in toxicology will find sections containing current reports on the status of circumscribed areas of special interest. Those concerned with community health, agriculture, food technology, pharmacy, veterinary medicine, and related disciplines will discover the contents to be most useful as a source of concepts and modes of thought that are applicable to other types of investigative and applied sciences. For those further removed from the field of toxicology or for those who have not entered a specific field of endeavor, this book attempts to present a selectively representative view of the many facets of the subject.

Toxicology: The Basic Science of Poisons has been organized to facilitate its use by these different types of users. The first section (Unit I) describes the elements of method and approach that identify toxicology. It includes those principles most frequently invoked in a full understanding of toxicologic events, such as dose-response, and is primarily mechanistically oriented. Mechanisms are also stressed in the subsequent sections of the book, particularly when these are well identified and extend across classic forms of chemicals and systems. However, the major focus in the second section (Unit II) is on the systemic site of action of toxins. The intent therein is to provide answers to two questions: What kinds of injury are produced in specific organs or systems by toxic agents? What are the agents that produce these effects?

A more conventional approach to toxicology has been utilized in the third section (Unit III), in which the toxic agents are grouped by chemical or use characteristics. In the final section (Unit IV) an attempt has been made to illustrate the ramifications of toxicology into all areas of the health sciences and even beyond. This unit is intended to provide perspective for the nontoxicologist in the application of the results of toxicologic studies and a better understanding of the activities of those engaged in the various aspects of the discipline of toxicology.

It will be obvious to the reader that the contents of this book represent a compromise between the basic, fundamental, mechanistic approach to toxicology and the desire to give a view of the broad horizons presented by the subject. While it is certain that the editors' selectivity might have been more severe, it is equally certain that it could have been less so, and we hope that the balance struck will prove to be appropriate for both toxicologic training and the scientific interest of our colleague.

L.J.C.
J.D.

Although the philosophy and design of this book evolved over a long period of friendship and mutual respect between the editors, the effort needed to convert ideas into reality was undertaken primarily by Louis J. Casarett. Thus, his death at a time when completion of the manuscript was in sight was particularly tragic. With the help and encouragement of his wife, Margaret G. Casarett, and the other contributors, we have finished Lou's task. This volume is a fitting embodiment of Louis J. Casarett's dedication to toxicology and to toxicologic education.

J.D.

CHAPTER 1

HISTORY AND SCOPE OF TOXICOLOGY

Michael A. Gallo

Toxicology has been defined as the study of the adverse effects of xenobiotics and thus is a borrowing science that has evolved from ancient poisoners. Modern toxicology goes beyond the study of the adverse effects of exogenous agents to the study of molecular biology, using toxicants as tools. Historically, toxicology formed the basis of therapeutics and experimental medicine. Toxicology in this century (1900 to the present) continues to develop and expand by assimilating knowledge and techniques from most branches of biology, chemistry, mathematics, and physics. A recent addition to the field of toxicology (1975 to the present) is the application of the discipline to safety evaluation and risk assessment.

The contributions and activities of toxicologists are diverse and widespread. In the biomedical area, toxicologists are concerned with mechanisms of action and exposure to chemical agents as a cause of acute and chronic illness. Toxicologists contribute to physiology and pharmacology by using toxic agents to understand physiological phenomena. They are involved in the recognition, identification, and quantification of hazards resulting from occupational exposure to chemicals and the public health aspects of chemicals in air, water, other parts of the environment, foods, and drugs. Traditionally, toxicologists have been intimately involved in the discovery and development of new drugs and pesticides. Toxicologists also participate in the development of standards and regulations designed to protect human health and the environment from the adverse effects of chemicals. Environmental toxicologists (a relatively new subset of the discipline) have expanded toxicology to study the effects of chemicals in flora and fauna. Molecular toxicologists are studying the mechanisms by which toxicants modulate cell growth and differentiation and cells respond to toxicants at the level of the gene. In all branches of toxicology, scientists explore the mechanisms by which chemicals produce adverse effects in biological systems. Clinical toxicologists develop antidotes and treatment regimes to ameliorate poisonings and xenobiotic injury. Toxicologists carry out some or all of these activities as members of academic, industrial, and governmental organizations. In doing so, they share methodologies for obtaining data about the toxicity of materials and the responsibility for using this information to make reasonable predictions regarding the hazards of the material to people and the environment. These different but complementary activities characterize the discipline of toxicology.

Toxicology, like medicine, is both a science and an art. The science of toxicology is defined as the observational and data-gathering phase, whereas the art of toxicology consists of the utilization of the data to predict outcomes of exposure in human and animal populations. In most cases, these phases are linked because the facts generated by the science of toxicology are used to develop extrapolations and hypotheses to explain the adverse effects of chemical agents in situations where there is little or no information. For example, the observation that the administration of TCDD (2,3,7,8-tetrachlorodibenzo- *p*-dioxin) to female Sprague-Dawley rats induces hepatocellular carcinoma is a fact. However, the conclusion that it will also do so in humans is a prediction or hypothesis. It is important to distinguish facts from predictions. When we fail to distinguish the science from the art, we confuse facts with predictions and argue that they have equal validity, which they clearly do not. In toxicology, as in all sciences, theories have a higher level of certainty than do hypotheses, which in turn are more certain than speculations, opinions, conjectures, and guesses. An insight into modern toxicology and the roles, points of view, and activities of toxicologists can be obtained by examining the historical evolution of the discipline.

HISTORY OF TOXICOLOGY

Antiquity

Toxicology dates back to the earliest humans, who used animal venoms and plant extracts for hunting, warfare, and assassination. The knowledge of these poisons must have predated recorded history. It is safe to assume that prehistoric humans categorized some plants as harmful and others as safe. The same is probably true for the classification of snakes and other animals. The Ebers papyrus (circa 1500 B.C.) contains information pertaining to many recognized poisons, including hemlock (the state poison of the Greeks), aconite (a Chinese arrow poison), opium (used as both a poison and an antidote), and metals such as lead, copper, and antimony. There is also an indication that plants containing substances similar to digitalis and belladonna alkaloids were known. Hippocrates (circa 400 B.C.) added a number of poisons and clinical toxicology principles pertaining to bioavailability in therapy and overdosage, while the Book of Job (circa 400 B.C.) speaks of poison arrows (Job 6:4). In the literature of ancient Greece, there are several references to poisons and their use. Some interpretations of Homer have Odysseus obtaining poisons for his arrows (Homer, circa 600 B.C.). Theophrastus (370–286 B.C.), a student of Aristotle, included numerous references to poisonous plants in *De Historia Plantarum*. Dioscorides, a Greek physician in the court of the Roman emperor Nero, made the first attempt at a classification of poisons, which was accompanied by descriptions and drawings. His classification into plant, animal, and mineral poisons not only remained a standard for 16 centuries but is still a convenient classification (Gunther, 1934). Dioscorides also dabbled in therapy, recognizing the use of emetics in poisoning and the use of caustic agents and cupping glasses in snakebite. Poisoning with plant and animal toxins was quite common. Perhaps the best-known recipient of poison used as a state method of execution was Socrates (470–399 B.C.), whose cup of hemlock extract was apparently estimated to be the proper dose. Expeditious suicide on a voluntary basis also made use of toxicologic knowledge. Demosthenes (385– 322 B.C.), who took poison hidden in his pen, was one of many examples. The mode of suicide calling for one to fall on his sword, although manly and noble, carried little appeal and less significance for the women of the day. Cleopatra's (69–30 B.C.) knowledge of natural primitive toxicology permitted her to use the more genteel method of falling on her asp.

The Romans too made considerable use of poisons in politics. One legend tells of King Mithridates VI of Pontus, whose numerous acute toxicity experiments on unfortunate criminals led to his eventual claim that he had discovered an antidote for every venomous reptile and poisonous substance (Guthrie, 1946). Mithridates was so fearful of poisons that he regularly ingested a mixture of 36 ingredients (Galen reports 54) as protection against assassination. On the occasion of his imminent capture by enemies, his attempts to kill himself with poison failed because of his successful antidote concoction, and he was forced to use a sword held by a servant. From this tale comes the term "mithridatic," referring to an antidotal or protective mixture. The term "theriac" also has become synonymous with "antidote," although the word comes from the poetic treatise *Theriaca* by Nicander of Colophon (204–135 B.C.), which dealt with poisonous animals; his poem "Alexipharmaca" was about antidotes.

Poisonings in Rome reached epidemic proportions during the fourth century B.C. (Livy). It was during this period that a conspiracy of women to remove men from whose death they might profit was uncovered. Similar large-scale poisoning continued until Sulla issued the *Lex Cornelia* (circa 82 B.C.). This appears to be the first law against poisoning, and it later became a regulatory statute directed at careless dispensers of drugs. Nero (A.D. 37–68) used poisons to do away with his stepbrother Brittanicus and employed his slaves as food tasters to differentiate edible mushrooms from their more poisonous kin.

Middle Ages

<div align="right">
Come bitter pilot, now at once run on
The dashing rocks thy seasick weary bark!
Here's to my love! O true apothecary!
Thy drugs are quick. Thus with a kiss I die.
Romeo and Juliet, act 5, scene 3
</div>

Before the Renaissance, the writings of Maimonides (Moses ben Maimon, A.D. 1135–1204) included a treatise on the treatment of poisonings from insects, snakes, and mad dogs (*Poisons and Their Antidotes*, 1198). Maimonides, like Hippocrates before him, wrote on the subject of bioavailability, noting that milk, butter, and

cream could delay intestinal absorption. Malmonides also refuted many of the popular remedies of the day and stated his doubts about others. It is rumored that alchemists of this period (circa A.D. 1200), in search of the universal antidote, learned to distill fermented products and made a 60% ethanol beverage that had many interesting powers.

In the early Renaissance, the Italians, with characteristic pragmatism, brought the art of poisoning to its zenith. The poisoner became an integral part of the political scene. The records of the city councils of Florence, particularly those of the infamous Council of Ten of Venice, contain ample testimony about the political use of poisons. Victims were named, prices set, and contracts recorded; when the deed was accomplished, payment was made.

An infamous figure of the time was a lady named Toffana who peddled specially prepared arsenic-containing cosmetics (*Agua Toffana*). Accompanying the product were appropriate instructions for its use. Toffana was succeeded by an imitator with organizational genius, Hieronyma Spara, who provided a new fillip by directing her activities toward specific marital and monetary objectives. A local club was formed of young, wealthy married women, which soon became a club of eligible young wealthy widows, reminiscent of the matronly conspiracy of Rome centuries earlier. Incidentally, arsenic-containing cosmetics were reported to be responsible for deaths well into the twentieth century (Kallett and Schlink, 1933).

Among the prominent families engaged in poisoning, the Borgias were the most notorious. However, many deaths that were attributed to poisoning are now recognized as having resulted from infectious diseases such as malaria. It appears true, however, that Alexander VI, his son Cesare, and Lucrezia Borgia were quite active. The deft application of poisons to men of stature in the Catholic Church swelled the holdings of the papacy, which was their prime heir.

In this period Catherine de Medici exported her skills from Italy to France, where the prime targets of women were their husbands. However, unlike poisoners of an earlier period, the circle represented by Catherine and epitomized by the notorious Marchioness de Brinvillers depended on developing direct evidence to arrive at the most effective compounds for their purposes. Under the guise of delivering provender to the sick and the poor, Catherine tested toxic concoctions, carefully noting the rapidity of the toxic response (onset of action), the effectiveness of the compound (potency), the degree of response of the parts of the body (specificity, site of action), and the complaints of the victim (clinical signs and symptoms).

The culmination of the practice in France is represented by the commercialization of the service by Catherine Deshayes, who earned the title "La Voisine." Her business was dissolved by her execution. Her trial was one of the most famous of those held by the Chambre Ardente, a special judicial commission established by Louis XIV to try such cases without regard to age, sex, or national origin. La Voisine was convicted of many poisonings, with over 2000 infants among her victims.

Age of Enlightenment

> All substances are poisons; there is none which is not a poison. The right dose differentiates a poison from a remedy.
> *Paracelsus*

A significant figure in the history of science and medicine in the late Middle Ages was the renaissance man Philippus Aureolus Theophrastus Bombastus von Hohenheim-Paracelsus (1493–1541). Between the time of Aristotle and the age of Paracelsus, there was little substantial change in the biomedical sciences. In the sixteenth century, the revolt against the authority of the Catholic Church was accompanied by a parallel attack on the godlike authority exercised by the followers of Hippocrates and Galen. Paracelsus personally and professionally embodied the qualities that forced numerous changes in this period. He and his age were pivotal, standing between the philosophy and magic of classical antiquity and the philosophy and science willed to us by figures of the seventeenth and eighteenth centuries. Clearly, one can identify in Paracelsus's approach, point of view, and breadth of interest numerous similarities to the discipline that is now called toxicology.

Paracelsus, a physician-alchemist and the son of a physician, formulated many revolutionary views that remain an integral part of the structure of toxicology, pharmacology, and therapeutics today (Pagel, 1958). He promoted a focus on the "toxicon," the primary toxic agent, as a chemical entity, as opposed to the Grecian concept of the mixture or blend. A view initiated by Paracelsus that became a lasting contribution held as corollaries that (1) experimentation is essential in the examination of responses to chemicals, (2) one should make a distinction between the therapeutic and toxic properties of chemicals, (3) these properties are sometimes but not always indistinguishable except by dose, and (4) one can ascertain a degree of specificity of chemicals and their therapeutic or toxic effects. These principles led Paracelsus to introduce mercury as the drug of choice for the treatment of syphilis, a practice that survived 300 years but led to his famous trial. This viewpoint presaged the "magic bullet" (arsphenamine) of Paul Ehrlich and the introduction of the therapeutic index. Further, in a very real sense, this was the first sound articulation of the dose-response relation, a bulwark of toxicology (Pachter, 1961).

The tradition of the poisoners spread throughout Europe, and their deeds played a major role in the distribution of political power throughout the Middle Ages. Pharmacology as it is known today had its beginnings during the Middle Ages and early Renaissance. Concurrently, the study of the toxicity and the dose-response relationship of therapeutic agents was commencing.

The occupational hazards associated with metalworking were recognized during the fifteenth century. Early publications by Ellenbog (circa 1480) warned of the toxicity of the mercury and lead exposures involved in goldsmithing. Agricola published a short treatise on mining diseases in 1556. However, the major work on the subject, *On the Miners' Sickness and Other Diseases of Miners* (1567), was published by Paracelsus. This treatise addressed the etiology of miners' disease, along with treatment and prevention strategies. Occupational toxicology was further advanced by the work of Bernardino Ramazzini. His classic, published in 1700 and entitled *Discourse on the Diseases of Workers,* set the standard for occupational medicine well into the nineteenth century. Ramazzini's work broadened the field by discussing occupations ranging from miners to midwives and including printers, weavers, and potters.

The developments of the industrial revolution stimulated a rise in many occupational diseases. Percival Pott's (1775) recognition of the role of soot in scrotal cancer among chimney sweeps was the first reported example of polyaromatic hydrocarbon carcinogenicity, a problem that still plagues toxicologists today. These findings led to improved medical practices, particularly in prevention. It should be noted that Paracelsus and Ramazzini also pointed out the toxicity of smoke and soot.

The nineteenth century dawned in a climate of industrial and political revolution. Organic chemistry was in its infancy in 1800, but by 1825 phosgene ($COCl_2$) and mustard gas (bis[B-chloroethyl]sulfide) had been synthesized. These two agents were used in World War I as war gases. By 1880 over 10,000 organic compounds had been synthesized including chloroform, carbon tetrachloride, diethyl ether, and carbonic acid, and petroleum and coal gasification by-products were used in trade (Zapp, 1982). Determination of the toxicologic potential of these newly created chemicals became the underpinning of the science of toxicology as it is practiced today. However, there was little interest during the mid-nineteenth century in hampering industrial development. Hence, the impact of industrial toxicology discoveries was not felt until the passage of worker's insurance laws, first in Germany (1883), then in England (1897), and later in the United States (1910).

Experimental toxicology accompanied the growth of organic chemistry and developed rapidly during the nineteenth century. Magendie (1783–1885), Orfila (1787–1853), and Bernard (1813–1878) carried out truly seminal research in experimental toxicology and laid the groundwork for pharmacology and experimental therapeutics as well as occupational toxicology.

Orfila, a Spanish physician in the French court, was the first toxicologist to use autopsy material and chemical analysis systematically as legal proof of poisoning. His introduction of this detailed type of analysis survives as the underpinning of forensic toxicology (Orfila, 1818). Orfila published the first major work devoted expressly to the toxicity of natural agents (1815). Magendie, a physician and experimental physiologist, studied the mechanisms of action of emetine, strychnine, and "arrow poisons" (Olmsted, 1944). His research into the absorption and distribution of these compounds in the body remains a classic in toxicology and pharmacology. One of Magendie's more famous students, Claude Bernard, continued the study of arrow poisons (Bernard, 1850) but also added works on the mechanism of action of carbon monoxide. Bernard's treatise, *An Introduction to the Study of Experimental Medicine* (translated by Greene in 1949), is a classic in the development of toxicology.

Many German scientists contributed greatly to the growth of toxicology in the late nineteenth and early twentieth centuries. Among the giants of the field are Oswald Schmiedeberg (1838–1921) and Louis Lewin (1850–1929). Schmiedeberg made many contributions to the science of toxicology, not the least of which was the training of approximately 120 students who later populated the most important laboratories of pharmacology and toxicology throughout the world. His research focused on the synthesis of hippuric acid in the liver and the detoxification mechanisms of the liver in several animal species (Schmiedeberg and Koppe, 1869). Lewin, who was educated originally in medicine and the natural sciences, trained in toxicology under Liebreich at the Pharmacological Institute of Berlin (1881). His contributions on the chronic toxicity of narcotics and other alkaloids remain a classic. Lewin also published much of the early work on the toxicity of methanol, glycerol, acrolein, and chloroform (Lewin, 1920, 1929).

MODERN TOXICOLOGY

Toxicology has evolved rapidly during this century. The exponential growth of the discipline can be traced to the World War II era with its marked increase in the production of drugs, pesticides, munitions, synthetic fibers, and industrial chemicals. The history of many sciences represents an orderly transition based on theory, hypothesis testing, and synthesis of new ideas. Toxicology, as a gathering and an applied science, has, by contrast, developed in fits and starts. Toxicology calls on almost all the basic sciences to test its hypotheses. This fact, coupled with the health and occupational regulations that have driven toxicology research since 1900, has made this discipline exceptional in the history of science. The differentiation of toxicology as an art and a science, though arbitrary, permits the presentation of historical highlights along two major lines.

Modern toxicology can be viewed as a continuation of the development of the biological and physical sciences in the late nineteenth and twentieth centuries (Table 1-1). During the second half of the nineteenth century, the world witnessed an explosion in science that produced the beginning of the modern era of medicine, synthetic chemistry, physics, and biology. Toxicology has drawn its strength and diversity from its proclivity to borrowing. With the advent of anesthetics and disinfectants and the advancement of experimental pharmacology in the late 1850s, toxicology as it is currently understood got its start. The introduction of ether, chloroform, and carbonic acid led to several iatrogenic deaths. These unfortunate outcomes spurred research into the causes of the deaths and early experiments on the physiological mechanisms by which these compounds caused both beneficial and adverse effects. By the late nineteenth century the use of organic chemicals was becoming more widespread, and benzene, toluene, and the xylenes went into larger-scale commercial production.

Table 1-1 Selection of Developments in Toxicology

During this period, the use of "patent" medicines was prevalent, and there were several incidents of poisonings from these medicaments. The adverse reactions to patent medicines, coupled with the response to Upton Sinclair's exposé of the meat-packing industry in *The Jungle,* culminated in the passage of the Wiley Bill (1906), the first of many U.S. pure food and drug laws (see Hutt and Hutt, 1984, for regulatory history).

A working hypothesis about the development of toxicology is that the discipline expands in response to legislation, which itself is a response to a real or perceived tragedy. The Wiley bill was the first such reaction in the area of food and drugs, and the worker's compensation laws cited above were a response to occupational toxicities. In addition, the National Safety Council was established in 1911, and the Division of Industrial Hygiene was established by the U.S. Public Health Service in 1914. A corollary to this hypothesis might be that the founding of scientific journals and/or societies is sparked by the development of a new field. The *Journal of Industrial Hygiene* began in 1918. The major chemical manufacturers in the United States (Dow, Union Carbide, and Du Pont) established internal toxicology research laboratories to help guide decisions on worker health and product safety.

During the 1890s and early 1900s, the French scientists Becquerel and the Curies reported the discovery of "radioactivity." This opened up for exploration a very large area in physics, biology, and medicine, but it would not actively affect the science of toxicology for another 40 years. However, another discovery, that of vitamins, or "vital amines," was to lead to the use of the first large-scale bioassays (multiple animal studies) to determine whether these "new" chemicals were beneficial or harmful to laboratory animals. The initial work in this area took place at around the time of World War I in several laboratories, including the laboratory of Philip B. Hawk in Philadelphia. Hawk and a young associate, Bernard L. Oser, were responsible for the development and verification of many early toxicologic assays that are still used in a slightly amended form. Oser's contributions to food and regulatory toxicology were extraordinary. These early bioassays were made possible by a major advance in toxicology: the availability of developed and refined strains of inbred laboratory rodents (Donaldson, 1912).

The 1920s saw many events that began to mold the fledgling field of toxicology. The use of arsenicals for the treatment of diseases such as syphilis (arsenicals had been used in agriculture since the mid-nineteenth century) resulted in acute and chronic toxicity. Prohibition of alcoholic beverages in the United States opened the door for early studies of neurotoxicology, with the discovery that triorthocresyl phosphate (TOCP), methanol, and lead (all products of "bootleg" liquor) are neurotoxicants. TOCP, which is a modern gasoline additive, caused a syndrome that became known as "ginger-jake" walk, a spastic gait resulting from drinking adulterated ginger beer. Mueller's discovery of DDT (dichlorodiphenyl-trichloroethane) and several other organohalides, such as hexachlorobenzene and hexachlorocyclohexane, during the late 1920s resulted in wider use of insecticidal agents. Other scientists were hard at work attempting to elucidate the structures and activity of the estrogens and androgens. Work on the steroid hormones led to the use of several assays for the determination of the biological activity of organ extracts and synthetic compounds. Efforts to synthesize steroid-like chemicals were spearheaded by E. C. Dodds and his coworkers, one of whom was Leon Golberg, a young organic chemist. Dodds's work on the bioactivity of the estrogenic compounds resulted in the synthesis of diethylstilbestrol (DES), hexestrol, and other stilbenes and the discovery of the strong estrogenic activity of substituted stilbenes. Golberg's intimate involvement in this work stimulated his interest in biology, leading to degrees in biochemistry and medicine and a career in toxicology in which he oversaw the creation of the laboratories of the British Industrial Biological Research Association (BIBRA) and the Chemical Industry Institute of Toxicology (CIIT). Interestingly, the initial observations that led to the discovery of DES were the findings of feminization of animals treated with the experimental carcinogen 7,12-dimethylbenz[*a*]anthracene (DMBA).

The 1930s saw the world preparing for World War II and a major effort by the pharmaceutical industry in Germany and the United States to manufacture the first mass-produced antibiotics. One of the first journals expressly dedicated to experimental toxicology, *Archiv für Toxikologie,* began publication in Europe in 1930, the same year that Herbert Hoover signed the act that established the National Institutes of Health (NIH) in the United States.

The discovery of sulfanilamide was heralded as a major event in combating bacterial diseases. However, for a drug to be effective, there must be a reasonable delivery system, and sulfanilamide is highly insoluble in an aqueous medium. Therefore, it was originally prepared in ethanol (elixir). However, it was soon discovered that the drug was more soluble in ethylene glycol, which is a dihydroxy rather than a monohydroxy ethane. The drug was sold in glycol solutions but was labeled as an elixir, and several patients died of acute kidney failure resulting from the metabolism of the glycol to oxalic acid and glycolic acid, with the acids, along with the active drug, crystallizing in the kidney tubules. This tragic event led to the passage of the Copeland bill in 1938, the second major bill involving the formation of the U.S. Food and Drug Administration (FDA). The sulfanilamide disaster played a critical role in the further development of toxicology, resulting in work by Eugene Maximillian Geiling in the Pharmacology Department of the University of Chicago that elucidated the mechanism of toxicity of both sulfanilamide and ethylene glycol. Studies of the glycols were simultaneously carried out at the U.S. FDA by a group led by Arnold Lehman. The scientists associated with Lehman and Geiling were to become the leaders of toxicology over the next 40 years. With few exceptions, toxicology in the United States owes its heritage to Geiling's innovativeness and ability to stimulate and direct young scientists and Lehman's vision of the use of experimental toxicology in public health decision making. Because of Geiling's reputation, the U.S. government turned to this group for help in the war effort. There were three main areas in which the Chicago group took part during World War II: the toxicology and pharmacology of organophosphate chemicals, antimalarial drugs, and radionuclides. Each of these areas produced teams of toxicologists who became academic, governmental, and industrial leaders in the field.

It was also during this time that DDT and the phenoxy herbicides were developed for increased food production and, in the case of DDT, control of insect-borne diseases. These efforts between 1940 and 1946 led to an explosion in toxicology. Thus, in line with the hypothesis advanced above, the crisis of World War II caused the next major leap in the development of toxicology.

If one traces the history of the toxicology of metals over the past 45 years, the role of the Chicago group is quite visible. This story commences with the use of

uranium for the "bomb" and continues today with research on the role of metals in their interactions with DNA, RNA, and growth factors. Indeed, the Manhattan Project created a fertile environment that resulted in the initiation of quantitative biology, radiotracer technology, and inhalation toxicology. These innovations have revolutionized modern biology, chemistry, therapeutics, and toxicology.

Inhalation toxicology began at the University of Rochester under the direction of Stafford Warren, who headed the Department of Radiology. He developed a program with colleagues such as Harold Hodge (pharmacologist), Herb Stokinger (chemist), Sid Laskin (inhalation toxicologist), and Lou and George Casarett (toxicologists). These young scientists were to go on to become giants in the field. The other sites for the study of radionuclides were Chicago for the "internal" effects of radioactivity and Oak Ridge, Tennessee, for the effects of "external" radiation. The work of the scientists on these teams gave the scientific community data that contributed to the early understanding of macromolecular binding of xenobiotics, cellular mutational events, methods for inhalation toxicology and therapy, and toxicological properties of trace metals, along with a better appreciation of the complexities of the dose-response curve.

Another seminal event in toxicology that occurred during the World War II era was the discovery of organophosphate cholinesterase inhibitors. This class of chemicals, which was discovered by Willy Lange and Gerhard Schrader, was destined to become a driving force in the study of neurophysiology and toxicology for several decades. Again, the scientists in Chicago played major roles in elucidating the mechanisms of action of this new class of compounds. Geiling's group, Kenneth Dubois in particular, were leaders in this area of toxicology and pharmacology. Dubois's students, particularly Sheldon Murphy, continued to be in the forefront of this special area. The importance of the early research on the organophosphates has taken on special meaning in the years since 1960, when these nonbioaccumulating insecticides were destined to replace DDT and other organochlorine insecticides.

Early in the twentieth century, it was demonstrated experimentally that quinine has a marked effect on the malaria parasite [it had been known for centuries that chincona bark extract is efficacious for "Jesuit fever" (malaria)]. This discovery led to the development of quinine derivatives for the treatment of the disease and the formulation of the early principles of chemotherapy. The pharmacology department at Chicago was charged with the development of antimalarials for the war effort. The original protocols called for testing of efficacy and toxicity in rodents and perhaps dogs and then the testing of efficacy in human volunteers. One of the investigators charged with generating the data needed to move a candidate drug from animals to humans was Fredrick Coulston. This young parasitologist and his colleagues, working under Geiling, were to evaluate potential drugs in animal models and then establish human clinical trials. It was during these experiments that the use of nonhuman primates came into vogue for toxicology testing. It had been noted by Russian scientists that some antimalarial compounds caused retinopathies in humans but did not apparently have the same adverse effect in rodents and dogs. This finding led the Chicago team to add one more step in the development process: toxicity testing in rhesus monkeys just before efficacy studies in people. This resulted in the prevention of blindness in untold numbers of volunteers and perhaps some of the troops in the field. It also led to the school of thought that nonhuman primates may be one of the better models for humans and the establishment of primate colonies for the study of toxicity. Coulston pioneered this area of toxicology and remains committed to it.

Another area not traditionally thought of as toxicology but one that evolved during the 1940s as an exciting and innovative field is experimental pathology. This branch of experimental biology developed from bioassays of estrogens and early experiments in chemical- and radiation-induced carcinogenesis. It is from these early studies that hypotheses on tumor promotion and cancer progression have evolved.

Toxicologists today owe a great deal to the researchers of chemical carcinogenesis of the 1940s. Much of today's work can be traced to Elizabeth and James Miller at Wisconsin. This husband and wife team started under the mentorship of Professor Rusch, the director of the newly formed McArdle Laboratory for Cancer Research, and Professor Baumann. The seminal research of the Millers led to the discovery of the role of reactive intermediates in carcinogenicity and that of mixed-function oxidases in the endoplasmic reticulum. These findings, which initiated the great works on the cytochrome-P450 family of proteins, were aided by two other major discoveries for which toxicologists (and all other biological scientists) are deeply indebted: paper chromatography in 1944 and the use of radiolabeled dibenzanthracene in 1948. Other major events of note in drug metabolism included the work of Bernard Brodie on the metabolism of methyl orange in 1947. This piece of seminal research led to the examination of blood and urine for chemical and drug metabolites. It became the tool with which one could study the relationship between blood levels and biological action. The classic treatise of R. T. Williams, *Detoxication Mechanisms,* was published in 1947. This text described the many pathways and possible mechanisms of detoxication and opened the field to several new areas of study.

The decade after World War II was not as boisterous as the period from 1935 to 1945. The first major U.S. pesticide act was signed into law in 1947. The significance of the initial Federal Insecticide, Fungicide, and Rodenticide Act was that for the first time in U.S. history a substance that was neither a drug nor a food had to be shown to be safe and efficacious. This decade, which coincided with the Eisenhower years, saw the dispersion of the groups from Chicago, Rochester, and Oak Ridge and the establishment of new centers of research. Adrian Albert's classic *Selective Toxicity* was published in 1951. This treatise, which has appeared in several editions, presented a concise documentation of the principles of the site-specific action of chemicals.

AFTER WORLD WAR II

> You too can be a toxicologist in two easy lessons, each of ten years.
> *Arnold Lehman* (circa 1955)

The mid-1950s witnessed the strengthening of the U.S. Food and Drug Administration's commitment to toxicology under the guidance of Arnold Lehman. Lehman's tutelage and influence are still felt today. The adage "You too can be a toxicologist" is as important a summation of toxicology as the often quoted statement of Paracelsus: "The dose makes the poison." The period from 1955 to 1958 produced two major events that would have a long-lasting impact on toxicology as a science and a professional discipline. Lehman, Fitzhugh, and their coworkers formalized the experimental program for the appraisal of food, drug, and cosmetic safety in 1955, updated by the U.S. FDA in 1982, and the Gordon Research Conferences established a conference on toxicology and safety evaluation, with Bernard L. Oser as its initial chairman. These two events led to close relationships among toxicologists from several groups and brought toxicology into a new phase. At about the same time, the U.S. Congress passed and the president of the United States signed the additives amendments to the Food, Drug, and Cosmetic Act. The Delaney clause (1958) of these amendments stated broadly that any chemical found to be carcinogenic in laboratory animals or humans could not be added to the U.S. food supply. The impact of this legislation cannot be overstated. Delaney became a battle cry for many groups and resulted in the inclusion at a new level of biostatisticians and mathematical modelers in the field of toxicology. It fostered the expansion of quantitative methods in toxicology and led to innumerable arguments about the "one-hit" theory of carcinogenesis. Regardless of one's view of Delaney, it has served as an excellent starting point for understanding the complexity of the biological phenomenon of carcinogenicity and the development of risk assessment models. One must remember that at the time of Delaney, the analytic detection level for most chemicals was 20 to 100 ppm (today, parts per quadrillion). Interestingly, the Delaney clause has been invoked only on a few occasions, and it has been stated that Congress added little to the food and drug law with this clause (Hutt and Hutt, 1984).

Shortly after the Delaney amendment and after three successful Gordon Conferences, the first American journal dedicated to toxicology was launched by Coulston, Lehman, and Hayes. *Toxicology and Applied Pharmacology* has been the flagship journal of toxicology ever since. The founding of the Society of Toxicology followed shortly afterward, and this journal became its official publication. The society's founding members were Fredrick Coulston, William Deichmann, Kenneth DuBois, Victor Drill, Harry Hayes, Harold Hodge, Paul Larson. Arnold Lehman, and C. Boyd Shaffer. These researchers deserve a great deal of credit for the growth of toxicology. DuBois and Geiling published their *Textbook of Toxicology* in 1959.

The 1960s were a tumultuous time for society, and toxicology was swept up in the tide. Starting with the tragic thalidomide incident, in which several thousand children were born with serious birth defects, and the publication of Rachel Carson's *Silent Spring* (1962), the field of toxicology developed at a feverish pitch. Attempts to understand the effects of chemicals on the embryo and fetus and on the environment as a whole gained momentum. New legislation was passed, and new journals were founded. The education of toxicologists spread from the deep traditions at Chicago and Rochester to Harvard, Miami, Albany, Iowa, Jefferson, and beyond. Geiling's fledglings spread as Schmiedeberg's had a half century before. Many new fields were influencing and being assimilated into the broad scope of toxicology, including environmental sciences, aquatic and avian biology, cell biology, analytic chemistry, and genetics.

During the 1960s, particularly the latter half of the decade, the analytic tools used in toxicology were developed to a level of sophistication that allowed the detection of chemicals in tissues and other substrates at part per billion concentrations (today parts per quadrillion may be detected). Pioneering work in the development of point mutation assays that were replicable, quick, and inexpensive led to a better understanding of the genetic mechanisms of carcinogenicity (Ames, 1983). The combined work of Ames and the Millers (Elizabeth C. and James A.) at McArdle Laboratory allowed the toxicology community to make major contributions to the understanding of the carcinogenic process.

The low levels of detection of chemicals and the ability to detect point mutations rapidly created several problems and opportunities for toxicologists and risk assessors that stemmed from interpretation of the Delaney amendment. Cellular and molecular toxicology developed as a subdiscipline, and risk assessment became

a major product of toxicological investigations.

The establishment of the National Center for Toxicologic Research (NCTR), the expansion of the role of the U.S. FDA, and the establishment of the U.S. Environmental Protection Agency (EPA) and the National Institute of Environmental Health Sciences (NIEHS) were considered clear messages that the government had taken a strong interest in toxicology. Several new journals appeared during the 1960s, and new legislation was written quickly after *Silent Spring* and the thalidomide disaster.

The end of the 1960s witnessed the "discovery" of TCDD as a contaminant in the herbicide Agent Orange (the original discovery of TCDD toxicity was reported in 1957). The research on the toxicity of this compound has produced some very good and some very poor research in the field of toxicology. The discovery of a high-affinity cellular binding protein designated the "Ah" receptor (see Poland and Knutsen, 1982, for a review) at the McArdle Laboratory and work on the genetics of the receptor at NIH (Nebert and Gonzalez, 1987) have revolutionized the field of toxicology. The importance of TCDD to toxicology lies in the fact that it forced researchers, regulators, and the legal community to look at the role of mechanisms of toxic action in a different fashion.

At least one other event precipitated a great deal of legislation during the 1970s: Love Canal. The "discovery" of Love Canal led to major concerns regarding hazardous wastes, chemical dump sites, and disclosure of information about those sites. Soon after Love Canal, the EPA listed several equally contaminated sites in the United States. The agency was given the responsibility to develop risk assessment methodology to determine health risks from exposure to effluents and to attempt to remediate these sites. These combined efforts led to broad-based support for research into the mechanisms of action of individual chemicals and complex mixtures. Love Canal and similar issues created the legislative environment that led to the Toxic Substances Control Act and eventually to the Superfund bill. These omnibus bills were created to cover the toxicology of chemicals from initial synthesis to disposal (cradle to grave).

The expansion of legislation, journals, and new societies involved with toxicology was exponential during the 1970s and 1980s and shows no signs of slowing down. Currently, in the United States there are dozens of professional, governmental, and other scientific organizations with thousands of members and over 120 journals dedicated to toxicology and related disciplines.

In addition, toxicology continues to expand in stature and in the number of programs worldwide. The International Congress of Toxicology is made up of toxicology societies from Europe, South America, Asia, Africa, and Australia and brings together the broadest representation of toxicologists.

The original Gordon Conference series has changed to Mechanisms of Toxicity, and several other conferences related to special areas of toxicology are now in existence. The American Society of Toxicology has formed specialty sections and regional chapters to accommodate the over 5000 scientists involved in toxicology today. Texts and reference books for toxicology students and scientists abound. Toxicology has evolved from a borrowing science to a seminal discipline seeding the growth and development of several related fields of science and science policy.

The history of toxicology has been interesting and varied but never dull. Perhaps as a science that has grown and prospered by borrowing from many disciplines, it has suffered from the absence of a single goal, but its diversification has allowed for the interspersion of ideas and concepts from higher education, industry, and government. As an example of this diversification, one now finds toxicology graduate programs in medical schools, schools of public health, and schools of pharmacy as well as programs in environmental science and engineering and undergraduate programs in toxicology at several institutions. Surprisingly, courses in toxicology are now being offered in several liberal arts undergraduate schools as part of their biology and chemistry curricula. This has resulted in an exciting, innovative, and diversified field that is serving science and the community at large.

Few disciplines can point to both basic sciences and direct applications at the same time. Toxicology—the study of the adverse effects of xenobiotics—may be unique in this regard.

CHAPTER 2

PRINCIPLES OF TOXICOLOGY

David L. Eaton and Curtis D. Klaassen

INTRODUCTION TO TOXICOLOGY

Toxicology is the study of the adverse effects of chemicals on living organisms. A *toxicologist* is trained to examine the nature of those effects (including their cellular, biochemical, and molecular mechanisms of action) and assess the probability of their occurrence. Thus, the principles of toxicology are integral to the proper use of science in the process commonly called *risk assessment,* where quantitative estimates are made of the potential effects on human health and environmental significance of various types of chemical exposures (e.g., pesticide residues on food, contaminants in drinking water). The variety of potential adverse effects and the diversity of chemicals in the environment make toxicology a very broad science. Therefore, toxicologists often specialize in one area of toxicology.

Different Areas of Toxicology

The professional activities of toxicologists fall into three main categories: descriptive, mechanistic, and regulatory (Fig. 2-1). Although each has distinctive characteristics, each contributes to the other, and all are vitally important to chemical risk assessment (see Chap. 4).

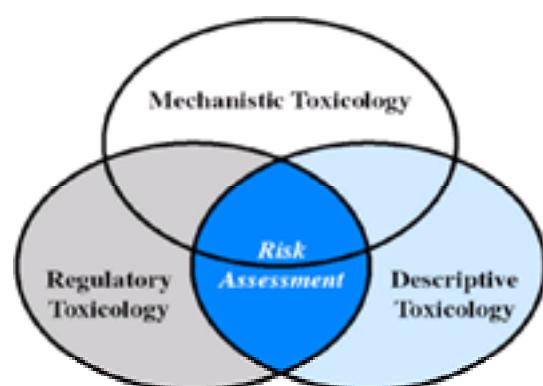

Figure 2-1. Graphical representation of the interconnections between different areas of toxicology.

A *mechanistic toxicologist* is concerned with identifying and understanding the cellular, biochemical, and molecular mechanisms by which chemicals exert toxic effects on living organisms (see Chap. 3 for a detailed discussion of mechanisms of toxicity). The results of mechanistic studies are very important in many areas of applied toxicology. In risk assessment, mechanistic data may be very useful in demonstrating that an adverse outcome (e.g., cancer, birth defects) observed in laboratory animals is directly relevant to humans. For example, the relative toxic potential of organophosphate insecticides in humans, rodents, and insects can be accurately predicted on the basis of an understanding of common mechanisms (inhibition of acetylcholinesterase) and differences in biotransformation for these insecticides among the different species. Similarly, mechanistic data may be very useful in identifying adverse responses in experimental animals that may not be relevant to humans. For example, the propensity of the widely used artificial sweetener saccharin to cause bladder cancer in rats may not be relevant to humans at normal dietary intake rates. This is because mechanistic studies have demonstrated that bladder cancer is induced only under conditions where saccharin is at such a high concentration in the urine that it forms a crystalline precipitate (Cohen, 1999). Dose–response studies suggest that such high concentrations would not be achieved in the human bladder even after extensive dietary consumption.

Mechanistic data also are useful in the design and production of safer alternative chemicals and in rational therapy for chemical poisoning and treatment of disease. For example, the drug thalidomide was originally marketed in Europe as a sedative agent for pregnant women. However, it was banned for clinical use in 1962 because of devastating birth defects that occurred if the drug was ingested during a critical period in pregnancy. But mechanistic studies over the past several decades have demonstrated that this drug may have a unique molecular mechanism of action that interferes with the expression of certain genes responsible for blood vessel formation (angiogenesis). With an understanding of this mechanism, thalidomide has been "rediscovered" as a valuable therapeutic agent that may be highly effective in the treatment of certain infectious diseases (e.g., leprosy and AIDS), a variety of inflammatory diseases, and some types of cancer. Obviously, its use in pregnant women is strictly prohibited, but the discovery of this mechanism of action may now allow this drug to be used safely and effectively in the treatment of many other diseases (Lary *et al.,* 1999). In addition to aiding directly in the identification, treatment, and prevention of chemical toxicity, an understanding of the mechanisms of toxic action contributes to the knowledge of basic physiology, pharmacology, cell biology, and biochemistry. For example, studies on the toxicity of fluoroorganic alcohols and acids contributed to the knowledge of basic carbohydrate and lipid metabolism, and knowledge of regulation of ion gradients in nerve axonal membranes has been greatly aided by studies of biological toxins such as tetrodotoxin and synthetic chemicals such as DDT (dichlorodiphenyltrichloroethane). The advent of new technologies in molecular biology and genomics now provide mechanistic toxicologists with the tools to explore exactly how humans may differ from laboratory animals in their response to toxic substances. These same tools are also being utilized to identify individuals who are genetically susceptible to factors in the environment. For example, it is now recognized that a small percentage of the population genetically lacks the ability to detoxify the chemotherapeutic drug, 6-mercaptopurine, used in the treatment of some forms of leukemia. Young children with leukemia who are homozygous for this genetic trait may experience serious toxic effects from a standard therapeutic dose of this drug. Genetic tests are now available that can identify genetically susceptible individuals in advance of treatment (Weinshilboum *et al.,* 1999). This new area of 'toxicogenomics' provides an exciting opportunity in the future for mechanistic toxicologists to identify and protect genetically susceptible individuals from harmful environmental exposures, and to customize drug therapies that enhance efficacy and minimize toxicity, based on their individual genetic makeup.

A *descriptive toxicologist* is concerned directly with toxicity testing, which provides information for safety evaluation and regulatory requirements. The appropriate toxicity tests (as described later in this chapter) in experimental animals are designed to yield information that can be used to evaluate risks posed to humans and the environment by exposure to specific chemicals. The concern may be limited to effects on humans, as in the case of drugs and food additives. Toxicologists in the chemical industry, however, must be concerned not only with the risk posed by a company's chemicals (insecticides, herbicides, solvents, etc.) to humans but also with potential effects on fish, birds, and plants, as well as other factors that might disturb the balance of the ecosystem. Descriptive toxicology studies provide important clues to a chemical's mechanism of action, and thus contribute to the development of mechanistic toxicology through hypothesis generation. Such studies are also a key component of risk assessments that are used by regulatory toxicologists.

A *regulatory toxicologist* has the responsibility for deciding, on the basis of data provided by descriptive and mechanistic toxicologists, whether a drug or another chemical poses a sufficiently low risk to be marketed for a stated purpose. The Food and Drug Administration (FDA) is responsible for allowing drugs, cosmetics, and food additives to be sold in the market according to the Federal Food, Drug and Cosmetic Act (FDCA). The U.S. Environmental Protection Agency (EPA) is responsible for regulating most other chemicals according to the Federal Insecticide, Fungicide and Rodenticide Act (FIFRA), the Toxic Substances Control Act

(TSCA), the Resource Conservation and Recovery Act (RCRA), the Safe Drinking Water Act, and the Clean Air Act. The EPA is also responsible for enforcing the Comprehensive Environmental Response, Compensation and Liability Act [CERCLA, later revised as the Superfund Amendments Reauthorization Act (SARA)], more commonly called the Superfund. This regulation provides direction and financial support for the cleanup of waste sites that contain toxic chemicals and may present a risk to human health or the environment. The Occupational Safety and Health Administration (OSHA) of the Department of Labor was established to ensure that safe and healthful conditions exist in the workplace. The Consumer Product Safety Commission is responsible for protecting consumers from hazardous household substances, whereas the Department of Transportation (DOT) ensures that materials shipped in interstate commerce are labeled and packaged in a manner consistent with the degree of hazard they present. Regulatory toxicologists are also involved in the establishment of standards for the amount of chemicals permitted in ambient air, industrial atmospheres, and drinking water, often integrating scientific information from basic descriptive and mechanistic toxicology studies with the principles and approaches used for risk assessment (Chap. 4). Some of the philosophic and legal aspects of regulatory toxicology are discussed in Chap. 34.

In addition to the above categories, there are other specialized areas of toxicology such as forensic, clinical, and environmental toxicology. *Forensic toxicology* is a hybrid of analytic chemistry and fundamental toxicological principles. It is concerned primarily with the medicolegal aspects of the harmful effects of chemicals on humans and animals. The expertise of forensic toxicologists is invoked primarily to aid in establishing the cause of death and determining its circumstances in a postmortem investigation (Chap. 31). *Clinical toxicology* designates an area of professional emphasis in the realm of medical science that is concerned with disease caused by or uniquely associated with toxic substances (see Chap. 32). Generally, clinical toxicologists are physicians who receive specialized training in emergency medicine and poison management. Efforts are directed at treating patients poisoned with drugs or other chemicals and at the development of new techniques to treat those intoxications. *Environmental toxicology* focuses on the impacts of chemical pollutants in the environment on biological organisms. Although toxicologists concerned with the effects of environmental pollutants on human health fit into this definition, it is most commonly associated with studies on the impacts of chemicals on nonhuman organisms such as fish, birds, and terrestrial animals. *Ecotoxicology* is a specialized area within environmental toxicology that focuses more specifically on the impacts of toxic substances on population dynamics in an ecosystem. The transport, fate, and interactions of chemicals in the environment constitute a critical component of both environmental toxicology and ecotoxicology.

Spectrum of Toxic Dose

One could define a *poison* as any agent capable of producing a deleterious response in a biological system, seriously injuring function or producing death. This is not, however, a useful working definition for the very simple reason that virtually every known chemical has the potential to produce injury or death if it is present in a sufficient amount. Paracelsus (1493–1541), a Swiss/German/ Austrian physician, scientist, and philosopher, phrased this well when he noted, "What is there that is not poison? All things are poison and nothing [is] without poison. Solely the dose determines that a thing is not a poison."

Among chemicals there is a wide spectrum of doses needed to produce deleterious effects, serious injury, or death. This is demonstrated in Table 2-1, which shows the dosage of chemicals needed to produce death in 50 percent of treated animals (LD $_{50}$). Some chemicals produce death in microgram doses and are commonly thought of as being extremely poisonous. Other chemicals may be relatively harmless after doses in excess of several grams. It should be noted, however, that measures of acute lethality such as LD_{50} may not accurately reflect the full spectrum of toxicity, or hazard, associated with exposure to a chemical. For example, some chemicals with low acute toxicity may have carcinogenic or teratogenic effects at doses that produce no evidence of acute toxicity.

AGENT	LD_{50}, mg/kg*
Ethyl alcohol	10,000
Sodium chloride	4,000
Ferrous sulfate	1,500
Morphine sulfate	900
Phenobarbital sodium	150
Picrotoxin	5
Strychnine sulfate	2
Nicotine	1
d-Tubocurarine	0.5
Hemicholinium-3	0.2
Tetrodotoxin	0.10
Dioxin (TCDD)	0.001
Botulinum toxin	0.00001

*LD_{50} is the dosage (mg/kg body weight) causing death in 50 percent of exposed animals.

Table 2-1 Approximate Acute LD$_{50}$s of Some Representative Chemical Agents

CLASSIFICATION OF TOXIC AGENTS

Toxic agents are classified in a variety of ways, depending on the interests and needs of the classifier. In this textbook, for example, toxic agents are discussed in terms of their target organs (liver, kidney, hematopoietic system, etc.), use (pesticide, solvent, food additive, etc.), source (animal and plant toxins), and effects (cancer, mutation, liver injury, etc.). The term *toxin* generally refers to toxic substances that are produced by biological systems such as plants, animals, fungi or bacteria. The term *toxicant* is used in speaking of toxic substances that are produced by or are a by-product of anthropogenic (human-made) activities. Thus, zeralanone, produced by a mold, is a toxin, whereas "dioxin" [2,3,7,8-tetrachlorodibenzo- *p*-dioxin (TCDD)], produced during the combustion of certain chlorinated organic chemicals, is a toxicant. Some toxicants can be produced by both natural and anthropogenic activities. For example, polyaromatic hydrocarbons are produced by the combustion of organic matter, which may occur both through natural processes (e.g., forest fires) and through anthropogenic activities (e.g., combustion of coal for energy production; cigarette smoking). Arsenic, a toxic metalloid, may occur as a natural contaminant of groundwater or may contaminate groundwater secondary to industrial activities. Generally, such toxic substances are referred to as toxicants, rather than toxins, because, although they are naturally produced, they are not produce by biological systems.

Toxic agents also may be classified in terms of their physical state (gas, dust, liquid), their chemical stability or reactivity (explosive, flammable, oxidizer), general chemical structure (aromatic amine, halogenated hydrocarbon, etc.), or poisoning potential (extremely toxic, very toxic, slightly toxic, etc.). Classification of toxic agents on the basis of their biochemical mechanisms of action (e.g., alkylating agent, sulfhydryl inhibitor, methemoglobin producer) is usually more informative than classification by general terms such as irritants and corrosives. But more general classifications such as air pollutants, occupation-related agents, and acute and chronic poisons can provide a useful focus on a specific problem. It is evident from this discussion that no single classification is applicable to the entire spectrum of toxic agents and that combinations of classification systems or a classification based on other factors may be needed to provide the best rating system for a special purpose. Nevertheless, classification systems that take into consideration both the chemical and the biological properties of an agent and the exposure characteristics are most likely to be useful for legislative or control purposes and for toxicology in general.

CHARACTERISTICS OF EXPOSURE

Toxic effects in a biological system are not produced by a chemical agent unless that agent or its metabolic breakdown (biotransformation) products reach appropriate sites in the body at a concentration and for a length of time sufficient to produce a toxic manifestation. Many chemicals are of relatively low toxicity in the "native" form but, when acted on by enzymes in the body, are converted to intermediate forms that interfere with normal cellular biochemistry and physiology. Thus, whether a toxic response occurs is dependent on the chemical and physical properties of the agent, the exposure situation, how the agent is metabolized by the system, and the overall susceptibility of the biological system or subject. Thus, to characterize fully the potential hazard of a specific chemical agent, we need to know not only what type of effect it produces and the dose required to produce that effect but also information about the agent, the exposure, and its disposition by the subject. The major factors that influence toxicity as it relates to the exposure situation for a specific chemical are the route of administration and the duration and frequency of exposure.

Route and Site of Exposure

The major routes (pathways) by which toxic agents gain access to the body are the gastrointestinal tract (ingestion), lungs (inhalation), skin (topical, percutaneous, or dermal), and other parenteral (other than intestinal canal) routes. Toxic agents generally produce the greatest effect and the most rapid response when given directly into the bloodstream (the intravenous route). An approximate descending order of effectiveness for the other routes would be inhalation, intraperitoneal, subcutaneous, intramuscular, intradermal, oral, and dermal. The "vehicle" (the material in which the chemical is dissolved) and other formulation factors can markedly alter absorption after ingestion, inhalation, or topical exposure. In addition, the route of administration can influence the toxicity of agents. For example, an agent that

is detoxified in the liver would be expected to be less toxic when given via the portal circulation (oral) than when given via the systemic circulation (inhalation).

Occupational exposure to toxic agents most frequently results from breathing contaminated air (inhalation) and/or direct and prolonged contact of the skin with the substance (dermal exposure), whereas accidental and suicidal poisoning occurs most frequently by oral ingestion. Comparison of the lethal dose of a toxic substance by different routes of exposure often provides useful information about its extent of absorption. In instances when the lethal dose after oral or dermal administration is similar to the lethal dose after intravenous administration, the assumption is that the toxic agent is absorbed readily and rapidly. Conversely, in cases where the lethal dose by the dermal route is several orders of magnitude higher than the oral lethal dose, it is likely that the skin provides an effective barrier to absorption of the agent. Toxic effects by any route of exposure also can be influenced by the concentration of the agent in its vehicle, the total volume of the vehicle and the properties of the vehicle to which the biological system is exposed, and the rate at which exposure occurs. Studies in which the concentration of a chemical in the blood is determined at various times after exposure are often needed to clarify the role of these and other factors in the toxicity of a compound. For more details on the absorption of toxicants, see Chap. 5.

Duration and Frequency of Exposure

Toxicologists usually divide the exposure of experimental animals to chemicals into four categories: acute, subacute, subchronic, and chronic. Acute exposure is defined as exposure to a chemical for less than 24 h, and examples of exposure routes are intraperitoneal, intravenous, and subcutaneous injection; oral intubation; and dermal application. While acute exposure usually refers to a single administration, repeated exposures may be given within a 24-h period for some slightly toxic or practically nontoxic chemicals. Acute exposure by inhalation refers to continuous exposure for less than 24 h, most frequently for 4 h. Repeated exposure is divided into three categories: subacute, subchronic, and chronic. *Subacute exposure* refers to repeated exposure to a chemical for 1 month or less, *subchronic* for 1 to 3 months, and *chronic* for more than 3 months. These three categories of repeated exposure can be by any route, but most often they occur by the oral route, with the chemical added directly to the diet.

In human exposure situations, the frequency and duration of exposure are usually not as clearly defined as in controlled animal studies, but many of the same terms are used to describe general exposure situations. Thus, workplace or environmental exposures may be described as *acute* (occurring from a single incident or episode), *subchronic* (occurring repeatedly over several weeks or months), or *chronic* (occurring repeatedly for many months or years).

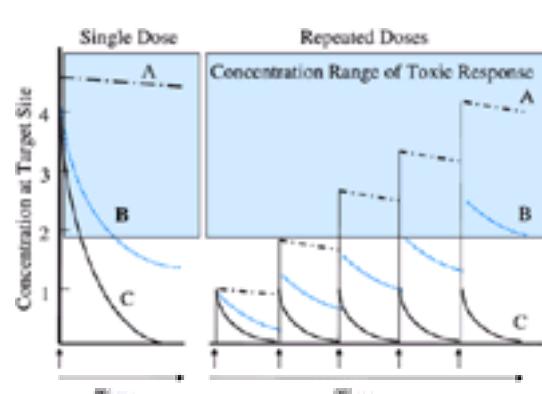
For many agents, the toxic effects that follow a single exposure are quite different from those produced by repeated exposure. For example, the primary acute toxic manifestation of benzene is central nervous system (CNS) depression, but repeated exposures can result in bone marrow toxicity and an increased risk for leukemia. Acute exposure to agents that are rapidly absorbed is likely to produce immediate toxic effects but also can produce delayed toxicity that may or may not be similar to the toxic effects of chronic exposure. Conversely, chronic exposure to a toxic agent may produce some immediate (acute) effects after each administration in addition to the long-term, low-level, or chronic effects of the toxic substance. In characterizing the toxicity of a specific chemical, it is evident that information is needed not only for the single-dose (acute) and long-term (chronic) effects but also for exposures of intermediate duration. The other time-related factor that is important in the temporal characterization of repeated exposures is the frequency of exposure. The relationship between elimination rate and frequency of exposure is shown in Fig. 2-2. A chemical that produces severe effects with a single dose may have no effect if the same total dose is given in several intervals. For the chemical depicted by line B in Fig. 2-2, in which the half-life for elimination (time necessary for 50 percent of the chemical to be removed from the bloodstream) is approximately equal to the dosing frequency, a theoretical toxic concentration of 2 U is not reached until the fourth dose, whereas that concentration is reached with only two doses for chemical A, which has an elimination rate much slower than the dosing interval (time between each repeated dose). Conversely, for chemical C, where the elimination rate is much shorter than the dosing interval, a toxic concentration at the site of toxic effect will never be reached regardless of how many doses are administered. Of course, it is possible that residual cell or tissue damage occurs with each dose even though the chemical itself is not accumulating. The important consideration, then, is whether the interval between doses is sufficient to allow for complete repair of tissue damage. It is evident that with any type of repeated exposure, the production of a toxic effect is influenced not only by the frequency of exposure but may, in fact, be totally dependent on the frequency rather than the duration of exposure. Chronic toxic effects may occur, therefore, if the chemical accumulates in the biological system (rate of absorption exceeds the rate of biotransformation and/or excretion), if it produces irreversible toxic effects, or if there is insufficient time for the system to recover from the toxic damage within the exposure frequency interval. For additional discussion of these relationships, consult Chap. 5 and Chap. 7.


Figure 2-2. Diagrammatic view of the relationship between dose and concentration at the target site under different conditions of dose frequency and elimination rate.

Line A. A chemical with very slow elimination (e.g., half-life of 1 year). *Line B.* A chemical with a rate of elimination equal to frequency of dosing (e.g., 1 day). *Line C.* Rate of elimination faster than the dosing frequency (e.g., 5 h). Blue-shaded area is representative of the concentration of chemical at the target site necessary to elicit a toxic response.

SPECTRUM OF UNDESIRED EFFECTS

The spectrum of undesired effects of chemicals is broad. Some effects are deleterious and others are not. In therapeutics, for example, each drug produces a number of effects, but usually only one effect is associated with the primary objective of the therapy; all the other effects are referred to as *undesirable* or *side effects* of that drug for that therapeutic indication. However, some of these side effects may be desired for another therapeutic indication. For example, the "first-generation" antihistamine diphenhydramine (Benadryl) is effective in reducing histamine responses associated with allergies, but it readily enters the brain and causes mild CNS depression (drowsiness, delayed reaction time). With the advent of newer histamine (H_1) receptor antagonists that do not cross the blood-brain barrier and thus do not have this CNS-depressant side effect, the drug is used less commonly today as an antihistamine. However, it is widely used as an "over the counter" sleep remedy in combination with analgesics (e.g., Tylenol PM, Excedrin PM, etc), taking advantage of the CNS-depressant effects. Some side effects of drugs are never desirable and are always deleterious to the well-being of humans. These are referred to as the *adverse, deleterious,* or *toxic* effects of the drug.

Allergic Reactions

Chemical allergy is an immunologically mediated adverse reaction to a chemical resulting from previous sensitization to that chemical or to a structurally similar one. The term *hypersensitivity* is most often used to describe this allergic state, but *allergic reaction* and *sensitization reaction* are also used to describe this situation when preexposure of the chemical is required to produce the toxic effect (see Chap. 12). Once sensitization has occurred, allergic reactions may result from exposure to relatively very low doses of chemicals; therefore population-based dose–response curves for allergic reactions have seldom been obtained. Because of this omission, some people assumed that allergic reactions are not dose-related. Thus, they do not consider the allergic reaction to be a true toxic response. However, for a given allergic individual, allergic reactions are dose-related. For example, it is well known that the allergic response to pollen in sensitized individuals is related to the concentration of pollen in the air. In addition, because the allergic response is an undesirable, adverse, deleterious effect, it obviously is also a toxic response. Sensitization reactions are sometimes very severe and may be fatal.

Most chemicals and their metabolic products are not sufficiently large to be recognized by the immune system as a foreign substance and thus must first combine with an endogenous protein to form an antigen (or immunogen). A molecule that must combine with an endogenous protein to elicit an allergic reaction is called a *hapten.*

The hapten-protein complex (antigen) is then capable of eliciting the formation of antibodies, and usually at least 1 or 2 weeks is required for the synthesis of significant amounts of antibodies. Subsequent exposure to the chemical results in an antigen–antibody interaction, which provokes the typical manifestations of allergy. The manifestations of allergy are numerous. They may involve various organ systems and range in severity from minor skin disturbance to fatal anaphylactic shock. The pattern of allergic response differs in various species. In humans, involvement of the skin (e.g., dermatitis, urticaria, and itching) and involvement of the eyes (e.g., conjunctivitis) are most common, whereas in guinea pigs, bronchiolar constriction leading to asphyxia is the most common. However, chemically induced asthma (characterized by bronchiolar constriction) certainly does occur in some humans, and the incidence of allergic asthma has increased substantially in recent years. Hypersensitivity reactions are discussed in more detail in Chap. 12.

Idiosyncratic Reactions

Chemical idiosyncrasy refers to a genetically determined abnormal reactivity to a chemical (Goldstein et al., 1974; Levine, 1978). The response observed is usually qualitatively similar to that observed in all individuals but may take the form of extreme sensitivity to low doses or extreme insensitivity to high doses of the chemical. However, while some people use the term *idiosyncratic* as a catchall to refer to all reactions that occur with low frequency, it should not be used in that manner (Goldstein et al., 1974). A classic example of an idiosyncratic reaction is provided by patients who exhibit prolonged muscular relaxation and apnea (inability to breathe) lasting several hours after a standard dose of succinylcholine. Succinylcholine usually produces skeletal muscle relaxation of only short duration because of its very rapid metabolic degradation by an enzyme that is present normally in the bloodstream called plasma butyrylcholinesterase (also referred to as pseudocholinesterase). Patients exhibiting this idiosyncratic reaction have a genetic polymorphism in the gene for the enzyme butyrylcholinesterase, which is less active in breaking down succinylcholine. Family pedigree and molecular genetic analyses have demonstrated that the presence of low plasma butyrylcholinesterase activity is due to the presence of one or more single nucleotide polymorphisms in this gene (Bartels et al., 1992). Similarly, there is a group of people who are abnormally sensitive to nitrites and certain other chemicals that have in common the ability to oxidize the iron in hemoglobin to produce *methemoglobin,* which is incapable of carrying oxygen to the tissues. The unusual phenotype is inherited as an autosomal recessive trait and is characterized by a deficiency in NADH-cytochrome b5 reductase activity. The genetic basis for this idiosyncratic response has been identified as a single nucleotide change in codon 127, which results in replacement of serine with proline (Kobayashi et al., 1990). The consequence of this genetic deficiency is that these individuals may suffer from a serious lack of oxygen delivery to tissues after exposure to doses of methemoglobin-producing chemicals that would be harmless to individuals with normal NADH-cytochrome b5 reductase activity.

Immediate versus Delayed Toxicity

Immediate toxic effects can be defined as those that occur or develop rapidly after a single administration of a substance, whereas delayed toxic effects are those that occur after the lapse of some time. Carcinogenic effects of chemicals usually have a long latency period, often 20 to 30 years after the initial exposure, before tumors are observed in humans. For example, daughters of mothers who took diethylstilbestrol (DES) during pregnancy have a greatly increased risk of developing vaginal cancer, but not other types of cancer, in young adulthood, some 20 to 30 years after their in utero exposure to DES (Hatch et al., 1998). Also, delayed neurotoxicity is observed after exposure to some organophosphorus insecticides that act by covalent modification of an enzyme referred to as *neuropathy target esterase* (NTE), a neuronal protein with serine esterase activity (Glynn et al., 1999). Binding of certain organophosphates (OP) to this protein initiates degeneration of long axons in the peripheral and central nervous system. The most notorious of the compounds that produce this type of neurotoxic effect is triorthocresylphosphate (TOCP). The effect is not observed until at least several days after exposure to the toxic compound. In contrast, most substances produce immediate toxic effects but do not produce delayed effects.

Reversible versus Irreversible Toxic Effects

Some toxic effects of chemicals are reversible, and others are irreversible. If a chemical produces pathological injury to a tissue, the ability of that tissue to regenerate largely determines whether the effect is reversible or irreversible. Thus, for a tissue such as liver, which has a high ability to regenerate, most injuries are reversible, whereas injury to the CNS is largely irreversible because differentiated cells of the CNS cannot divide and be replaced. Carcinogenic and teratogenic effects of chemicals, once they occur, are usually considered irreversible toxic effects.

Local versus Systemic Toxicity

Another distinction between types of effects is made on the basis of the general site of action. Local effects are those that occur at the site of first contact between the biological system and the toxicant. Such effects are produced by the ingestion of caustic substances or the inhalation of irritant materials. For example, chlorine gas reacts with lung tissue at the site of contact, causing damage and swelling of the tissue, with possibly fatal consequences, even though very little of the chemical is absorbed into the bloodstream. The alternative to local effects is systemic effects. Systemic effects require absorption and distribution of a toxicant from its entry point to a distant site, at which deleterious effects are produced. Most substances except highly reactive materials produce systemic effects. For some materials, both effects can be demonstrated. For example, tetraethyl lead produces effects on skin at the site of absorption and then is transported systemically to produce its typical effects on the CNS and other organs. If the local effect is marked, there may also be indirect systemic effects. For example, kidney damage after a severe acid burn is an indirect systemic effect because the toxicant does not reach the kidney.

Most chemicals that produce systemic toxicity do not cause a similar degree of toxicity in all organs; instead, they usually elicit their major toxicity in only one or two organs. These sites are referred to as the *target organs* of toxicity of a particular chemical. The target organ of toxicity is often not the site of the highest concentration of the chemical. For example, lead is concentrated in bone, but its toxicity is due to its effects in soft tissues, particularly the brain. DDT is concentrated in adipose tissue but produces no known toxic effects in that tissue.

The target organ of toxicity most frequently involved in systemic toxicity is the CNS (brain and spinal cord). Even with many compounds having a prominent effect elsewhere, damage to the CNS can be demonstrated by the use of appropriate and sensitive methods. Next in order of frequency of involvement in systemic toxicity are the circulatory system; the blood and hematopoietic system; visceral organs such as the liver, kidney, and lung; and the skin. Muscle and bone are least often the target sites for systemic effects. With substances that have a predominantly local effect, the frequency with which tissues react depends largely on the portal of entry (skin, gastrointestinal tract, or respiratory tract).

INTERACTION OF CHEMICALS

Because of the large number of different chemicals an individual may come in contact with at any given time (workplace, drugs, diet, hobbies, etc.), it is necessary, in assessing the spectrum of responses, to consider how different chemicals may interact with each other. Interactions can occur in a variety of ways. Chemical interactions are known to occur by a number of mechanisms, such as alterations in absorption, protein binding, and the biotransformation and excretion of one or both of the interacting toxicants. In addition to these modes of interaction, the response of the organism to combinations of toxicants may be increased or decreased because of toxicologic responses at the site of action.

The effects of two chemicals given simultaneously produce a response that may simply be additive of their individual responses or may be greater or less than that expected by addition of their individual responses. The study of these interactions often leads to a better understanding of the mechanism of toxicity of the chemicals involved. A number of terms have been used to describe pharmacologic and toxicologic interactions. An *additive* effect occurs when the combined effect of two chemicals is equal to the sum of the effects of each agent given alone (example: 2 + 3 = 5). The effect most commonly observed when two chemicals are given together is an additive effect. For example, when two organophosphate insecticides are given together, the cholinesterase inhibition is usually additive. A *synergistic* effect occurs when the combined effects of two chemicals are much greater than the sum of the effects of each agent given alone (example: 2 + 2 = 20). For example, both carbon tetrachloride and ethanol are hepatotoxic compounds, but together they produce much more liver injury than the mathematical sum of their individual effects on liver at a given dose would suggest. *Potentiation* occurs when one substance does not have a toxic effect on a certain organ or system but when added to another chemical makes that chemical much more toxic (example: 0 + 2 = 10). Isopropanol, for example, is not hepatotoxic, but when it is administered in addition to carbon tetrachloride, the hepatotoxicity of carbon tetrachloride is much greater than that when it is given alone. *Antagonism* occurs when two chemicals administered together interfere with each other's actions or one interferes with the action of the other (example: 4 + 6 = 8; 4 + (−4) = 0; 4 + 0 = 1). Antagonistic effects of chemicals are often very desirable in toxicology and are the basis of many antidotes. There are four major types of antagonism: functional, chemical, dispositional, and receptor. *Functional antagonism* occurs when two chemicals counterbalance each other by producing opposite effects on the same physiologic function. Advantage is taken of this principle in that the blood pressure can markedly fall during severe barbiturate intoxication, which can be effectively antagonized by the intravenous administration of a vasopressor agent such as norepinephrine or metaraminol. Similarly, many chemicals, when given at toxic dose levels, produce convulsions, and the convulsions often can be controlled by giving anticonvulsants such as the benzodiazepines (e.g., diazepam). *Chemical antagonism* or *inactivation* is simply a

chemical reaction between two compounds that produces a less toxic product. For example, dimercaprol (British antilewisite, or BAL) chelates with metal ions such as arsenic, mercury, and lead and decreases their toxicity. The use of antitoxins in the treatment of various animal toxins is also an example of chemical antagonism. The use of the strongly basic low-molecular-weight protein protamine sulfate to form a stable complex with heparin, which abolishes its anticoagulant activity, is another example. *Dispositional antagonism* occurs when the disposition—that is, the absorption, biotransformation, distribution, or excretion of a chemical—is altered so that the concentration and/or duration of the chemical at the target organ are diminished. Thus, the prevention of absorption of a toxicant by ipecac or charcoal and the increased excretion of a chemical by administration of an osmotic diuretic or alteration of the pH of the urine are examples of dispositional antagonism. If the parent compound is responsible for the toxicity of the chemical (such as the anticoagulant warfarin) and its metabolic breakdown products are less toxic than the parent compound, increasing the compound's metabolism (biotransformation) by administering a drug that increases the activity of the metabolizing enzymes (e.g., a "microsomal enzyme inducer" such as phenobarbital) will decrease its toxicity. However, if the chemical's toxicity is largely due to a metabolic product (as in the case of the organophosphate insecticide parathion), inhibiting its biotransformation by an inhibitor of microsomal enzyme activity (SKF-525A or piperonyl butoxide) will decrease its toxicity. *Receptor antagonism* occurs when two chemicals that bind to the same receptor produce less of an effect when given together than the addition of their separate effects (example: 4 + 6 = 8) or when one chemical antagonizes the effect of the second chemical (example: 0 + 4 = 1). Receptor antagonists are often termed *blockers.* This concept is used to advantage in the clinical treatment of poisoning. For example, the receptor antagonist naloxone is used to treat the respiratory depressive effects of morphine and other morphine-like narcotics by competitive binding to the same receptor. Another example of receptor antagonism is the use of the antiestrogen drug tamoxifen to lower breast cancer risk among women at high risk for this estrogen-related cancer. Tamoxifen competitively block estradiol from binding to its receptor. Treatment of organophosphate insecticide poisoning with atropine is an example not of the antidote competing with the poison for the receptor (cholinesterase) but involves blocking the receptor (cholinergic receptor) for the excess acetylcholine that accumulates by poisoning of the cholinesterase by the organophosphate (see Chap. 22).

TOLERANCE

Tolerance is a state of decreased responsiveness to a toxic effect of a chemical resulting from prior exposure to that chemical or to a structurally related chemical. Two major mechanisms are responsible for tolerance: one is due to a decreased amount of toxicant reaching the site where the toxic effect is produced (*dispositional tolerance*), and the other is due to a reduced responsiveness of a tissue to the chemical. Comparatively less is known about the cellular mechanisms responsible for altering the responsiveness of a tissue to a toxic chemical than is known about dispositional tolerance. Two chemicals known to produce dispositional tolerance are carbon tetrachloride and cadmium. Carbon tetrachloride produces tolerance to itself by decreasing the formation of the reactive metabolite (trichloromethyl radical) that produces liver injury (Chap. 13). The mechanism of cadmium tolerance is explained by induction of metallothionein, a metal-binding protein. Subsequent binding of cadmium to metallothionein rather than to critical macromolecules thus decreases its toxicity.

DOSE RESPONSE

The characteristics of exposure and the spectrum of effects come together in a correlative relationship customarily referred to as the *dose–response relationship.* Whatever response is selected for measurement, the relationship between the degree of response of the biological system and the amount of toxicant administered assumes a form that occurs so consistently as to be considered the most fundamental and pervasive concept in toxicology.

From a practical perspective, there are two types of dose–response relationships: (1) the individual dose–response relationship, which describes the response of an *individual* organism to varying doses of a chemical, often referred to as a "graded" response because the measured effect is continuous over a range of doses, and (2) a quantal dose–response relationship, which characterizes the distribution of responses to different doses in a *population* of individual organisms.

Individual, or Graded, Dose–Response Relationships

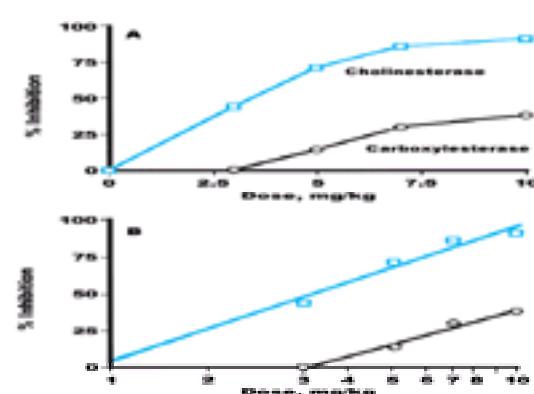
Individual dose–response relationships are characterized by a dose-related increase in the severity of the response. The dose relatedness of the response often results from an alteration of a specific biochemical process. For example, Fig. 2-3 shows the dose–response relationship between different dietary doses of the organophosphate insecticide chlorpyrifos and the extent of inhibition of two different enzymes in the brain and liver: acetylcholinesterase and carboxylesterase. In the brain, the degree of inhibition of both enzymes is clearly dose-related and spans a wide range, although the amount of inhibition per unit dose is different for the two enzymes. From the shapes of these two dose–response curves it is evident that, in the brain, cholinesterase is more easily inhibited than carboxylesterase. The toxicologic response that results is directly related to the degree of cholinesterase enzyme inhibition in the brain. Thus, clinical signs and symptoms for chlorpyrifos would follow a dose–response relationship similar to that for brain cholinesterase. However, for many chemicals, more than one effect may result because of multiple different target sites in different tissues. Thus, the observed response to varying doses of a chemical in the whole organism is often complicated by the fact that most toxic substances have multiple sites or mechanisms of toxicity, each with its own "dose–response" relationship and subsequent adverse effect. Note that when these dose–response data are plotted using the base 10 log of the dose on the abscissa (Fig. 2.3 *B*), a better "fit" of the data to a straight line occurs. This is typical of many graded as well as quantal dose–response relationships.


Figure 2-3. Dose–response relationship between different doses of the organophosphate insecticide chlorpyrifos and esterase enzyme inhibition in the brain.

Open circles and blue lines represent acetylcholinesterase activity and closed circles represent carboxylesterase activity in the brains of pregnant female Long-Evans rats given 5 daily doses of chlorpyrifos. *A.* Dose–response curve plotted on an arithmetic scale. *B.* Same data plotted on a semi-log scale. (Data derived from Lassiter et al., Gestational exposure to chlorpyrifos: Dose response profiles for cholinesterase and carboxylesterase activity. *Toxicol Sci.* 52:92–100, 1999, with permission.)

Quantal Dose–Response Relationships

In contrast to the "graded" or continuous-scale dose–response relationship that occurs in individuals, the dose–response relationships in a *population* are by definition quantal—or "all or none"—in nature; that is, at any given dose, an individual in the population is classified as either a "responder" or a "nonresponder." Although these distinctions of "quantal population" and "graded individual" dose–response relationships are useful, the two types of responses are conceptually identical. The ordinate in both cases is simply labeled *the response,* which may be the degree of response in an individual or system or the fraction of a population responding, and the abscissa is the range in administered doses.

In toxicology, the quantal dose response is used extensively. Determination of the median lethal dose (LD_{50}) is usually the first experiment performed with a new chemical. The LD_{50} is the statistically derived single dose of a substance that can be expected to cause death in 50 percent of the animals tested. Typically, groups of animals are dosed at different levels, and the mortality that results in each dose group is recorded. The top panel of Fig. 2-4 shows that quantal dose responses such as lethality exhibit a normal or gaussian distribution. The frequency histogram in this panel also shows the relationship between dose and effect. The bars represent the percentage of animals that died at each dose minus the percentage that died at the immediately lower dose. One can clearly see that only a few animals responded to the lowest dose and the highest dose. Larger numbers of animals responded to doses intermediate between these two extremes, and the maximum frequency of response occurred in the middle portion of the dose range. Thus, we have a bell-shaped curve known as a *normal frequency distribution.* The reason for this normal distribution is that there are differences in susceptibility to chemicals among individuals; this is known as biological variation. Animals responding at the

left end of the curve are referred to as *hypersusceptible,* and those at the right end of the curve are called *resistant.* If the numbers of individuals responding at each consecutive dose are added together, a cumulative, quantal dose–response relationship is obtained. When a sufficiently large number of doses is used with a large number of animals per dose, a sigmoid dose–response curve is observed, as depicted in the middle panel of Fig. 2-4. With the lowest dose (6 mg/kg), 1 percent of the animals die. A normally distributed sigmoid curve such as this one approaches a response of 0 percent as the dose is decreased and approaches 100 percent as the dose is increased; but—theoretically—it never passes through 0 and 100 percent. However, the minimally effective dose of any chemical that evokes a stated all-or-none response is called the *threshold dose* even though it cannot be determined experimentally.

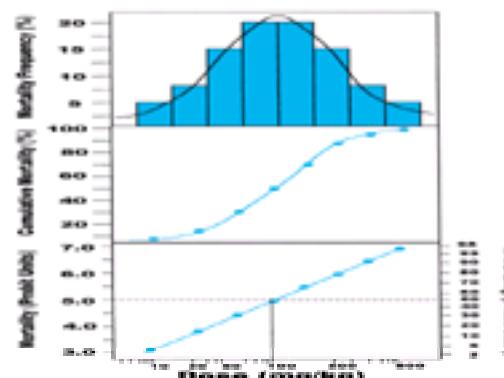

Figure 2-4. Diagram of quantal dose–response relationship.

The abscissa is a log dosage of the chemical. In the top panel the ordinate is mortality frequency, in the middle panel the ordinate is percent mortality, and in the bottom panel the mortality is in probit units (see text).

The sigmoid curve has a relatively linear portion between 16 and 84 percent. These values represent the limits of 1 standard deviation (SD) of the mean (and the median) in a population with truly normal or gaussian distribution. However, it is usually not practical to describe the dose–response curve from this type of plot because one does not usually have large enough sample sizes to define the sigmoid curve adequately. In a normally distributed population, the mean ±1 SD represents 68.3 percent of the population, the mean ±2 SD represents 95.5 percent of the population, and the mean ±3 SD equals 99.7 percent of the population. Since quantal dose–response phenomena are usually normally distributed, one can convert the percent response to units of deviation from the mean or normal equivalent deviations (NEDs). Thus, the NED for a 50 percent response is 0; an NED of +1 is equated with an 84.1 percent response. Later, it was suggested (Bliss, 1957) that units of NED be converted by the addition of 5 to the value to avoid negative numbers and that these converted units be called *probit units.* The probit (from the contraction of *prob*ability un*it*), then, is an NED plus 5. In this transformation, a 50 percent response becomes a probit of 5, a +1 deviation becomes a probit of 6, and a −1 deviation is a probit of 4.

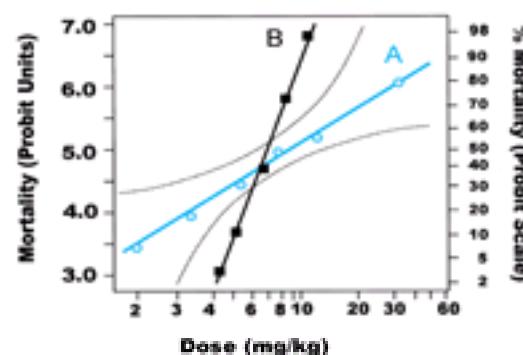
The data given in the top two panels of Fig. 2-4 are replotted in the bottom panel with the mortality plotted in probit units. The data in the middle panel (which was in the form of a sigmoid curve) and the top panel (a bell-shaped curve) form a straight line when transformed into probit units. In essence, what is accomplished in a probit transformation is an adjustment of mortality or other quantal data to an assumed normal population distribution, resulting in a straight line. The LD_{50} is obtained by drawing a horizontal line from the probit unit 5, which is the 50 percent mortality point, to the dose–effect line. At the point of intersection, a vertical line is drawn, and this line intersects the abscissa at the LD_{50} point. It is evident from the line that information with respect to the lethal dose for 90 percent or for 10 percent of the population also may be derived by a similar procedure. Mathematically, it can be demonstrated that the range of values encompassed by the confidence limits is narrowest at the midpoint of the line (LD_{50}) and widest at both extremes (LD_{10} and LD_{90}) of the dose–response curve (dotted lines in Fig. 2-5). In addition to the LD_{50}, the slope of the dose–response curve can also be obtained. Figure 2-5 demonstrates the dose–response curves for the mortality of two compounds. Compound A exhibits a "flat" dose–response curve, showing that a large change in dosage is required before a significant change in response will be observed. However, compound B exhibits a "steep" dose–response curve, where a relatively small change in dosage will cause a large change in response. It is evident that the LD_{50} for both compounds is the same (8 mg/kg). However, the slopes of the dose–response curves are quite different. At one-half of LD_{50} of the compounds (4 mg/kg), less than 1 percent of the animals exposed to compound B would die but 20 percent of the animals given compound A would die.


Figure 2-5. Comparison of dose–response relationship for two different chemicals, plotted on a log dose-probit scale.

Note that the slope of the dose–response is steeper for chemical *B* than chemical *A.* Dotted lines represents the confidence limits for chemical *A.*

The *quantal all-or-none response* is not limited to lethality. Similar dose–response curves can be constructed for cancer, liver injury, and other types of toxic responses as well as for beneficial therapeutic responses such as anesthesia or lowering of blood pressure. This is usually performed by measuring a particular parameter (e.g., blood pressure) in a large number of control animals and determining its standard deviation, which is a measure of its variability. Because the mean +3 SD represents 99.7 percent of the population, one can assign all animals that lie outside this range after treatment with a chemical as being affected and those lying within this range as not being affected by the chemical. Using a series of doses of the chemical, one thus can construct a quantal dose–response curve similar to that described above for lethality.

In Fig. 2-4 and Fig. 2-5 the dosage has been given on a log basis. Although the use of the log of the dosage is empiric, log-dosage plots for normally distributed quantal data provide a more nearly linear representation of the data. It must be remembered, however, that this is not universally the case. Some radiation effects, for example, give a better probit fit when the dose is expressed arithmetically rather than logarithmically. There are other situations in which other functions (e.g., exponentials) of dosage provide a better fit to the data than does the log function. It is also conventional to express the dosage in milligrams per kilogram. It might be argued that expression of dosage on a mole-per-kilogram basis would be better, particularly for making comparisons among a series of compounds. Although such an argument has considerable merit, dosage is usually expressed in milligrams per kilogram.

One might also view dosage on the basis of body weight as being less appropriate than other bases, such as surface area, which is approximately proportional to (body weight)$^{2/3}$. In Table 2-2 selected values are given to compare the differences in dosage by the two alternatives. Given a dose of 100 mg/kg, it can be seen that the dose (milligrams per animal), of course, is proportional to the dose administered by body weight. Surface area is not proportional to weight: While the weight of a human is 3500 times greater than that of a mouse, the surface area of humans is only about 390 times greater than that of mice. Chemicals are usually administered in toxicologic studies as milligrams per kilogram. The same dose given to humans and mice on a weight basis (mg/kg) would be approximately 10 times greater in humans than mice if that dosage were expressed per surface area (mg/cm^2). Cancer chemotherapeutic agents are usually administered on the basis of surface area.

Table 2-2 Comparison of Dosage by Weight and Surface Area

	WEIGHT g	DOSAGE mg/kg	DOSE mg/animal	SURFACE AREA cm²	DOSAGE mg/cm²
Mouse	20	100	2	46	0.043
Rat	200	100	20	325	0.061
Guinea pig	400	100	40	565	0.071
Rabbit	1500	100	150	1270	0.118
Cat	2000	100	200	1380	0.145
Monkey	4000	100	400	2980	0.134
Dog	12,000	100	1200	5770	0.207
Human	70,000	100	7000	18,000	0.388

Shape of the Dose–Response Curve

Essential Nutrients The shape of the dose–response relationship has many important implications in toxicity assessment. For example, for substances that are required for normal physiologic function and survival (e.g., vitamins and essential trace elements such as chromium, cobalt, and selenium), the shape of the "graded" dose–response relationship in an individual over the entire dose range is actually U-shaped (Fig. 2-6). That is, at very low doses, there is a high level of adverse effect, which decreases with an increasing dose. This region of the dose–response relationship for essential nutrients is commonly referred to as a *deficiency.* As the dose is increased to a point where the deficiency no longer exists, no adverse response is detected and the organism is in a state of homeostasis. However, as the dose is increased to abnormally high levels, an adverse response (usually qualitatively different from that observed at deficient doses) appears and increases in magnitude with increasing dose, just as with other toxic substances. Thus, it is recognized that high doses of vitamin A can cause liver toxicity and birth defects, high doses of selenium can affect the brain, and high doses of estrogens may increase the risk of breast cancer, even though low doses of all these substances are essential for life.

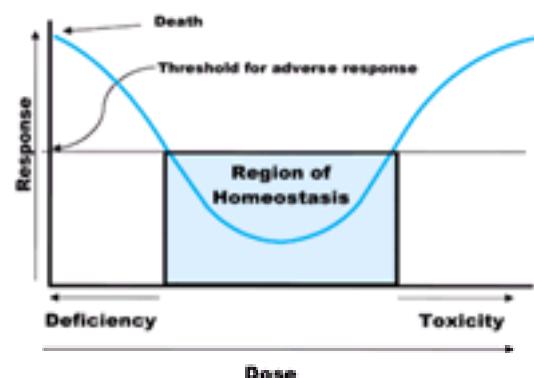

Figure 2-6. Individual dose–response relationship for an essential substance such as a vitamin or trace element.

It is generally recognized that, for most types of toxic responses, a threshold exists such that at doses below the threshold, no toxicity is evident. For essential substances, doses below the minimum daily requirement, as well as those above the threshold for safety, may be associated with toxic effects. The blue-shaded region represents the "region of homeostasis"—the dose range that results in neither deficiency or toxicity.

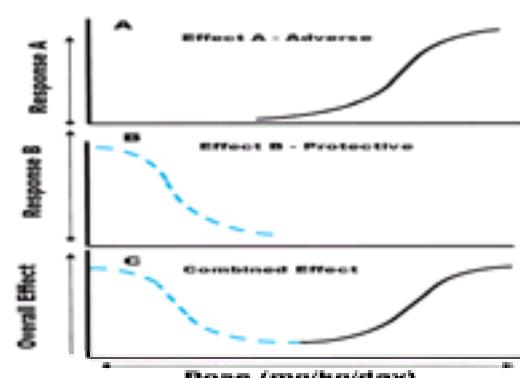
Hormesis There is considerable evidence to suggest that some nonnutritional toxic substances may also impart beneficial or stimulatory effects at low doses but that, at higher doses, they produce adverse effects. This concept of "hormesis" was first described for radiation effects but may also pertain to certain chemical responses (Calabrese and Baldwin, 1999). Thus, in plotting dose versus response over a wide range of doses, the effects of hormesis may also result in a "U-shaped" dose–response curve. In its original development, the concept of hormesis pertained to the ability of substances to stimulate biological systems at low doses but to inhibit them at high doses. The application of the concept of hormesis to whole-animal toxicologic dose–response relationships may also be relevant but requires that the "response" on the ordinate be variant with dose. For example, chronic alcohol consumption is well recognized to increase the risk of esophageal cancer, liver cancer, and cirrhosis of the liver at relatively high doses, and this response is dose-related (curve A, Fig. 2-7). However, there is also substantial clinical and epidemiologic evidence that low to moderate consumption of alcohol reduces the incidence of coronary heart disease and stroke (curve B, Fig. 2-7) (Hanna *et al.,* 1997). Thus, when all responses are plotted on the ordinate, a "U-shaped" dose–response curve is obtained (curve C, Fig. 2-7). U-shaped dose–response relationships have obvious implications for the process of low dose extrapolation in risk assessment.


Figure 2-7. Hypothetical dose–response relationship depicting characteristics of hormesis.

Hormetic effects of a substance are hypothesized to occur when relatively low doses result in the stimulation of a beneficial or protective response (*B*), such as induction of enzymatic pathways that protect against oxidative stress. Although low doses provide a potential beneficial effect, a threshold is exceeded as the dose increases and the net effects will be detrimental (*A*), resulting in a typical dose-related increase in toxicity. The complete dose–response curve (*C*) is conceptually similar to the individual dose–response relationship for essential nutrients shown in Fig. 2-6.

Another important aspect of the dose–response relationship at low doses is the concept of the threshold. It has long been recognized that acute toxicologic responses are associated with thresholds; that is, there is some dose below which the probability of an individual responding is zero. Obviously, the identification of a threshold depends on the particular response that is measured, the sensitivity of the measurement, and the number of subjects studied. For the individual dose–response relationship, thresholds for most toxic effects certainly exist, although interindividual variability in response and qualitative changes in response pattern with dose make it difficult to establish a true "no effects" threshold for any chemical. The biological basis of thresholds for acute responses is well established and frequently can be demonstrated on the basis of mechanistic information (Aldridge, 1986). The traditional approaches to establishing acceptable levels of exposure to chemicals are inherently different for threshold versus nonthreshold responses. The existence of thresholds for chronic responses is less well defined, especially in the area of chemical carcinogenesis. It is, of course, impossible to scientifically prove the absence of a threshold, as one can never prove a negative. Nevertheless, for the

identification of "safe" levels of exposure to a substance, the absence or presence of a threshold is important for practical reasons (Chap. 4). A classic example of the difficulty of establishing thresholds experimentally is provided by the "ED01" study, where over 24,000 mice and 81 different treatment groups were used to determine the shape of the dose–response relationship for the prototypical carcinogen 2-acetylaminofluorene (2-AAF). The study was designed to identify a statistically significant response of 1 percent (0.01 probability). The mice were exposed to 2-AAF at one of seven different doses in the dose range of 30 to 150 ppm (plus 0 dose control) (Littlefield et al., 1979). Eight "sacrifice intervals" were used to determine how quickly tumors developed. The dose–response relationship between 2-AAF exposure and liver and bladder cancer at 24 and 33 months of exposure are shown in Fig. 2-8. Both types of tumors demonstrated increasing incidence with increasing dose, but the shapes of the two curves are dramatically different. For liver tumors, no clear threshold was evident, whereas for bladder tumors, an apparent threshold was evident. However, the apparent threshold, or "no observable adverse effect level" (NOAEL), for bladder cancer was lower at 33 months (45 ppm) than at 24 months (75 ppm). Of course, the ability to detect a low incidence of tumors depends on the number of animals used in the study. Thus, although a threshold (a dose below which no response occurs) appears evident for bladder tumors in Fig. 2-8, one cannot say for certain that tumors would not occur if more animals had been included in the lower-dose groups. (See Chap. 4 for more discussion on statistical issues related to extrapolation of dose–response curves and the determination of NOAELs.)

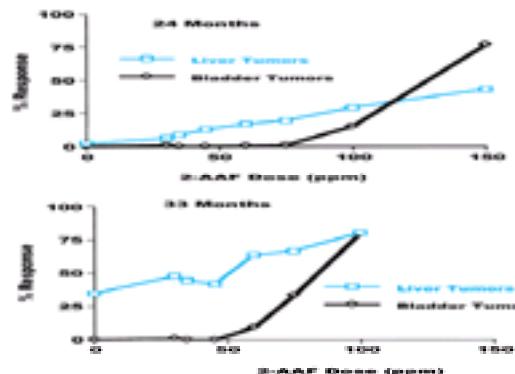

Figure 2-8. Dose–response relationship for carcinogens.

Eight groups of male mice were administered 2-acetylaminofluorine (2-AAF) in the diet from weaning. The percent of animals with liver (*blue line*) or bladder (*black line*) tumors at 24 months (*A*) or 33 months (*B*) are shown. Most of the animals in the high-dose group (150 ppm) did not survive to 33 months; thus, those data are not shown in *B.*

In evaluating the shape of the dose–response relationship in populations, it is realistic to consider inflections in the shape of the dose–response curve rather than absolute thresholds. That is, the slope of the dose–response relationship at high doses may be substantially different from the slope at low doses, usually because of dispositional differences in the chemical. Saturation of biotransformation pathways, protein-binding sites or receptors, and depletion of intracellular cofactors represent some reasons why sharp inflections in the dose–response relationship may occur. For example, the widely used analgesic acetaminophen has a very low rate of liver toxicity at normal therapeutic doses. Even though a toxic metabolite [*N*-acetyl-*p*-benzoquinoneimine (NAPQI)] is produced in the liver at therapeutic doses, it is rapidly detoxified through conjugation with the intracellular antioxidant glutathione. However, at very high doses, the level of intracellular glutathione in the liver is depleted and NAPQI accumulates, causing serious and potentially fatal liver toxicity. This effect is analogous to the rapid change in pH of a buffered solution that occurs when the buffer capacity is exceeded. Some toxic responses, most notably the development of cancer after the administration of genotoxic carcinogens, are often considered to be linear at low doses and thus do not exhibit a threshold. In such circumstances, there is no dose with "zero" risk, although the risk decreases proportionately with a decrease in the dose. The existence or lack of existence of a threshold dose for carcinogens has many regulatory implications and is a point of considerable controversy and research in the field of quantitative risk assessment for chemical carcinogens (Chap. 4).

Assumptions in Deriving the Dose–Response Relationship

A number of assumptions must be considered before dose–response relationships can be used appropriately. The first is that the response is due to the chemical administered. To describe the relationship between a toxic material and an observed effect or response, one must know with reasonable certainty that the relationship is indeed a causal one. For some data, it is not always apparent that the response is a result of chemical exposure. For example, an epidemiologic study might result in the discovery of an "association" between a response (e.g., disease) and one or more variables. Frequently, the data are presented similarly to the presentation of "dose response" in pharmacology and toxicology. Use of the dose response in this context is suspect unless other convincing evidence supports a causal connection between the estimated dose and the measured endpoint (response). Unfortunately, in nearly all retrospective and case-control studies and even in many prospective studies, the dose, duration, frequency, and routes of exposure are seldom quantified, and other potential etiologic factors are frequently present. In its most strict usage, then, the dose–response relationship is based on the knowledge that the effect is a result of a known toxic agent or agents.

A second assumption seems simple and obvious: The magnitude of the response is in fact related to the dose. Perhaps because of its apparent simplicity, this assumption is often a source of misunderstanding. It is really a composite of three other assumptions that recur frequently:

1. There is a molecular target site (or sites) with which the chemical interacts to initiate the response.
2. The production of a response and the degree of response are related to the concentration of the agent at the target site.
3. The concentration at the site is, in turn, related to the dose administered.

The third assumption in using the dose–response relationship is that there exists both a quantifiable method of measuring and a precise means of expressing the toxicity. For any given dose–response relationship, a great variety of criteria or endpoints of toxicity could be used. The ideal criterion would be one closely associated with the molecular events resulting from exposure to the toxicant. It follows from this that a given chemical may have a family of dose–response relationships, one for each toxic endpoint. For example, a chemical that produces cancer through genotoxic effects, liver damage through inhibition of a specific enzyme, and CNS effects via a different mechanism may have three distinct dose–response relationships, one for each endpoint. Early in the assessment of toxicity, little mechanistic information is usually available; thus establishing a dose–response relationship based on the molecular mechanism of action is usually impossible. Indeed, it might not be approachable even for well-known toxicants. In the absence of a mechanistic, molecular ideal criterion of toxicity, one looks to a measure of toxicity that is unequivocal and clearly relevant to the toxic effect. Such measures are often referred to as "effects-related biomarkers." For example, with a new compound chemically related to the class of organophosphate insecticides, one might approach the measurement of toxicity by measuring the inhibition of cholinesterase in blood. In this way, one would be measuring, in a readily accessible system and using a technique that is convenient and reasonably precise, a prominent effect of the chemical and one that is usually pertinent to the mechanism by which toxicity is produced.

The selection of a toxic endpoint for measurement is not always so straightforward. Even the example cited above may be misleading, as an organophosphate may produce a decrease in blood cholinesterase, but this change may not be directly related to its toxicity. As additional data are gathered to suggest a mechanism of toxicity for any substance, other measures of toxicity may be selected. Although many endpoints are quantitative and precise, they are often indirect measures of toxicity. Changes in enzyme levels in blood can be indicative of tissue damage. For example, alanine aminotransferase (ALT) and aspartate aminotransferase (AST) are used to detect liver damage. Use of these enzymes in serum is yet another example of an effects-related biomarker because the change in enzyme activity in the blood is directly related to damage to liver cells. Much of clinical diagnostic medicine relies on effects-related biomarkers, but to be useful the relationship between the biomarker and the disease must be carefully established. Patterns of isozymes and their alteration may provide insight into the organ or system that is the site of toxic effects.

Many direct measures of effects also are not necessarily related to the mechanism by which a substance produces harm to an organism but have the advantage of permitting a causal relation to be drawn between the agent and its action. For example, measurement of the alteration of the tone of smooth or skeletal muscle for substances acting on muscles represents a fundamental approach to toxicological assessment. Similarly, measures of heart rate, blood pressure, and electrical activity of heart muscle, nerve, and brain are examples of the use of physiologic functions as indices of toxicity. Measurement can also take the form of a still higher level of integration, such as the degree of motor activity or behavioral change.

The measurements used as examples in the preceding discussion all assume prior information about the toxicant, such as its target organ or site of action or a

fundamental effect. However, such information is usually available only after toxicologic screening and testing based on other measures of toxicity. With a new substance, the customary starting point in toxicologic evaluation utilizes lethality as an index. Determination of lethality is precise, quantal, and unequivocal and is therefore useful in its own right, if only to suggest the level and magnitude of the potency of a substance. Lethality provides a measure of comparison among many substances whose mechanisms and sites of action may be markedly different. Furthermore, from these studies, clues to the direction of further studies are obtained. This comes about in two important ways. First, simply recording a death is not an adequate means of conducting a lethality study with a new substance. A key element must be a careful, disciplined, detailed observation of the intact animal extending from the time of administration of the toxicant to the death of the animal. From properly conducted observations, immensely informative data can be gathered by a trained toxicologist. Second, a lethality study ordinarily is supported by histologic examination of major tissues and organs for abnormalities. From these observations, one can usually obtain more specific information about the events leading to the lethal effect, the target organs involved, and often a suggestion about the possible mechanism of toxicity at a relatively fundamental level.

Evaluating the Dose–Response Relationship

Comparison of Dose Responses Figure 2-9 illustrates a hypothetical quantal dose–response curve for a desirable effect of a chemical effective dose (ED) such as anesthesia, a toxic dose (TD) effect such as liver injury, and the lethal dose (LD). As depicted in Fig. 2-9, a parallelism is apparent between the (ED) curve and the curve depicting mortality (LD). It is tempting to view the parallel dose–response curves as indicative of identity of mechanism—that is, to conclude that the lethality is a simple extension of the therapeutic effect. While this conclusion may ultimately prove to be correct in any particular case, it is not warranted solely on the basis of the two parallel lines. The same admonition applies to any pair of parallel "effect" curves or any other pair of toxicity or lethality curves.

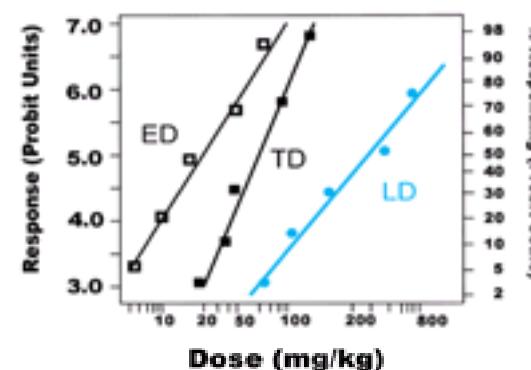

Figure 2-9. Comparison of effective dose (ED), toxic dose (TD), and lethal dose (LD).

The plot is of log dosage versus percentage of population responding in probit units.

Therapeutic Index The hypothetical curves in Fig. 2-9 illustrate two other interrelated points: the importance of the selection of the toxic criterion and the interpretation of comparative effect. The concept of the "therapeutic index," which was introduced by Paul Ehrlich in 1913, can be used to illustrate this relationship. Although the therapeutic index is directed toward a comparison of the therapeutically effective dose to the toxic dose of a chemical, it is equally applicable to considerations of comparative toxicity. The *therapeutic index* (TI) in its broadest sense is defined as the ratio of the dose required to produce a toxic effect and the dose needed to elicit the desired therapeutic response. Similarly, an index of comparative toxicity is obtained by the ratio of doses of two different materials to produce an identical response or the ratio of doses of the same material necessary to yield different toxic effects.

The most commonly used index of effect, whether beneficial or toxic, is the median dose—that is, the dose required to result in a response in 50 percent of a population (or to produce 50 percent of a maximal response). The therapeutic index of a drug is an approximate statement about the relative safety of a drug expressed as the ratio of the lethal or toxic dose to the therapeutic dose:

$$ TI = LD_{50}/ED_{50} $$

From Fig. 2-9 one can approximate a therapeutic index by using these median doses. The larger the ratio, the greater the relative safety. The ED_{5c} is approximately 20, and the LD_{50} is about 200; thus, the therapeutic index is 10, a number indicative of a relatively safe drug. However, the use of the median effective and median lethal doses is not without disadvantages, because median doses tell nothing about the slopes of the dose–response curves for therapeutic and toxic effects.

Margins of Safety and Exposure One way to overcome this deficiency is to use the ED_{99} for the desired effect and the LD_1 for the undesired effect. These parameters are used in the calculation of the margin of safety:

$$ Margin\ of\ safety = LD_1/ED_{99} $$

The quantitative comparisons described above have been used mainly after a single administration of chemicals. However, for chemicals for which there is no beneficial or effective dose and exposures are likely to occur repeatedly, the ratio of LD_1 to ED_{99} has little relevance. Thus, for non drug chemicals, the term *margin of safety* has found use in risk-assessment procedures as an indicator of the magnitude of the difference between an estimated "exposed dose" to a human population and the NOAEL determined in experimental animals.

A measure of the degree of accumulation of a chemical and/or its toxic effects can also be estimated from quantal toxicity data. The *chronicity index* of a chemical is a unitless value obtained by dividing its 1-dose LD_{50} by its 90-dose (90-day) LD_{5c}, with both expressed in milligrams per kilogram per day. Theoretically, if no cumulative effect occurs over the doses, the chronicity index will be 1. If a compound were absolutely cumulative, the chronicity index would be 90.

Statistical procedures similar to those used to calculate the LD_{50} can also be used to determine the lethal time 50 (LT_{50}), or the time required for half the animals to die (Litchfield, 1949). The LT_{50} value for a chemical indicates the time course of the toxic effects but does not indicate whether one chemical is more toxic than another.

Frequently, dose–response curves from repeated-dose experimental animal studies (subacute, subchronic, or chronic) are used to estimate the NOAEL, or some other "benchmark" measure of minimal toxic response, such as the dose estimated to produce toxic effects in 10 percent of the population (TD_{10}) (see also Chap. 4). These estimates of minimal toxic dose, derived from quantal dose–response curves, can be used in risk assessment to derive a "margin of exposure" (MOE) index. This index compares the estimated daily exposure, in milligrams per kilogram per day, that might occur under a given set of circumstances to some estimated value from the quantal dose–response relationship (e.g., NOAEL or TD_{10}). Like the MOS, the MOE is often expressed as a ratio of these two values. Thus, for example, if an estimate of human exposure to a pesticide residue yielded a value of 0.001 mg/kg/day, and a TD_{10} of 1 mg/kg/day was determined for that same pesticide, the MOE would be 1000. This value indicates that the estimate of daily exposure under the described set of conditions is 1000 times lower than the estimated daily dose that would cause evident toxicity in 10% of exposed animals. (See Chap. 4 for a more complete discussion of benchmark doses, NOAELs, and MOE.)

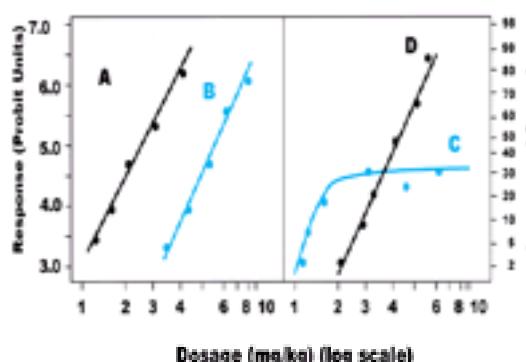
Potency versus Efficacy To compare the toxic effects of two or more chemicals, the dose response to the toxic effects of each chemical must be established. One can then compare the potency and maximal efficacy of the two chemicals to produce a toxic effect. These two important terms can be explained by reference to Fig. 2-10, which depicts dose–response curves to four different chemicals for the frequency of a particular toxic effect, such as the production of tumors. Chemical A is said to be more potent than chemical B because of their relative positions along the dosage axis. Potency thus refers to the range of doses over which a chemical produces increasing responses. Thus, A is more potent than B and C is more potent than D. Maximal efficacy reflects the limit of the dose–response relationship on the response axis to a certain chemical. Chemicals A and B have equal maximal efficacy, whereas the maximal efficacy of C is less than that of D.


Figure 2-10. Schematic representation of the difference in the dose–response curves for four chemicals (A–D), illustrating the difference between potency and efficacy (see text).

VARIATION IN TOXIC RESPONSES

Selective Toxicity

Selective toxicity means that a chemical produces injury to one kind of living matter without harming another form of life even though the two may exist in intimate contact (Albert, 1965, 1973). The living matter that is injured is termed the *uneconomic form* (or undesirable), and the matter protected is called the *economic form* (or desirable). They may be related to each other as parasite and host or may be two tissues in one organism. This biological diversity interferes with the ability of ecotoxicologists to predict the toxic effects of a chemical in one species (humans) from experiments performed in another species (laboratory animals). However, by taking advantage of the biological diversity, it is possible to develop agents that are lethal for an undesired species and harmless for other species. In agriculture, for example, there are fungi, insects, and even competitive plants that injure the crop, and thus selective pesticides are needed. Similarly, animal husbandry and human medicine require agents, such as antibiotics, that are selectively toxic to the undesirable form but do not produce damage to the desirable form.

Drugs and other chemical agents used for selective toxic purposes are selective for one of two reasons. Either (1) the chemical is equitoxic to both economic and uneconomic cells but is accumulated mainly by uneconomic cells or (2) it reacts fairly specifically with a cytological or a biochemical feature that is absent from or does not play an important role in the economic form (Albert, 1965, 1973). Selectivity resulting from differences in distribution usually is caused by differences in the absorption, biotransformation, or excretion of the toxicant. The selective toxicity of an insecticide spray may be partly due to a larger surface area per unit weight that causes the insect to absorb a proportionally larger dose than does the mammal being sprayed. The effectiveness of radioactive iodine in the treatment of hyperthyroidism (as well as its thyroid carcinogenicity) is due to the selective ability of the thyroid gland to accumulate iodine. A major reason why chemicals are toxic to one but not to another type of tissue is that there are differences in accumulation of the ultimate toxic compound in various tissues. This, in turn, may be due to differences in the ability of various tissues to biotransform the chemical into the ultimate toxic product.

Selective toxicity caused by differences in comparative cytology is exemplified by a comparison of plant and animal cells. Plants differ from animals in many ways—for example, absence of a nervous system, an efficient circulatory system, and muscles as well as the presence of a photosynthetic mechanism and cell walls. The fact that bacteria contain cell walls and humans do not has been utilized in developing selective toxic chemotherapeutic agents, such as penicillin and cephalosporins, that kill bacteria but are relatively nontoxic to mammalian cells.

Selective toxicity also can be a result of a difference in biochemistry in the two types of cells. For example, bacteria do not absorb folic acid but synthesize it from *p*-aminobenzoic acid, glutamic acid, and pteridine, whereas mammals cannot synthesize folic acid but have to absorb it from the diet. Thus, sulfonamide drugs are selectively toxic to bacteria because the sulfonamides, which resemble *p*-aminobenzoic acid in both charge and dimensions, antagonize the incorporation of *p*-aminobenzoic acid into the folic acid molecule—a reaction that humans do not carry out.

Species Differences

Although a basic tenet of toxicology is that "experimental results in animals, when properly qualified, are applicable to humans," it is important to recognize that both quantitative and qualitative differences in response to toxic substances may occur among different species. As discussed above, there are many reasons for selective toxicity among different species. Even among phylogenetically similar species (e.g., rats, mice, guinea pigs, and hamsters), large differences in response may occur. For example, the LD_{50} for the highly toxic dioxin, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), differs by more than 1000-fold between guinea pigs and hamsters. Not only does the lethal dose for TCDD vary widely among species, so do the particular target organs affected. Species differences in response to carcinogenic chemicals represent an important issue in regulatory risk assessment. As discussed in Chap. 4, extrapolation of laboratory animal data to infer human cancer risk is currently a key component of regulatory decision making. The validity of this approach of course depends on the relevance of the experimental animal model to humans. Large differences in carcinogenic response between experimental animal species are not unusual. For example, mice are highly resistant to the hepatocarcinogenic effects of the fungal toxin aflatoxin B_1. Dietary doses as high as 10,000 parts per billion (ppb) failed to produce liver cancer in mice, whereas in rats dietary doses as low as 15 ppb produced a significant increase in liver tumors (Wogan et al., 1974). The mechanistic basis for this dramatic difference in response appears to be entirely related to species differences in the expression of a particular form of glutathione S-transferase (mGSTA3-3) that has unusually high catalytic activity toward the carcinogenic epoxide of aflatoxin (Eaton and Gallagher, 1994). Mice express this enzyme constitutively, whereas rats normally express a closely related form with much less detoxifying activity toward aflatoxin epoxide. Interestingly, rats do possess the gene for a form of glutathione S-transferase with high catalytic activity toward aflatoxin epoxide (rGSTA5-5) that is inducible by certain dietary antioxidants and drugs. Thus, dietary treatment can dramatically change the sensitivity of a species to a carcinogen.

Other examples in which large species differences in response to carcinogens have been observed include the development of renal tumors from 2,3,5-trimethylpentane and *d*-limonene in male rats (Lehman-McKeeman and Caudill, 1992), the production of liver tumors from "peroxisomal proliferators" such as the antilipidemic drug clofibrate and the common solvent trichloroethylene (Roberts, 1999), and the induction of nasal carcinomas in rats after inhalation exposure to formaldehyde (Monticello and Morgan, 1997).

Identifying the mechanistic basis for species differences in response to chemicals is an important part of toxicology because only through a thorough understanding of these differences can the relevance of animal data to human response be verified.

Individual Differences in Response

Even within a species, large interindividual differences in response to a chemical can occur because of subtle genetic differences. Hereditary differences in a single gene that occur in more than 1 percent of the population are referred to as *genetic polymorphism* and may be responsible for idiosyncratic reactions to chemicals, as discussed earlier in this chapter. However, genetic polymorphism may have other important but less dramatic effects than those described for acute idiosyncratic responses (such as that occurring in pseudocholinesterase-deficient individuals after succinylcholine exposure). For example, it is recognized that approximately 50 percent of the Caucasian population has a gene deletion for the enzyme glutathione S-transferase M1. This enzyme has no apparent significant physiologic function, and thus homozygotes for the gene deletion (e.g., those who lack both copies of the normal gene) are functionally and physiologically normal. However, epidemiologic studies have indicated that smokers who are homozygous for the null allele may be at slightly increased risk of developing lung cancer compared with smokers who have one or both copies of the normal gene (Houlston, 1999; Strange and Fryer, 1999). Chapter 6 provides additional examples of genetic differences in biotransformation enzymes that may be important determinants of variability in individual susceptibility to chemical exposures.

Genetic polymorphism in physiologically important genes may also be responsible for interindividual differences in toxic responses. For example, studies in transgenic mice have shown that mice possessing one copy of a mutated *p53* gene (a so-called tumor suppressor gene; see Chap. 8) are much more susceptible to some chemical carcinogens than are mice with two normal copies of the gene (Tennant et al., 1999). In humans, there is evidence that possessing one mutated copy of a tumor suppressor gene greatly increases the risk of developing certain cancers. For example, retinoblastoma is a largely inherited form of cancer that arises because of the presence of two copies of a defective tumor suppressor gene (the Rb gene) (Wiman, 1993). Individuals with one mutated copy of the Rb gene and one normal

copy are not destined to acquire the disease (as are those with two copies of the mutated gene), although their chance of acquiring it is much greater than that of persons with two normal Rb genes. This is the case because both copies of the gene must be nonfunctional for the disease to develop. With one mutated copy present genetically, the probability of acquiring a mutation of the second gene (potentially from exposure to environmental mutagens) is much greater than the probability of acquiring independent mutations in both copies of the gene as would be necessary in people with two normal Rb alleles. (See Chap. 8 for additional discussion of tumor suppressor genes.)

As our understanding of the human genome increases, more "susceptibility" genes will be discovered, and it is likely that the etiology of many chronic diseases will be shown to be related to a combination of genetics and environment. Simple blood tests may ultimately be developed that allow an individual to learn whether he or she may be particularly susceptible to specific drugs or environmental pollutants. Although the public health significance of this type of information could be immense, the disclosure of such information raises many important ethical and legal issues that must be addressed before wide use of such tests.

DESCRIPTIVE ANIMAL TOXICITY TESTS

Two main principles underlie all descriptive animal toxicity testing. The first is that the effects produced by a compound in laboratory animals, when properly qualified, are applicable to humans. This premise applies to all of experimental biology and medicine. On the basis of dose per unit of body surface, toxic effects in humans are usually in the same range as those in experimental animals. On a body weight basis, humans are generally more vulnerable than are experimental animals, probably by a factor of about 10. When one has an awareness of these quantitative differences, appropriate safety factors can be applied to calculate relatively safe doses for humans. All known chemical carcinogens in humans, with the possible exception of arsenic, are carcinogenic in some species but not in all laboratory animals. It has become increasingly evident that the converse—that all chemicals carcinogenic in animals are also carcinogenic in humans—is not true (Dybing and Sanner, 1999; Grisham, 1997; Hengstler et al., 1999). However, for regulatory and risk assessment purposes, positive carcinogenicity tests in animals are usually interpreted as indicative of potential human carcinogenicity. If a clear understanding of the mechanism of action of the carcinogen indicates that a positive response in animals is not relevant to humans, a positive animal bioassay may be considered irrelevant for human risk assessment (see Chap. 4). This species variation in carcinogenic response appears to be due in many instances to differences in biotransformation of the procarcinogen to the ultimate carcinogen (see Chap. 6).

The second principle is that exposure of experimental animals to toxic agents in high doses is a necessary and valid method of discovering possible hazards in humans. This principle is based on the quantal dose–response concept that the incidence of an effect in a population is greater as the dose or exposure increases. Practical considerations in the design of experimental model systems require that the number of animals used in toxicology experiments always be small compared with the size of human populations at risk. Obtaining statistically valid results from such small groups of animals requires the use of relatively large doses so that the effect will occur frequently enough to be detected. However, the use of high doses can create problems in interpretation if the response(s) obtained at high doses does not occur at low doses. Thus, for example, it has been shown that bladder tumors observed in rats fed very high doses of saccharin will not occur at the much lower doses of saccharin encountered in the human diet. At the high concentrations fed to rats, saccharin forms an insoluble precipitate in the bladder that subsequently results in chronic irritation of bladder epithelium, enhanced cell proliferation, and ultimately bladder tumors (Cohen, 1998, 1999). In vitro studies have shown that precipitation of saccharin in human urine will not occur at the concentrations that could be obtained from even extraordinary consumption of this artificial sweetener. Examples such as this illustrate the importance of considering the molecular, biochemical, and cellular mechanisms responsible for toxicological responses when extrapolating from high to low dose and across species.

Toxicity tests are not designed to demonstrate that a chemical is safe but to characterize the toxic effects a chemical can produce. There are no set toxicology tests that have to be performed on every chemical intended for commerce. Depending on the eventual use of the chemical, the toxic effects produced by structural analogs of the chemical, as well as the toxic effects produced by the chemical itself, contribute to the determination of the toxicology tests that should be performed. However, the FDA, EPA, and Organization for Economic Cooperation and Development (OECD) have written good laboratory practice (GLP) standards. These guidelines are expected to be followed when toxicity tests are conducted in support of the introduction of a chemical to the market.

The following sections provide an overview of basic toxicity testing procedures in use today. For a detailed description of these tests, the reader is referred to several authoritative texts on this subject (Auletta, 1995; Hayes, 2001; Weathereholtz, 1997).

Acute Lethality

The first toxicity test performed on a new chemical is acute toxicity. The LD_{50} and other acute toxic effects are determined after one or more routes of administration (one route being oral or the intended route of exposure) in one or more species. The species most often used are the mouse and rat, but sometimes the rabbit and dog are employed. Studies are performed in both adult male and female animals. Food is often withheld the night before dosing. The number of animals that die in a 14-day period after a single dosage is tabulated. In addition to mortality and weight, daily examination of test animals should be conducted for signs of intoxication, lethargy, behavioral modifications, morbidity, food consumption, and so on. Acute toxicity tests (1) give a quantitative estimate of acute toxicity (LD_{50}) for comparison with other substances, (2) identify target organs and other clinical manifestations of acute toxicity, (3) establish the reversibility of the toxic response, and (4) provide dose-ranging guidance for other studies.

Determination of the LD_{50} has become a public issue because of increasing concern for the welfare and protection of laboratory animals. The LD_{50} is not a biological constant. Many factors influence toxicity and thus may alter the estimation of the LD_{50} in any particular study. Factors such as animal strain, age and weight, type of feed, caging, pretrial fasting time, method of administration, volume and type of suspension medium, and duration of observation have all been shown to influence adverse responses to toxic substances. These and other factors have been discussed in detail in earlier editions of this textbook (Doull, 1980). Because of this inherent variability in LD_{50} estimates, it is now recognized that for most purposes it is only necessary to characterize the LD_{50} within an order of magnitude range such as 5 to 50 mg/kg, 50 to 500 mg/kg, and so on.

There are several traditional approaches to determining the LD_{50} and its 95 percent confidence limit as well as the slope of the probit line. The reader is referred to the classic works of Litchfield and Wilcoxon (1949) , Bliss (1957), and Finney (1971) for a description of the mechanics of these procedures. A computer program in BASIC for determining probit and log-probit or logit correlations has been published (Abou-Setta et al., 1986). These traditional methods for determining LD_{50}s require a relatively large number of animals (40 to 50). Other statistical techniques that require fewer animals, such as the "moving averages" method of Thompson and Weill (Weil, 1952), are available but do not provide confidence limits for the LD_{50} and the slope of the probit line. Finney (1985) has succinctly summarized the advantages and deficiencies of many of the traditional methods. For most circumstances, an adequate estimate of the LD_{50} and an approximation of the 95 percent confidence intervals can be obtained with as few as 6 to 9 animals, using the "up-and-down" method as modified by Bruce (1985). When this method was compared with traditional methods that typically utilize 40 to 50 animals, excellent agreement was obtained for all 10 compounds tested (Bruce, 1987). In mice and rats the LD_{50} is usually determined as described above, but in the larger species only an approximation of the LD_{50} is obtained by increasing the dose in the same animal until serious toxic effects are evident.

If there is a reasonable likelihood of substantial exposure to the material by dermal or inhalation exposure, acute dermal and acute inhalation studies are performed. When animals are exposed acutely to chemicals in the air they breathe or the water they (fish) live in, the dose the animals receive is usually not known. For these situations, the lethal concentration 50 (LC_{50}) is usually determined; that is, the concentration of chemical in the air or water that causes death to 50 percent of the animals. In reporting an LC_{50}, it is imperative that the time of exposure be indicated. The acute dermal toxicity test is usually performed in rabbits. The site of application is shaved. The test substance is kept in contact with the skin for 24 h by wrapping the skin with an impervious plastic material. At the end of the exposure period, the wrapping is removed and the skin is wiped to remove any test substance still remaining. Animals are observed at various intervals for 14 days, and the LD_{50} is calculated. If no toxicity is evident at 2 g/kg, further acute dermal toxicity testing is usually not performed. Acute inhalation studies are performed that are similar to other acute toxicity studies except that the route of exposure is inhalation. Most often, the length of exposure is 4 h.

Although by themselves LD_{50} and LC_{50} values are of limited significance, acute lethality studies are essential for characterizing the toxic effects of chemicals and their hazard to humans. The most meaningful scientific information derived from acute lethality tests comes from clinical observations and postmortem examination of animals rather than from the specific LD_{50} value.

Skin and Eye Irritations

The ability of a chemical to irritate the skin and eye after an acute exposure is usually determined in rabbits. For the dermal irritation test (Draize test), rabbits are

prepared by removal of fur on a section of the back by electric clippers. The chemical is applied to the skin (0.5 mL of liquid or 0.5 g of solid) under four covered gauze patches (1 in. square; one intact and two abraded skin sites on each animal) and usually kept in contact for 4 h. The nature of the covering patches depends on whether occlusive, semiocclusive, or nonocclusive tests are desired. For occlusive testing, the test material is covered with an impervious plastic sheet; for semiocclusive tests, a gauze dressing may be used. Occasionally, studies may require that the material be applied to abraded skin. The degree of skin irritation is scored for erythema (redness), eschar (scab) and edema (swelling) formation, and corrosive action. These dermal irritation observations are repeated at various intervals after the covered patch has been removed. To determine the degree of ocular irritation, the chemical is instilled into one eye (0.1 mL of liquid or 100 mg of solid) of each test rabbit. The contralateral eye is used as the control. The eyes of the rabbits are then examined at various times after application.

Controversy over this test has led to the development of alternative in vitro models for evaluating cutaneous and ocular toxicity of substances. The various in vitro methods that have been evaluated for this purpose include epidermal keratinocyte and corneal epithelial cell culture models. These and other in vitro tests have been reviewed recently (Davila et al., 1998).

Sensitization

Information about the potential of a chemical to sensitize skin is needed in addition to irritation testing for all materials that may repeatedly come into contact with the skin. Numerous procedures have been developed to determine the potential of substances to induce a sensitization reaction in humans (delayed hypersensitivity reaction), including the Draize test, the open epicutaneous test, the Buehler test, Freund's complete adjuvant test, the optimization test, the split adjuvant test, and the guinea pig maximization test (Maibach and Patrick, 2001; Rush et al., 1995). Although they differ in regard to route and frequency of duration, they all utilize the guinea pig as the preferred test species. In general, the test chemical is administered to the shaved skin topically, intradermally, or both and may include the use of adjuvant to enhance the sensitivity of the assay. Multiple administrations of the test substance are generally given over a period of 2 to 4 weeks. Depending on the specific protocol, the treated area may be occluded. Some 2 to 3 weeks after the last treatment, the animals are challenged with a nonirritating concentration of the test substance and the development of erythema is evaluated.

Subacute (Repeated-Dose Study)

Subacute toxicity tests are performed to obtain information on the toxicity of a chemical after repeated administration and as an aid to establish doses for subchronic studies. A typical protocol is to give three to four different dosages of the chemicals to the animals by mixing it in their feed. For rats, 10 animals per sex per dose are often used; for dogs, three dosages and 3 to 4 animals per sex are used. Clinical chemistry and histopathology are performed after 14 days of exposure, as described below in the section on subchronic toxicity testing.

Subchronic

The toxicity of a chemical after subchronic exposure is then determined. Subchronic exposure can last for different periods of time, but 90 days is the most common test duration. The principal goals of the subchronic study are to establish a NOAEL and to further identify and characterize the specific organ or organs affected by the test compound after repeated administration. One may also obtain a "lowest observed adverse effect level" (LOAEL) as well as the NOAEL for the species tested. The numbers obtained for NOAEL and LOAEL will depend on how closely the dosages are spaced and the number of animals examined. Determinations of NOAELs and LOAELs have numerous regulatory implications. For example, the EPA utilizes the NOAEL to calculate the *reference dose* (RfD), which may be used to establish regulatory values for "acceptable" pollutant levels (Barnes and Dourson, 1988) (Chap. 4). An alternative to the NOAEL approach referred to as the *benchmark dose* uses all the experimental data to fit one or more dose–response curves (Crump, 1984). These curves are then used to estimate a benchmark dose that is defined as "the statistical lower bound on a dose corresponding to a specified level of risk" (Allen et al., 1994a). Although subchronic studies are frequently the primary or sole source of experimental data to determine both the NOAEL and the benchmark dose, these concepts can be applied to other types of toxicity testing protocols, such as that for chronic toxicity or developmental toxicity (Allen et al., 1994a, 1994b; Faustman et al., 1994) (see also Chap. 4 for a complete discussion of the derivation and use of NOAELs, RfDs, and benchmark doses). If chronic studies have been completed, these data are generally used for NOAEL and LOAEL estimates in preference to data from subchronic studies.

A subchronic study is usually conducted in two species (rat and dog) by the route of intended exposure (usually oral). At least three doses are employed (a high dose that produces toxicity but does not cause more than 10 percent fatalities, a low dose that produces no apparent toxic effects, and an intermediate dose) with 10 to 20 rats and 4 to 6 dogs of each sex per dose. Each animal should be uniquely identified with permanent markings such as ear tags, tattoos, or electronically coded microchip implants. Only healthy animals should be used, and each animal should be housed individually in an adequately controlled environment. Animals should be observed once or twice daily for signs of toxicity, including changes in body weight, diet consumption, changes in fur color or texture, respiratory or cardiovascular distress, motor and behavioral abnormalities, and palpable masses. All premature deaths should be recorded and necropsied as soon as possible. Severely moribund animals should be terminated immediately to preserve tissues and reduce unnecessary suffering. At the end of the 90-day study, all the remaining animals should be terminated and blood and tissues should be collected for further analysis. The gross and microscopic condition of the organs and tissues (about 15 to 20) and the weight of the major organs (about 12) are recorded and evaluated. Hematology and blood chemistry measurements are usually done before, in the middle of, and at the termination of exposure. Hematology measurements usually include hemoglobin concentration, hematocrit, erythrocyte counts, total and differential leukocyte counts, platelet count, clotting time, and prothrombin time. Clinical chemistry determinations commonly made include glucose, calcium, potassium, urea nitrogen, alanine aminotransferase (ALT), serum aspartate aminotransferase (AST), gamma-glutamyltranspeptidase (GGT), sorbitol dehydrogenase, lactic dehydrogenase, alkaline phosphatase, creatinine, bilirubin, triglycerides, cholesterol, albumin, globulin, and total protein. Urinalysis is usually performed in the middle of and at the termination of the testing period and often includes determination of specific gravity or osmolarity, pH, proteins, glucose, ketones, bilirubin, and urobilinogen as well as microscopic examination of formed elements. If humans are likely to have significant exposure to the chemical by dermal contact or inhalation, subchronic dermal and/or inhalation experiments may also be required. Subchronic toxicity studies not only characterize the dose–response relationship of a test substance after repeated administration but also provide data for a more reasonable prediction of appropriate doses for chronic exposure studies.

For chemicals that are to be registered as drugs, acute and subchronic studies (and potentially additional special tests if a chemical has unusual toxic effects or therapeutic purposes) must be completed before the company can file an Investigational New Drug (IND) application with the FDA. If the application is approved, clinical trials can commence. At the same time phase I, phase II, and phase III clinical trials are performed, chronic exposure of the animals to the test compound can be carried out in laboratory animals, along with additional specialized tests.

Chronic

Long-term or chronic exposure studies are performed similarly to subchronic studies except that the period of exposure is longer than 3 months. In rodents, chronic exposures are usually for 6 months to 2 years. Chronic studies in nonrodent species are usually for 1 year but may be longer. The length of exposure is somewhat dependent on the intended period of exposure in humans. If the agent is a drug planned to be used for short periods, such as an antimicrobial agent, a chronic exposure of 6 months may be sufficient, whereas if the agent is a food additive with the potential for lifetime exposure in humans, a chronic study up to 2 years in duration is likely to be required.

Chronic toxicity tests are performed to assess the cumulative toxicity of chemicals, but the study design and evaluation often include a consideration of the carcinogenic potential of chemicals so that a separate lifetime feeding study that addresses carcinogenicity does not have to be performed. These studies usually are performed in rats and mice and extend over the average lifetime of the species (18 months to 2 years for mice; 2 to 2.5 years for rats). To ensure that 30 rats per dose survive the 2-year study, 60 rats per group per sex are often started in the study. Both gross and microscopic pathological examinations are made not only on animals that survive the chronic exposure but also on those that die prematurely.

Dose selection is critical in these studies to ensure that premature mortality from chronic toxicity does not limit the number of animals that survive to a normal life expectancy. Most regulatory guidelines require that the highest dose administered be the estimated maximum tolerable dose (MTD). This is generally derived from subchronic studies, but additional longer studies (e.g., 6 months) may be necessary if delayed effects or extensive cumulative toxicity are indicated in the 90-day subchronic study. The MTD has had various definitions (Haseman, 1985). The MTD has been defined by some regulatory agencies as the dose that suppresses body weight gain slightly (i.e., 10 percent) in a 90-day subchronic study (Reno, 1997). However, regulatory agencies may also consider the use of parameters other than weight gain, such as physiological and pharmacokinetic considerations and urinary metabolite profiles, as indicators of an appropriate MTD (Reno, 1997). Generally, one or two additional doses, usually fractions of the MTD (e.g., one-half and one-quarter MTD), and a control group are tested.

The use of the MTD in carcinogenicity has been the subject of controversy. The premise that high doses are necessary for testing the carcinogenic potential of

chemicals is derived from the statistical and experimental design limitations of chronic bioassays. Consider that a 0.5 percent increase in cancer incidence in the United States would result in over 1 million additional cancer deaths each year—clearly an unacceptably high risk. However, identifying with statistical confidence a 0.5 percent incidence of cancer in a group of experimental animals would require a minimum of 1000 test animals, and this assumes that no tumors were present in the absence of exposure (zero background incidence).

Figure 2-11 shows the statistical relationship between minimum detectable tumor incidence and the number of test animals per group. This curve shows that in a chronic bioassay with 50 animals per test group, a tumor incidence of about 8 percent could exist even though no animals in the test group had tumors. This example assumes that there are no tumors in the control group. These statistical considerations illustrate why animals are tested at doses higher than those which occur in human exposure. Because it is impractical to use the large number of animals that would be required to test the potential carcinogenicity of a chemical at the doses usually encountered by people, the alternative is to assume that there is a relationship between the administered dose and the tumorigenic response and give animals doses of the chemical that are high enough to produce a measurable tumor response in a reasonable size test group, such as 40 to 50 animals per dose. The limitations of this approach are discussed in Chap. 4.

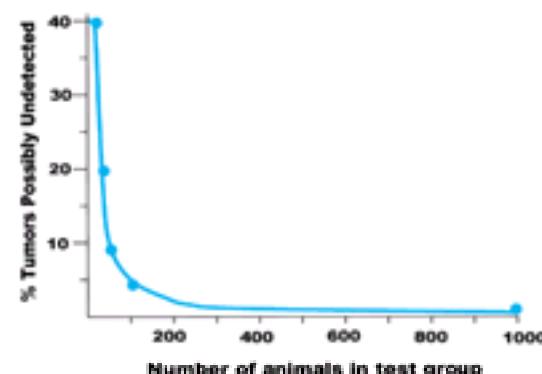

Figure 2-11. Statistical limitations in the power of experimental animal studies to detect tumorigenic effects.

Recently a new approach for establishing maximum doses for use in chronic animal toxicity testing of drugs has been proposed for substances for which basic human pharmacokinetic data are available (for example, new pharmaceutical agents which have completed phase I clinical trials). For chronic animal studies performed on drugs where single-dose human pharmacokinetic data are available, it has been suggested that a daily dose be used that would provide an area under the curve (AUC) in laboratory animals equivalent to 25 times the AUC in humans given the highest (single) daily dose to be used therapeutically. This value would then be used in place of the traditional MTD for chronic bioassays.

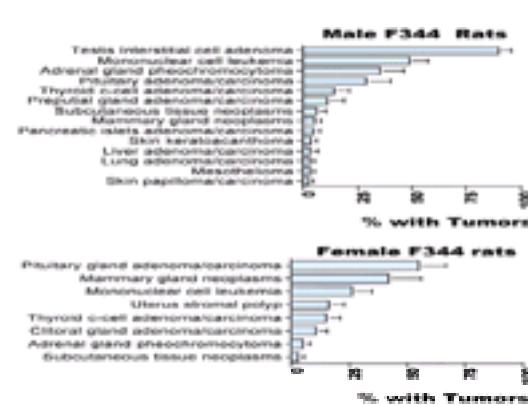
Chronic toxicity assays are commonly used to evaluate the potential oncogenicity of test substances (Huff, 1999). Most regulatory guidelines require that both benign and malignant tumors be reported in the evaluation. Statistical increases above the control incidence of tumors (either all tumors or specific tumor types) in the treatment groups are considered indicative of carcinogenic potential of the chemical unless there are qualifying factors that suggest otherwise (lack of a dose response, unusually low incidence of tumors in the control group compared with "historic" controls, etc.). Thus, the conclusion as to whether a given chronic bioassay is positive or negative for carcinogenic potential of the test substance requires careful consideration of background tumor incidence. Properly designed chronic oncogenicity studies require that a concurrent control group matched for variables such as age, diet, housing conditions be used. For some tumor types, the "background" incidence of tumors is surprisingly high. Figure 2-12 shows the background tumor incidence for various tumors in male and female F-344 rats used in 27 National Toxicology Program 2-year rodent carcinogenicity studies. The data shown represent the percent of animals in control (nonexposed) groups that developed the specified tumor type by the end of the 2-year study. These studies involved more than 1300 rats of each sex. Figure 2-13 shows similar data for control (nonexposed) male and female B6C3F1 mice from 30 recent NTP 2-year carcinogenicity studies and includes data from over 1400 mice of each sex. There are several key points that can be derived from these summary data:


Figure 2-12. Most frequently occurring tumors in untreated control rats from recent NTP 2-year rodent carcinogenicity studies.

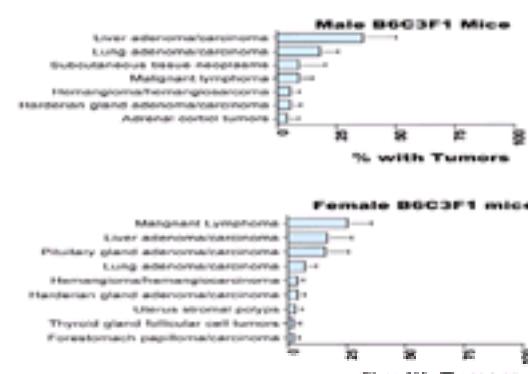
The values shown represent the mean ±SD of the percentage of animals developing the specified tumor type at the end of the 2-year study. The values were obtained from 27 different studies involving a combined total of between 1319 and 1353 animals per tumor type.


Figure 2-13. Most frequently occurring tumors in untreated control mice from recent NTP 2-year rodent carcinogenicity studies.

The values shown represent the mean ±SD of the percentage of animals developing the specified tumor type at the end of the 2-year study. The values were obtained from 30 different studies involving a total of between 1447 and 1474 animals per tumor type.

1. Tumors, both benign and malignant, are not uncommon events in animals even in the absence of exposure to any known carcinogen.
2. There are numerous different tumor types that develop "spontaneously" in both sexes of both rats and mice, but at different rates.
3. Background tumors that are common in one species may be uncommon in another (for example, testicular interstitial cell adenomas are very common in male rats but rare in male mice; liver adenomas/carcinomas are about 10 times more prevalent in male mice than in male rats).

4. Even within the same species and strain, large gender differences in background tumor incidence are sometimes observed (for example, adrenal gland pheochromocytomas are about seven times more prevalent in male F344 rats than in female F344 rats; lung and liver tumors are twice as prevalent in male B6C3F1 mice as in female B6C3F1 mice).
5. Even when the general protocols, diets, environment, strain and source of animals, and other variables are relatively constant, background tumor incidence can vary widely, as shown by the relatively large standard deviations for some tumor types in the NTP bioassay program. For example, the range in liver adenoma/carcinoma incidence in 30 different groups of unexposed (control) male B6C3F1 mice went from a low of 10 percent to a high of 68 percent. Pituitary gland adenomas/carcinomas ranged from 12 to 60 percent and 30 to 76 percent in unexposed male and female F344 rats, respectively, and from 0 to 36 percent in unexposed female B6C3F1 mice.

Taken together, these data demonstrate the importance of including concurrent control animals in such studies. In addition, comparisons of the concurrent control results to "historic" controls accumulated over years of study may be important in identifying potentially spurious "false-positive" results. The relatively high variability in background tumor incidence among groups of healthy, highly inbred strains of animals maintained on nutritionally balanced and consistent diets in rather sterile environments highlights the dilemma in interpreting the significance of both positive and negative results in regard to the human population, which is genetically diverse, has tremendous variability in diet, nutritional status, and overall health; and lives in an environment full of potentially carcinogenic substances, both natural and human-made.

Developmental and Reproductive Toxicity

The effects of chemicals on reproduction and development also need to be determined. *Developmental toxicology* is the study of adverse effects on the developing organism occurring anytime during the life span of the organism that may result from exposure to chemical or physical agents before conception (either parent), during prenatal development, or postnatally until the time of puberty. *Teratology* is the study of defects induced during development between conception and birth (see Chap. 10). *Reproductive toxicology* is the study of the occurrence of adverse effects on the male or female reproductive system that may result from exposure to chemical or physical agents (see Chap. 20).

Several types of animal tests are utilized to examine the potential of an agent to alter development and reproduction. Although different countries have often had different testing requirements for reproductive and developmental toxicity, efforts to "harmonize" such testing protocols have resulted in more flexible guidelines for reproductive toxicity testing strategies [see (Christian, 1997) for a summary description of the ICH guidelines]. General fertility and reproductive performance (segment I) tests are usually performed in rats with two or three doses (20 rats per sex per dose) of the test chemical (neither produces maternal toxicity). Males are given the chemical 60 days and females 14 days before mating. The animals are given the chemical throughout gestation and lactation. Typical observations made include the percentage of the females that become pregnant, the number of stillborn and live offspring, and the weight, growth, survival, and general condition of the offspring during the first 3 weeks of life.

The potential of chemicals to disrupt normal embryonic and/or fetal development (teratogenic effects) is also determined in laboratory animals. Current guidelines for these segment II studies call for the use of two species, including one nonrodent species (usually rabbits). Teratogens are most effective when administered during the first trimester, the period of organogenesis. Thus, the animals (usually 12 rabbits and 24 rats or mice per group) are usually exposed to one of three dosages during organogenesis (day 7 to 17 in rodents and days 7 to 19 in rabbits), and the fetuses are removed by cesarean section a day before the estimated time of delivery (gestational days 29 for rabbit, 20 for rat, and 18 for mouse). The uterus is excised and weighed and then examined for the number of live, dead, and resorbed fetuses. Live fetuses are weighed; half of each litter is examined for skeletal abnormalities and the remaining half for soft tissue anomalies.

The perinatal and postnatal toxicities of chemicals also are often examined (segment III). This test is performed by administering the test compound to rats from the 15th day of gestation throughout delivery and lactation and determining its effect on the birthweight, survival, and growth of the offspring during the first 3 weeks of life.

In some instances a multigenerational study may be chosen, often in place of segment III studies, to determine the effects of chemicals on the reproductive system. At least three dosage levels are given to groups of 25 female and 25 male rats shortly after weaning (30 to 40 days of age). These rats are referred to as the F_0 generation. Dosing continues throughout breeding (about 140 days of age), gestation, and lactation. The offspring (F_1 generation) have thus been exposed to the chemical in utero, via lactation, and in the feed thereafter. When the F_1 generation is about 140 days old, about 25 females and 25 males are bred to produce the F_2 generation, and administration of the chemical is continued. The F_2 generation is thus also exposed to the chemical in utero and via lactation. The F_1 and F_2 litters are examined as soon as possible after delivery. The percentage of F_0 and F_1 females that get pregnant, the number of pregnancies that go to full term, the litter size, the number of stillborn, and the number of live births are recorded. Viability counts and pup weights are recorded at birth and at 4, 7, 14, and 21 days of age. The fertility index (percentage of mating resulting in pregnancy), gestation index (percentage of pregnancies resulting in live litters), viability index (percentage of animals that survive 4 days or longer), and lactation index (percentage of animals alive at 4 days that survived the 21-day lactation period) are then calculated. Gross necropsy and histopathology are performed on some of the parents (F_0 and F_1), with the greatest attention being paid to the reproductive organs, and gross necropsy is performed on all weanlings.

The International Commission on Harmonization (ICH) guidelines provide for flexible guidelines that address six "ICH stages" of development: premating and conception (stage A), conception to implantation (stage B), implantation to closure of the hard palate (Stage C), closure of the hard palate to end of pregnancy (stage D), birth and weaning (stage E), and weaning to sexual maturity (stage F). All of these stages are covered in the segment I to segment III studies described above (Christian, 1997).

Numerous short-term tests for teratogenicity have been developed (Faustman, 1988). These tests utilize whole-embryo culture, organ culture, and primary and established cell cultures to examine developmental processes and estimate the potential teratogenic risks of chemicals. Many of these in utero test systems are under evaluation for use in screening new chemicals for teratogenic effects. These systems vary in their ability to identify specific teratogenic events and alterations in cell growth and differentiation. In general, the available assays cannot identify functional or behavioral teratogens (Faustman, 1988).

Mutagenicity

Mutagenesis is the ability of chemicals to cause changes in the genetic material in the nucleus of cells in ways that allow the changes to be transmitted during cell division. Mutations can occur in either of two cell types, with substantially different consequences. Germinal mutations damage DNA in sperm and ova, which can undergo meiotic division and therefore have the potential for transmission of the mutations to future generations. If mutations are present at the time of fertilization in either the egg or the sperm, the resulting combination of genetic material may not be viable, and the death may occur in the early stages of embryonic cell division. Alternatively, the mutation in the genetic material may not affect early embryogenesis but may result in the death of the fetus at a later developmental period, resulting in abortion. Congenital abnormalities may also result from mutations. Somatic mutations refer to mutations in all other cell types and are not heritable but may result in cell death or transmission of a genetic defect to other cells in the same tissue through mitotic division. Because the initiating event of chemical carcinogenesis is thought to be a mutagenic one, mutagenic tests are often used to screen for potential carcinogens.

Numerous in vivo and in vitro procedures have been devised to test chemicals for their ability to cause mutations. Some genetic alterations are visible with the light microscope. In this case, cytogenetic analysis of bone marrow smears is used after the animals have been exposed to the test agent. Because some mutations are incompatible with normal development, the mutagenic potential of a chemical can also be measured by the dominant lethal test. This test is usually performed in rodents. The male is exposed to a single dose of the test compound and then is mated with two untreated females weekly for 8 weeks. The females are killed before term, and the number of live embryos and the number of corpora lutea are determined.

The test for mutagens that has received the widest attention is the *Salmonella*/microsome test developed by Ames and colleagues (Ames et al., 1975). This test uses several mutant strains of *Salmonella typhimurium* that lack the enzyme phosphoribosyl ATP synthetase, which is required for histidine synthesis. These strains are unable to grow in a histidine-deficient medium unless a reverse or back-mutation to the wild type has occurred. Other mutations in these bacteria have been introduced to enhance the sensitivity of the strains to mutagenesis. The two most significant additional mutations enhance penetration of substances into the bacteria and decrease the ability of the bacteria to repair DNA damage. Since many chemicals are not mutagenic or carcinogenic unless they are biotransformed to a toxic product by enzymes in the endoplasmic reticulum (microsomes), rat liver microsomes are usually added to the medium containing the mutant strain and the test chemical. The number of reverse mutations is then quantitated by the number of bacterial colonies that grow in a histidine-deficient medium.

Strains of yeast have recently been developed that detect genetic alterations arising during cell division after exposure to non-genotoxic carcinogens as well as

mutations that arise from directly genotoxic carcinogens. This test identifies deletions of genetic material that occur during recombination events in cell division that may result from oxidative damage to DNA, direct mutagenic effects, alterations in fidelity of DNA repair, and/or changes in cell cycle regulation (Galli and Schiestl, 1999). Mutagenicity is discussed in detail in Chap. 9.

Other Tests

Most of the tests described above will be included in a "standard" toxicity testing protocol because they are required by the various regulatory agencies. Additional tests also may be required or included in the protocol to provide information relating a special route of exposure (inhalation) or a special effect (behavior). Inhalation toxicity tests in animals usually are carried out in a dynamic (flowing) chamber rather than in static chambers to avoid particulate settling and exhaled gas complications. Such studies usually require special dispersing and analytic methodologies, depending on whether the agent to be tested is a gas, vapor, or aerosol; additional information on methods, concepts, and problems associated with inhalation toxicology is provided in Chap. 15 and Chap. 28. A discussion of behavioral toxicology can be found in Chap. 16. The duration of exposure for both inhalation and behavioral toxicity tests can be acute, subchronic, or chronic, but acute studies are more common with inhalation toxicology and chronic studies are more common with behavioral toxicology. Other special types of animal toxicity tests include immunotoxicology, toxicokinetics (absorption, distribution, biotransformation, and excretion), the development of appropriate antidotes and treatment regimes for poisoning, and the development of analytic techniques to detect residues of chemicals in tissues and other biological materials. The approximate costs of some descriptive toxicity tests are given in Table 2-3.

TEST	COST, $
General Acute toxicity:	
Acute toxicity (rat, two routes)	6,500
Acute dermal toxicity (rabbit)	3,500
Acute inhalation toxicity (rat)	10,000
Acute dermal irritation (rabbit)	2,000
Acute eye irritation (rabbit)	1,500
Skin sensitization (guinea pig)	5,000
Repeated dose toxicity	
14-day exposure (rat)	45,000
90-day exposure (rat)	110,000
1-year (dog; rat)	250,000
1-year (oral gavage; rat)	300,000
2-year (dog; rat)	665,000
2-year (oral gavage; rat)	860,000
Genetic toxicology tests	
Bacterial reverse mutation (Ames test)	7,000
Mammalian cell forward mutation	25,000
In vitro cytogenetics (CHO cells)	20,000
In vivo micronucleus (mouse)	11,000
In vivo chromosome aberration (rat)	22,500
Dominant lethal (mouse)	85,000
Drosophila sex-linked recessive lethal	55,000
Mammalian bone marrow cytogenetics (in vivo; rat)	22,500
Reproduction	
Segment I (rat)	90,000
Segment II (rat)	75,000
Segment II (rabbit)	72,000
Segment III (rat)	160,000

Table 2-3 Typical Costs of Descriptive Toxicity Tests

CHAPTER 3

MECHANISMS OF TOXICITY

Zoltán Gregus and Curtis D. Klaassen

Depending primarily on the degree and route of exposure, chemicals may adversely affect the function and/or structure of living organisms. The qualitative and quantitative characterization of these harmful or toxic effects is essential for an evaluation of the potential hazard posed by a particular chemical. It is also valuable to understand the mechanisms responsible for the manifestation of toxicity—that is, how a toxicant enters an organism, how it interacts with target molecules, and how the organism deals with the insult.

An understanding of the mechanisms of toxicity is of both practical and theoretical importance. Such information provides a rational basis for interpreting descriptive toxicity data, estimating the probability that a chemical will cause harmful effects, establishing procedures to prevent or antagonize the toxic effects, designing drugs and industrial chemicals that are less hazardous, and developing pesticides that are more selectively toxic for their target organisms. Elucidation of the mechanisms of chemical toxicity has led to a better understanding of fundamental physiologic and biochemical processes ranging from neurotransmission (e.g., curare-type arrow poisons) to deoxyribonucleic acid (DNA) repair (e.g., alkylating agents). Pathologic conditions such as cancer and Parkinson's disease are better understood because of studies on the mechanism of toxicity of chemical carcinogens and 1,2,3,6-tetrahydro-1-methyl-4-phenylpyridine (MPTP), respectively. Continued research on mechanisms of toxicity will undoubtedly continue to provide such insights.

This chapter reviews the cellular mechanisms that contribute to the manifestation of toxicities. Although such mechanisms are dealt with elsewhere in this volume, they are discussed in detail in this chapter in an integrated and comprehensive manner. We provide an overview of the mechanisms of chemical toxicity by relating a series of events that begins with exposure, involves a multitude of interactions between the invading toxicant and the organism, and culminates in a toxic effect. This chapter focuses on mechanisms that have been identified definitively or tentatively in humans or animals.

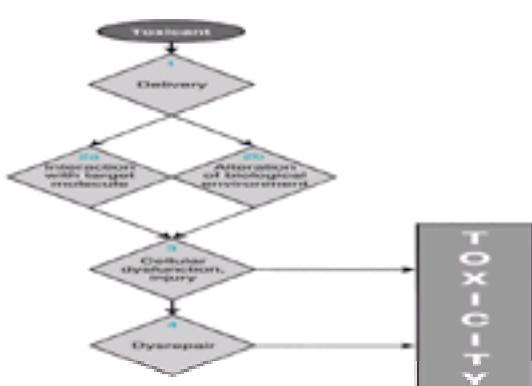
As a result of the huge number of potential toxicants and the multitude of biological structures and processes that can be impaired, there are a tremendous number of possible toxic effects. Correspondingly, there are various pathways that may lead to toxicity (Fig. 3-1). A common course is when a toxicant delivered to its target reacts with it, and the resultant cellular dysfunction manifests itself in toxicity. An example of this route to toxicity is that taken by the puffer fish poison, tetrodotoxin. After ingestion, this poison reaches the voltage-gated Na $^+$ channels of motoneurons (step 1). Interaction of tetrodotoxin with this target (step 2a) results in blockade of Na$^+$ channels, inhibition of the activity of motor neurons (step 3), and ultimately skeletal muscle paralysis. No repair mechanisms can prevent the onset of such toxicity.


Figure 3-1. Potential stages in the development of toxicity after chemical exposure.

Sometimes a xenobiotic does not react with a specific target molecule but rather adversely influences the biological (micro) environment, causing molecular, organellar, cellular, or organ dysfunction leading to deleterious effects. For example, 2,4-dinitrophenol, after entering the mitochondrial matrix space (step 1), collapses the outwardly directed proton gradient across the inner membrane by its mere presence there (step 2b), causing mitochondrial dysfunction (step 3), which is manifest in toxic effects such as hyperthemia and seizures. Chemicals that precipitate in renal tubules and block urine formation represent another example for such a course (step 2b).

The most complex path to toxicity involves more steps (Fig. 3-1). First, the toxicant is delivered to its target or targets (step 1), after which the ultimate toxicant interacts with endogenous target molecules (step 2a), triggering perturbations in cell function and/or structure (step 3), which initiate repair mechanisms at the molecular, cellular, and/or tissue levels (step 4). When the perturbations induced by the toxicant exceed repair capacity or when repair becomes malfunctional, toxicity occurs. Tissue necrosis, cancer, and fibrosis are examples of chemically induced toxicities whose development follow this four-step course.

STEP 1—DELIVERY: FROM THE SITE OF EXPOSURE TO THE TARGET

Theoretically, the intensity of a toxic effect depends primarily on the concentration and persistence of the ultimate toxicant at its site of action. The ultimate toxicant is the chemical species that reacts with the endogenous target molecule (e.g., receptor, enzyme, DNA, microfilamental protein, lipid) or critically alters the biological (micro)environment, initiating structural and/or functional alterations that result is toxicity. Often the ultimate toxicant is the original chemical to which the organism is exposed (parent compound). In other cases, the ultimate toxicant is a metabolite of the parent compound or a reactive oxygen or nitrogen species (ROS or RNS)

generated during the biotransformation of the toxicant. Occasionally, the ultimate toxicant is an endogenous molecule (Table 3-1).

Table 3-1 Types of Ultimate Toxicants and Their Sources

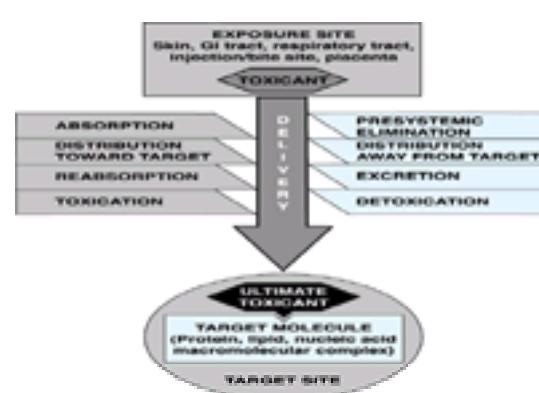
The concentration of the ultimate toxicant at the target molecule depends on the relative effectiveness of the processes that increase or decrease its concentration at the target site (Fig. 3-2). The accumulation of the ultimate toxicant at its target is facilitated by its absorption, distribution to the site of action, reabsorption, and toxication (metabolic activation). Presystemic elimination, distribution away from the site of action, excretion, and detoxication oppose these processes and work against the accumulation of the ultimate toxicant at the target molecule.


Figure 3-2. The process of toxicant delivery is the first step in the development of toxicity.

Delivery—that is, movement of the toxicant from the site of exposure to the site of its action in an active form—is promoted by the processes listed on the left and opposed by the events indicated on the right.

Absorption versus Presystemic Elimination

Absorption Absorption is the transfer of a chemical from the site of exposure, usually an external or internal body surface (e.g., skin, mucosa of the alimentary and respiratory tracts), into the systemic circulation. The vast majority of toxicants traverse epithelial barriers and reach the blood capillaries by diffusing through cells. The rate of absorption is related to the concentration of the chemical at the absorbing surface, which depends on the rate of exposure and the dissolution of the chemical. It is also related to the area of the exposed site, the characteristics of the epithelial layer through which absorption takes place (e.g., the thickness of the stratum corneum in the skin), the intensity of the subepithelial microcirculation, and the physicochemical properties of the toxicant. Lipid solubility is usually the most important property influencing absorption. In general, lipid-soluble chemicals are absorbed more readily than are water-soluble substances.

Presystemic Elimination During transfer from the site of exposure to the systemic circulation, toxicants may be eliminated. This is not unusual for chemicals absorbed from the gastrointestinal (GI) tract because they must first pass through the GI mucosal cells, liver, and lung before being distributed to the rest of the body by the systemic circulation. The GI mucosa and the liver may eliminate a significant fraction of a toxicant during its passage through these tissues, decreasing its systemic availability. For example, ethanol is oxidized by alcohol dehydrogenase in the gastric mucosa (Lim et al., 1993), cyclosporine is returned from the enterocyte into the intestinal lumen by P-glycoprotein (an ATP-dependent xenobiotic transporter) and is also hydroxylated by cytochrome P450 (CP3A4) in these cells (Lin et al., 1999), morphine is glucuronidated in the intestinal mucosa and the liver, and manganese is taken up from the portal blood into the liver and excreted into bile. Such processes may prevent a considerable quantity of chemicals from reaching the systemic blood. Thus, presystemic or first-pass elimination reduces the toxic effects of chemicals that reach their target sites by way of the systemic circulation. In contrast, the processes involved in presystemic elimination may contribute to injury of the digestive mucosa, the liver, and the lungs by chemicals such as ethanol, iron salts, a-amanitin, and paraquat because these processes promote their delivery to those sites.

Distribution to and Away from the Target

Toxicants exit the blood during the distribution phase, enter the extracellular space, and may penetrate into cells. Chemicals dissolved in plasma water may diffuse through the capillary endothelium via aqueous intercellular spaces and transcelluar pores called fenestrae and/or across the cell membrane. Lipid-soluble compounds move readily into cells by diffusion. In contrast, highly ionized and hydrophilic xenobiotics (e.g., tubocurarine and aminoglycosides) are largely restricted to the extracellular space unless specialized membrane carrier systems are available to transport them.

During distribution, toxicants reach their site or sites of action, usually a macromolecule on either the surface or the interior of a particular type of cell. Chemicals also may be distributed to the site or sites of toxication, usually an intracellular enzyme, where the ultimate toxicant is formed. Some mechanisms facili-tate whereas others delay the distribution of toxicants to their targets.

Mechanisms Facilitating Distribution to a Target Distribution of toxicants to specific target sites may be enhanced by (1) the porosity of the capillary endothelium, (2) specialized membrane transport, (3) accumulation in cell organelles, and (4) reversible intracellular binding.

Porosity of the Capillary Endothelium Endothelial cells in the hepatic sinusoids and in the renal peritubular capillaries have larger fenestrae (50 to 150 nm in diameter) that permit passage of even protein-bound xenobiotics. This favors the accumulation of chemicals in the liver and kidneys.

Specialized Transport Across the Plasma Membrane Specialized ion channels and membrane transporters can contribute to the delivery of toxicants to intracellular targets. For example, Na^+,K^+-ATPase promotes intracellular accumulation of thallous ion and voltage-gated Ca^{2+} channels permit the entry of cations such as lead or barium ions into excitable cells. Paraquat enters into pneumocytes, a-amanitin and microcystins enter into hepatocytes (Kröncke et al., 1986), ochratoxin and the cysteine conjugate of mercuric ion enter into renal tubular cells, and an MPTP metabolite (MPP^+) enters into extrapyramidal dopaminergic neurons by means of carrier-mediated uptake. Endocytosis of some toxicant-protein complexes, such as Cd-metallothionein or hydrocarbons bound to the male rat–specific a_{2u}-globulin, by renal proximal tubular cells also can occur. In addition, lipoprotein receptor–mediated endocytosis contributes to entry of lipoprotein-bound toxicants into cells equipped with such transporters. Membrane recycling can internalize catioinic aminoglycosides associated with anionic phopholipides in the brush border membrane of renal tubular cells (Laurent et al., 1990). This process also may contribute to cellular uptake of heavy metal ions. Such uptake mechanisms facilitate the entry of toxicants into specific cells, rendering those cells targets. Thus, carrier-mediated uptake of paraquat by pneumocytes and internalization of aminoglycosides

by renal proximal tubular cells expose those cells to toxic concentrations of those chemicals.

Accumulation in Cell Organelles Amphipathic xenobiotics with a protonable amine group and lipophilic character accumulate in lysosomes as well as mitochondria and cause adverse effects there. Lysosomal accumulation occurs by pH trapping, i.e., diffusion of the amine in unprotonated from into the acidic interior of the organelle, where the amine is protonated, preventing its efflux. Binding of the amine to lysosomal phospholipids impairs their degradation and causes phospholipidosis. Mitochondrial accumulation takes place electrophoretically. The amine is protonated in the intermembrane space (to where the mitochondria eject protons). The cation thus formed will then be sucked into the matrix space by the strong negative potential there (–220 mV), where it may impair b-oxidation and oxidative phosphorylation. By such mechanisms, the valued antiarrhytmic drug amiodarone is entrapped in the hepatic lysosomes and mitochondria, causing phospholipidosis (Kodovanti and Mehendale, 1990) and microvesiculas steatosis with other liver lesions (Fromenty and Pessayre, 1997), respectively. The cationic metabolite of MPTP (MPP$^+$) also electrophoretically accumulates in the mitochondria of dopaminergic neurones, causing mitochondrial dysfunction and cell death.

Reversible Intracellular Binding Binding to the pigment melanin, an intracellular polyanionic aromatic polymer, is a mechanism by which chemicals such as organic and inorganic cations and polycyclic aromatic hydrocarbons can accumulate in melanin-containing cells (Larsson, 1993). The release of melanin-bound toxicants is thought to contribute to the retinal toxicity associated with chlorpromazine and chloroquine, injury to substantia nigra neurons by MPTP and manganese, and the induction of melanoma by polycyclic aromatics.

Mechanisms Opposing Distribution to a Target Distribution of toxicants to specific sites may be hindered by several processes. The processes include (1) binding to plasma proteins, (2) specialized barriers, (3) distribution to storage sites such as adipose tissue, (4) association with intracellular binding proteins, and (5) export from cells.

Binding to Plasma Proteins As long as xenobiotics such as DDT and TCDD are bound to high-molecular-weight proteins or lipoproteins in plasma, they cannot leave the capillaries by diffusion. Even if they exit the bloodstream through fenestrae, they have difficulty permeating cell membranes. Dissociation from proteins is required for most xenobiotics to leave the blood and enter cells. Therefore, strong binding to plasma proteins delays and prolongs the effects and elimination of toxicants.

Specialized Barriers Brain capillaries have very low aqueous porosity because their endothelial cells lack fenestrae and are joined by extremely tight junctions. This blood-brain barrier prevents the access of hydrophilic chemicals to the brain except for those that can be actively transported. Water-soluble toxicants also have restricted access to reproductive cells, which are separated from capillaries by multiple layers to cells. The oocyte is surrounded by the granulosa cells, and the spermatogenic cells are surrounded by Sertoli cells that are tightly joined to form the blood-testis barrier (Chap. 20). Transfer of hydrophilic toxicants across the placenta is also restricted. However, none of these barriers are effective against lipophilic substances.

Distribution to Storage Sites Some chemicals accumulate in tissues (i.e., storage sites) where they do not exert significant effects. For example, highly lipophilic substances such as chlorinated hydrocarbon insecticides concentrate in adipocytes, whereas lead is deposited in bone by substituting for Ca $^{2+}$ in hydroxyapatite. Such storage decreases the availability of these toxicants for their target sites and acts as a temporary protective mechanism. However, insecticides may return to the circulation and be distributed to their target site, the nervous tissue, when there is a rapid lipid loss as a result of fasting. This is thought to contribute to the lethality to pesticide-exposed birds during migration or during the winter months, when food is restricted. The possibility that lead is mobilized from the bone during pregnancy is of concern.

Association with Intracellular Binding Proteins Binding to nontarget intracellular sites also reduces the concentration of toxicants at the target site, at least temporarily. Metallothionein, a cysteine-rich cytoplasmic protein, serves such a function in acute cadmium intoxication (Goering et al., 1995).

Export from Cells Intracellular toxicants may be transported back into the extracellular space. This occurs in brain capillary endothelial cells. These cells contain in their luminal membrane an ATP-dependent membrane transporter known as the multidrug-resistance (mdr) protein, or P-glycoprotein, which extrudes chemicals and contributes to the blood-brain barrier (Schinkel, 1999). Compared to normal mice, mice with disrupted *mdr 1a* gene exhibit 100-fold higher brain levels of and sensitivity to ivermectin, a neurotoxic pesticide and human anthelmintic drug that is one of many P-glycoprotein substrates (Schinkel, 1999). The ooctye is also equipped with the P-glycoprotein that provides protection against chemicals that are substrates for this efflux pump (Elbling et al., 1993).

Excretion versus Reabsorption

Excretion Excretion is the removal of xenobiotics from the blood and their return to the external environment. Excretion is a physical mechanism whereas biotransformation is a chemical mechanism for eliminating the toxicant.

For nonvolatile chemicals, the major excretory structures in the body are the renal glomeruli, which hydrostatically filter small molecules (<60 kDa) through their pores, and the proximal renal tubular cells and hepatocytes, which actively transport chemicals from the blood into the renal tubules and bile canaliculi, respectively. These cells are readily exposed to blood-borne chemicals throught the large endothelial fenestrae; they have membrane transporters that mediate the uptake and luminal extrusion of certain chemicals (Chap. 5). Renal transporters have a preferential affinity for smaller (<300-Da), and hepatic transporters for larger (>400-Da), amphiphilic molecules. A less common "excretory" mechanism consists of diffusion and partition into the excreta on the basis of their lipid content (see below) or acidity. For example, morphine is transferred into milk and amphetamine is transferred into gastric juice by nonionic diffusion. This is facilitated by pH trapping of those organic bases in those fluids, which are acidic relative to plasma (Chap. 5).

The route and speed of excretion depend largely on the physicochemical properties of the toxicant. The major excretory organs—the kidney and the liver—can efficiently remove only highly hydrophilic, usually ionized chemicals such as organic acids and bases. The reasons for this are as follows: (1) In the renal glomeruli, only compounds dissolved in the plasma water can be filtered; (2) transporters in hepatocytes and renal proximal tubular cells are specialized for the secretion of highly hydrophilic organic acids and bases; (3) only hydrophilic chemicals are freely soluble in the aqueous urine and bile; and (4) lipid-soluble compounds are readily reabsorbed by transcellular diffusion.

There are no efficient elimination mechanisms for nonvolatile, highly lipophilic chemicals such as polyhalogenated biphenyls and chlorinated hydrocarbon insecticides. If they are resistant to biotransformation, such chemicals are eliminated very slowly and tend to accumulate in the body upon repeated exposure. Three rather inefficient processes are available for the elimination of such chemicals: (1) excretion by the mammary gland after the chemical is dissolved in the milk lipids; (2) excretion in bile in association with biliary micelles and/or phospholipid vesicles; and (3) intestinal excretion, an incompletely understood transport from the blood into the intestinal lumen. Volatile, nonreactive toxicants such as gases and volatile liquids diffuse from pulmonary capillaries into the alveoli and are exhaled.

Reabsorption Toxicants delivered into the renal tubules may diffuse back across the tubular cells into the peritubular capillaries. This process is facilitated by tubular fluid reabsorption, which increases the intratubular concentration as well as the residence time of the chemical by slowing urine flow. Reabsorption by diffusion is dependent on the lipid solubility of the chemical. For organic acids and bases, diffusion is inversely related to the extent of ionization, because the nonionized molecule is more lipid-soluble. The ionization of weak organic acids such as salicylic acid and phenobarbital and bases such as amphetamine, procainamide, and quinidine is strongly pH-dependent in the physiologic range. Therefore their reabsorption is influenced significantly by the pH of the tubular fluid. Acidification of urine favors the excretion of weak organic bases, while alkalinization favors the elimination of weak organic acids. Carriers for the physiologic oxyanions mediate the reabsorption of some toxic metal oxyanions in the kidney. Chromate and molybdate are reabsorbed by the sulfate transporter, whereas arsenate is reabsorbed by the phosphate transporter.

Toxicants delivered to the GI tract by biliary, gastric, and intestinal excretion and secretion by salivary glands and the exocrine pancreas may be reabsorbed by diffusion across the intestinal mucosa. Because compounds secreted into bile are usually organic acids, their reabsorption is possible only if they are sufficiently lipophilic or are converted to more lipid-soluble forms in the intestinal lumen. For example, glucuronides of toxicants such as diethylstilbestrol and glucuronides of the hydroxylated metabolites of polycyclic aromatic hydrocarbons, chlordecone, and halogenated biphenyls are hydrolyzed by the b-glucuronidase of intestinal microorganisms, and the released aglycones are reabsorbed (Gregus and Klaassen, 1986). Glutathione conjugates of hexachlorobutadiene and trichloroethylene are hydrolyzed by intestinal and pancreatic peptidases, yielding the cysteine conjugates, which are reabsorbed and serve as precursors of additional metabolites with nephrotoxic properties (Dekant et al., 1989).

Toxication versus Detoxication

Toxication A number of xenobiotics (e.g., strong acids and bases, nicotine, aminoglycosides, ethylene oxide, methylisocyanate, heavy-metal ions, HCN, CO) are directly toxic, whereas the toxicity of others is due largely to metabolites. Biotransformation to harmful products is called *toxication* or *metabolic activation*. With some xenobiotics, toxication confers physicochemical properties that adversely alter the microenvironment of biological processes or structures. For example, oxalic acid formed from ethylene glycol may cause acidosis and hypocalcemia as well as obstruction of renal tubules by precipitation as calcium oxalate. Occasionally, chemicals acquire structural features and reactivity by biotransformation that allows for a more efficient interaction with specific receptors or enzymes. For example, the organophosphate insecticide parathion is biotransformed to paraoxon, an active cholinestrase inhibitor; the rodenticide fluoroacetate is converted in the citric acid cycle to fluorocitrate, a false substrate that inhibits aconitase; and fialuridine, an antiviral drug withdrawn because it produced lethal hepatotoxicity in patients, is phosphorylated to the triphosphate, which inhibits DNA polymerase-g and thus impairs synthesis of mitochondrial DNA (Lewis et al., 1996). Most often, however, toxication renders xenobiotics and occasionally other molecules in the body, such as oxygen and nitric oxide ($^\bullet$NO), indiscriminately reactive toward endogenous molecules with susceptible functional groups. This increased reactivity may be due to conversion into (1) electrophiles, (2) free radicals, (3) nucleophiles, or (4) redox-active reactants.

Formation of Electrophiles Electrophiles are molecules containing an electron-deficient atom with a partial or full positive charge that allows it to react by sharing electron pairs with electron-rich atoms in nucleophiles. The formation of electrophiles is involved in the toxication of numerous chemicals (Table 3-2) (Chap. 6). Such reactants are often produced by insertion of an oxygen atom, which withdraws electrons from the atom it is attached to, making that electrophilic. This is the case when aldehydes, ketones, epoxides, arene oxides, sulfoxides, nitroso compounds, phosphonates, and acyl halides are formed (Table 3-2). In other instances, conjugated double bonds are formed, which become polarized by the electron-withdrawing effect of an oxygen, making one of the double-bonded carbons electron-deficient (that is, electrophilic). This occurs when a,b-unsaturated aldehydes and ketones as well as quinones and quinoneimines are produced (Table 3-2). Formation of many of these electrophilic metabolites is catalyzed by cytochrome P450.

Table 3-2 Toxication by Formation of Electrophilic Metabolites

Cationic electrophiles are produced as a result of heterolytic bond cleavage. For example, methyl-substituted aromatics such as 7,12-dimethylbenzanthracene and aromatic amines (amides) such as 2-acetylaminofluorene are hydroxylated to form benzylic alcohols and *N*-hydroxy arylamines (amides), respectively (Miller and Surh, 1994). These substances are esterified, typically by sulfotransferases. Heterolytic cleavage of the C—O or N—O bonds of these esters results in a hydrosulfate anion and the concomitant formation of a benzylic carbonium ion or arylnitrenium ion, respectively. The oxidation of metallic mercury to Hg $^{2+}$ and the reduction of CrO_4^{2-} to Cr^{3+} as well as that of AsO_4^{3-} to AsO_3^{2-}/As^{3+} are examples of the formation of electrophilic toxicants from inorganic chemicals.

Formation of Free Radicals A free radical is a molecule or molecular fragment that contains one or more unpaired electrons in its outer orbital. Radicals are formed by (1) accepting an electron or (2) losing an electron or by (3) homolytic fission of a covalent bond.

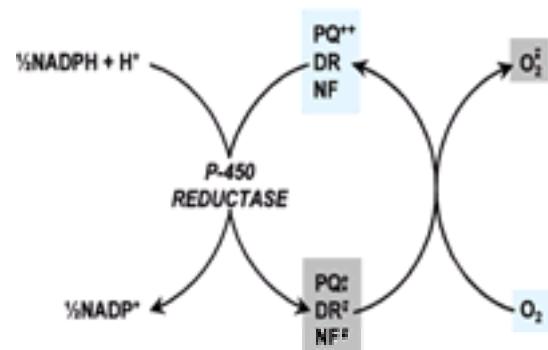
1. Xenobiotics such as paraquat, doxorubicin, and nitrofurantoin can accept an electron from reductases to give rise to radicals (Fig. 3-3). These radicals typically transfer the extra electron to molecular oxygen, forming a superoxide anion radical ($O_2^{\bullet-}$) and regenerating the parent xenobiotic, which is ready to gain a new electron (Kappas, 1986). Through this "redox cycling," one electron acceptor xenobiotic molecule can generate many $O_2^{\bullet-}$ molecules. There are also endogenous sources of $O_2^{\bullet-}$. This radical is generated in large quantities by NAD(P)H oxidase in activated macrophages and granulocytes during "respiratory burst" and is also produced by the mitochondrial electron transport chain, especially in the "uncoupled" state. The significance of $O_2^{\bullet-}$ stems to a large extent from the fact that $O_2^{\bullet-}$ is a starting compound in two toxication pathways (Fig. 3-4); one leading to formation of hydrogen peroxide (HOOH) and then hydroxyl radical (HO$^\bullet$), whereas the other produces peroxynitrite (ONOO$^-$) and ultimately nitrogen dioxide ($^\bullet$NO$_2$), and carbonate anion radical ($CO_3^{\bullet-}$).


Figure 3-3. Production of superoxide anion radical ($O_2^{\bullet-}$) by paraquat (PQ^{++}), doxorubicin (DR), and nitrofurantoin (NF).

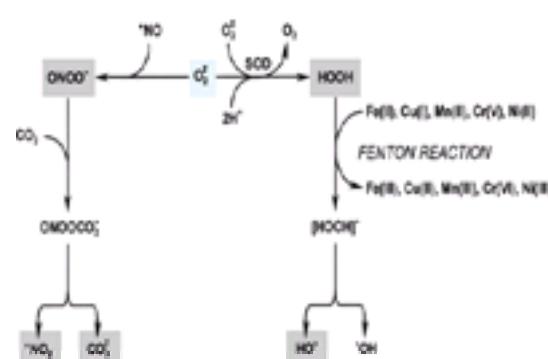
Note that formation of ($O_2^{\bullet-}$) is not the final step in the toxication of these xenobiotics, because $O_2^{\bullet-}$ can yield the much more reactive hydroxyl radical, as depicted in Fig. 3-4.


Figure 3-4. Two pathways for toxication of superoxide anion radical ($O_2^{\bullet-}$) via nonradical products (ONOO$^-$ and HOOH) to radical products $^\bullet$NO$_2$, CO$_3^{\bullet-}$ and HO$^{\bullet-}$).

In one pathway, conversion of ($O_2^{\bullet-}$) to HOOH is spontaneous or is catalyzed by superoxide dismutase (SOD). Homolytic cleavage of HOOH to hydroxyl radical and hydroxyl ion is called the Fenton reaction and is catalyzed by the transition metal ions shown. Hydroxyl radical formation is the ultimate toxication for

xenobiotics that form $O_2^{\bullet-}$ (see Fig. 3-3) or for HOOH, the transition metal ions listed, and some chemicals that form complexes with these transiton metal ions. In the other pathway, $O_2^{\bullet-}$ reacts avidly with nitric oxide ($^{\bullet}NO$), the product of $^{\bullet}NO$ synthase (NOS), forming peroxynitrite ($ONOO^-$). Spontaneous reaction of $ONOO^-$ with carbon dioxide (CO_2) yields nitrosoperoxy carbonate ($ONOOCO_2^-$) that is homolytically cleaved to nitrogen dioxide ($^{\bullet}NO_2$) and carbonate anion radical ($CO_3^{\bullet-}$). All three radical products indicated in this figure are oxidants, whereas $^{\bullet}NO_2$ is also a nitrating agent.

2. Nucleophilic xenobiotics such as phenols, hydroquinones, aminophenols, amines, hydrazines, phenothiazines, and thiols are prone to lose an electron and form free radicals in a reaction catalyzed by peroxidases (Aust et al., 1993). Some of these chemicals, such as catechols and hydroquinones, may undergo two sequential one-electron oxidations, producing first semiquinone radicals and then quinones. Quinones are not only reactive electrophiles (Table 3-2) but also electron acceptors with the capacity to initiate redox cycling or oxidation of thiols and NAD(P)H. Polycyclic aromatic hydrocarbons with sufficiently low ionization potential, such as benzo[a]pyrene and 7,12-dimethylbenzanthracene, can be converted via one-electron oxidation by peroxidases or cytochrome P450 to radical cations, which may be the ultimate toxicants for these carcinogens (Cavalieri and Rogan, 1992). Like peroxidases, oxyhemoglobin (Hb-FeII-O_2) can catalyze the oxidation of aminophenols to semiquinone radicals and quinoneimines. This is another example of toxication, because these products, in turn, oxidize ferrohemoglobin (Hb-FeII) to methemoglobin (Hb-FeIII), which cannot carry oxygen.
3. Free radicals also are formed by homolytic bond fission, which can be induced by electron transfer to the molecule (reductive fission). This mechanism is involved in the conversion of CCl_4 to the trichloromethyl free radical ($Cl_3C^{\bullet}$) by an electron transfer from cytochrome P450 or the mitochondrial electron transport chain (reductive dehalogenation) (Recknagel et al., 1989). The $Cl_3C^{\bullet}$ reacts with O_2 to form the even more reactive trichloromethylperoxy radical ($Cl_3COO^{\bullet}$) (Hippeli and Elstner, 1999).

The hydroxyl radical (HO$^{\bullet}$), a free radical of paramount toxicologic significance, also is generated by homolytic fission. Such a process yields large amounts of HO$^{\bullet}$ from water upon ionizing radiation. Reductive homolytic fission of hydrogen peroxide (HOOH) to HO$^{\bullet}$ and HO$^-$ is called the *Fenton reaction* (Fig. 3-4). This is catalyzed by transition metal ions, typically Fe(II) or, Cu(I), Cr(V), Ni(II), or Mn(II), and is a major toxication mechanism for HOOH and its precursor $O_2^{\bullet-}$ as well as for transition metals. Moreover, the toxicity of chemicals, such as nitrilotriacetic acid, bleomycin, and orellanin (Hippeli and Elstner, 1999), that chelate transition metal ions is also based on Fenton chemistry because chelation increases the catalytic efficiency of some transition metal ions. The pulmonary toxicity of inhaled mineral particles such as asbestos and silica is caused, at least in part, by the formation of HO$^{\bullet}$ triggered by Fe ions on the particle surface (Vallyathan et al., 1998). Hydrogen peroxide is a direct or indirect by-product of several enzymatic reactions, including monoamine oxidase, xanthine oxidase, and acyl-coenzyme A oxidase. It is produced in large quantities by spontaneous or superoxide dismutase-catalyzed dismutation of $O_2^{\bullet-}$.

Homolytic cleavage is also thought to be involved in free radical generation from $ONOO^-$ (Squadrito and Pryor, 1998) (Fig. 3-4). The facile reaction of $ONOO^-$ with the ubiquitous CO_2 yields nitrosoperoxycarbonate ($ONOOCO_2^-$), which can spontaneously homolyze into two radicals, the oxidant and nitrating agent nitrogen dioxide ($^{\bullet}NO_2$) and the oxidant carbonate anion radical ($CO_3^{\bullet-}$). Thus, formation of $ONOO^-$ and the latter radicals represent a toxication mechanism for $O_2^{\bullet-}$ and $^{\bullet}NO$. As $^{\bullet}NO$ is the product of nitric oxide synthase (NOS), this mechanism is especially relevant in and around cells that express NOS consitutively (i.e., neurons and endothelial cells) as well as in and around cells that express the inducible form of NOS in response to cytokines.

Formation of Nucleophiles The formation of nucleophiles is a relatively uncommon mechanism for activating toxicants. Examples include the formation of cyanide from amygdalin, which is catalyzed by bacterial b-glucosidase in the gut; from acrylonitrile after epoxidation and subsequent glutathione conjugation; and from sodium mitroprusside by thiol-induced decomposition. Carbon monoxide is a toxic metabolite of dihalomethanes that undergo oxidative dehalogenation. Hydrogen selenide, a strong nucleophile and reductant, is formed from selenite by reaction with glutathione or other thiols.

Formation of Redox-Active Reactants There are specific mechanisms for the creation of redox-active reactants other than those already mentioned. Examples include the formation of the methemoglobin-producing nitrite from nitrate by bacterial reduction in the intestine or from esters of nitrous or nitric acids in reaction with glutathione. Dapsone hydroxylamine and 5-hydroxyprimaquine, hydroxylated metabolites of the respective drugs, produce methemoglobin by cooxidation (Fletcher et al., 1988). Reductants such as ascorbic acid and reductases such as NADPH-dependent flavoenzymes reduce Cr(VI) to Cr(V) (Shi and Dalai, 1990). Xenobiotic radicals formed in redox cycling (e.g., those depicted in Fig. 3-3) as well as $O_2^{\bullet-}$ and $^{\bullet}NO$ can reduce Fe(III) bound to ferritin and consequently release it as Fe(II). Cr(V) and Fe(II) thus formed catalyze HO$^{\bullet}$ formation (Fig. 3-4).

In summary, the most reactive metabolites are electron-deficient molecules and molecular fragments such as electrophiles and neutral or cationic free radicals. Although some nucleophiles are reactive (e.g., HCN, CO), many are activated by conversion to electrophiles. Similarly, free radicals with an extra electron cause damage by giving rise to the neutral HO$^{\bullet}$ radical after the formation and subsequent homolytic cleavage of HOOH.

Detoxication Biotransformations that eliminate the ultimate toxicant or prevent its formation are called *detoxications.* In some cases, detoxication may compete with toxication for a chemical. Detoxication can take several pathways, depending on the chemical nature of the toxic substance.

Detoxication of Toxicants with No Functional Groups In general, chemicals without functional groups, such as benzene and toluene, are detoxicated in two phases. Initially, a functional group such as hydroxyl or carboxyl is introduced into the molecule, most often by cytochrome-P450 enzymes. Subsequently, an endogenous acid such as glucuronic acid, sulfuric acid, or an amino acid is added to the functional group by a transferase. With some exceptions, the final products are inactive, highly hydrophilic organic acids that are readily excreted.

Detoxication of Nucleophiles Nucleophiles generally are detoxicated by conjugation at the nucleophilic functional group. Hydroxylated compounds are conjugated by sulfation, glucuronidation, or rarely by methylation, whereas thiols are methylated or glucuronidated and amines and hydrazines are acetylated. These reactions prevent peroxidase-catalyzed conversion of the nucleophiles to free radicals and biotransformation of phenols, aminophenols, catechols, and hydroquinones to electrophilic quinones and quinoneomines. An alternative mechanism for the elimination of thiols and hydrazines is oxidation by flavin-containing monooxygenases (Jakoby and Ziegler, 1990). Some alcohols, such as ethanol, are detoxicated by oxidation to carboxylic acids by alcohol and aldehyde dehydrogenases. A specific detoxication mechanism is the biotransformation of cyanide to thiocyanate by rhodanese.

Detoxication of Electrophiles A general mechanism for the detoxication of electrophilic toxicants is conjugation with the thiol nucleophile glutathione (Ketterer, 1988). This reaction may occur spontaneously or can be facilitated by glutathione *S*-transferases. Metal ions—such as Ag^+, Cd^{2+}, Hg^{2+}, and CH_3Hg^+ ions—readily react with and are detoxicated by glutathione. Specific mechanisms for the detoxication of electrophilic chemicals include epoxide hydrolase-catalyzed biotransformation of epoxides and arene oxides to diols and dihydrodiols, respectively, and carboxyl-esterase-catalyzed hydrolysis of organophosphate ester pesticides. Others are two-electron reduction of quinones to hydroquinones by DT-diaphorase, reduction of a,b-unsaturated aldehydes to alcohols by alcohol dehydrogenase or oxidation to acids by aldehyde dehydrogenase, and complex formation of thiol-reactive metal ions by metallothionein and the redox-active ferrous iron by ferrin. Covalent binding of electrophiles to proteins can also be regarded as detoxification provided that the protein has no critical function and does not become a neoantigen or otherwise harmful. Carboxylesterases, for example, inactivate organophosphates not only by hydrolysis but also by covalent binding.

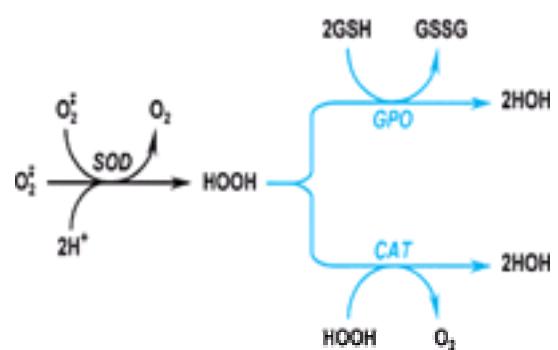
Detoxication of Free Radicals Because $O_2^{\bullet-}$ can be converted into much more reactive compounds (Fig. 3-4), its elimination is an important detoxication mechanism. This is carried out by superoxide dismutases (SOD), high-capacity enzymes located in the cytosol (Cu,Zn-SOD) and the mitochondria (Mn-SOD), which convert $O_2^{\bullet-}$ to HOOH (Fig. 3-5). Subsequently, HOOH is reduced to water by the selenocysteine-containing glutathione peroxidase in the cytosol or by catalase in the peroxisomes (Fig. 3-5) (Cotgrave et al., 1988).


Figure 3-5. Detoxication of superoxide anion radical ($O_2^{\overline{\bullet}}$) by superoxide dismutase (SOD), glutathione peroxidase (GPO), and catalase (CAT).

No enzyme eliminates $HO^\bullet$. While some relatively stable radicals, such as peroxyl radicals, can readily abstract a hydrogen atom from glutathione, a-tocopherol (vitamin E), or ascorbic acid (vitamin C), thus becoming nonradicals, these antioxidants are generally ineffective in detoxifying $HO^\bullet$ (Sies, 1993). This is due to its extremely short half-life (10^{-9} s), which provides little time for the $HO^\bullet$ to reach and react with antioxidants. Therefore the only effective protection against $HO^\bullet$ is to prevent its formation by elimination of its precursor, HOOH, via conversion to water (Fig. 3-5).

$ONOO^-$ (which is not a free radical oxidant) is significantly more stable than $HO^\bullet$ (half-life of about 1 s). Nevertheless, the small biological antioxidant molecules (glutathione, uric acid, ascorbic acid, a-tocopherol) are relatively inefficient in intercepting it because $ONOO^-$ rapidly reacts with CO_2 (Squadrito and Pryor, 1998) to form reactive free radicals (Fig. 3-4). More efficient is the selenocysteine-containing glutathione peroxidase, which can reduce $ONOO^-$ to nitrite (ONO^-) the same way it reduces HOOH to water (Arteel et al., 1999). Selenoprotein P, which contains 10 selenocysteine residues and coats the surface of endothelial cells, also reduces $ONOO^-$ and may serve as a protectant against this oxidant in blood (Arteel et al., 1999; Burk and Hill, 1999). In addition, $ONOO^-$ reacts with oxyhemoglobin, heme-containing peroxidases and albumin, all of which could be important sinks for $ONOO^-$. Furthermore, elimination of the two $ONOO^-$ precursors—i.e., $^\bullet NO$ by reaction with oxyhemoglobin (to yield methemoglobin and nitrate) and $O_2^{\overline{\bullet}}$ by SODs (see above)—is a significant mechanism in preventing $ONOO^-$ buildup (Squadrito and Pryor, 1998).

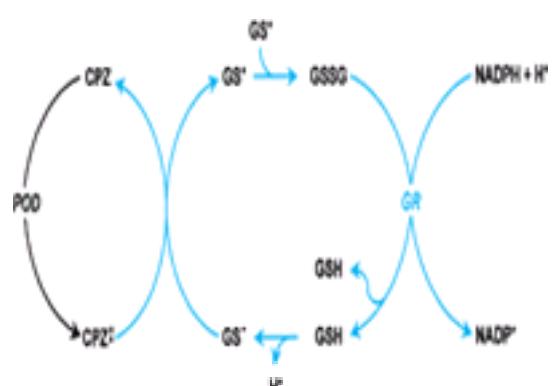
Peroxidase-generated free radicals are eliminated by electron transfer from glutathione. This results in the oxidation of glutathione, which is reversed by NADPH-dependent glutathione reductase (Fig. 3-6). Thus, glutathione plays an important role in the detoxication of both electrophiles and free radicals.


Figure 3-6. Detoxication of peroxidase (POD) – generated free radicals such as chlorpromazine free radical (CPZ $\overset{\bullet}{\updownarrow}$) by glutathione (GSH).

The by-products are glutathione thiyl radical ($GS^\bullet$) and glutathione disulfide (GSSG), from which GSH is regenerated by glutathione reductase (GR).

Detoxication of Protein Toxins Presumably, extra- and intracellular proteases are involved in the inactivation of toxic polypeptides. Several toxins found in venoms, such as a- and b-bungaratoxin, erabutoxin, and phospholipase, contain intramolecular disulfide bonds that are required for their activity. These proteins are inactivated by thioredoxin, an endogenous dithiol protein that reduces the essential disulfide bond (Lozano et al., 1994).

When Detoxication Fails Detoxication may be insufficient for several reasons:

1. Toxicants may overwhelm detoxication processes, leading to exhaustion of the detoxication enzymes, consumption of the cosubtrates, or depletion of cellular antioxidants such as glutathione, ascorbic acid, and a-tocopherol. This results in the accumulation of the ultimate toxicant.
2. Occasionally, a reactive toxicant inactivates a detoxicating enzyme. For example, $ONOO^-$ incapacitates Mn-SOD, which normally would counteract $ONOO^-$ formation (Murphy, 1999) (see Fig. 3-4).
3. Some conjugation reactions can be reversed. For example, 2-naphthylamine, a bladder carcinogen, is *N*-hydroxylated and glucuronidated in liver, with the glucuronide excreted into urine. While in the bladder, the glucuronide is hydrolyzed, and the released arylhydroxylamine is converted by protonation and dehydration to the reactive electrophilic arylnitrenium ion (Bock and Lilienblum, 1994). Isocyanates and isothiocyanates form labile glutathione conjugates from which they can be released. Thus, methylisocyanate readily forms a glutathione conjugate in the lung after inhalation. From there, the conjugate is distributed to other tissues, where the reactive electrophilic parent compound may be regenerated (Baillie and Kassahun, 1994). Such conjugates are considered transport forms of toxicants.
4. Sometimes detoxication generates potentially harmful by-products such as the glutathione thiyl radical and glutathione disulfide, which are produced during the detoxication of free radicals (Fig. 3-6). Glutathione disulfide can form mixed disulfides with protein thiols, whereas the thiyl radical (GS $^\bullet$), after reacting with thiolate (GS^-), forms a glutathione disulfide radical anion (GSSG $^{\overline{\bullet}}$), which can reduce O_2 to $O_2^{\overline{\bullet}}$.

STEP 2— REACTION OF THE ULTIMATE TOXICANT WITH THE TARGET MOLECULE

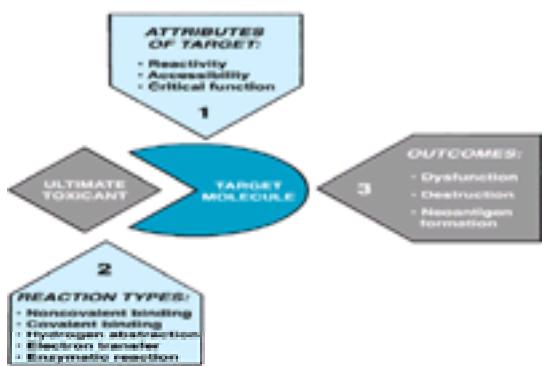
Toxicity is typically mediated by a reaction of the ultimate toxicant with a target molecule (step 2a in Fig. 3-1). Subsequently, a series of secondary biochemical events occur, leading to dysfunction or injury that is manifest at various levels of biological organization, such as at the target molecule itself, cell organelles, cells, tissues and organs, and even the whole organism. Because interaction of the ultimate toxicant with the target molecule triggers the toxic effect, consideration is given to (1) the attributes of target molecules, (2) the types of reactions between ultimate toxicants and target molecules, and (3) the effects of toxicants on the target molecules (Fig. 3-7). Finally, consideration is given to toxicities that are initiated not by reaction of the ultimate toxicant with target molecules but rather by alteration of the biological (micro)environment in which critical endogenous molecules, cell organelles, cells, and organs operate.


Figure 3-7. Reaction of the ultimate toxicant with the target molecule: the second step in the development of toxicity.

Attributes of Target Molecules

Practically all endogenous compounds are potential targets for toxicants. The identification and characteristics of the target molecules involved in toxicity constitute a major research priority, but a comprehensive inventory of potential target molecules is impossible. Nevertheless, the most prevalent and toxicologically relevant targets are macromolecules such as nucleic acids (especially DNA) and proteins. Among the small molecules, membrane lipids are frequently involved, whereas cofactors such as coenzyme A and pyridoxal rarely are involved.

To be a target, an endogenous molecule must possess the appropriate reactivity and/or steric configuration to allow the ultimate toxicant to enter into covalent or noncovalent reactions. For these reactions to occur, the target molecule must be accessible to a sufficiently high concentration of the ultimate toxicant. Thus, endogenous molecules that are in the vicinity of reactive chemicals or are adjacent to sites where they are formed are frequently targets. The first target for reactive metabolites is often the enzyme responsible for their production or the adjacent intracellular structures. For example, thyroperoxidase, the enzyme responsible for thyroid hormone synthesis, converts some nucleophilic xenobiotics (such as methimazole, amitrole, and resorcinol) into reactive free radical metabolites that inactivate the thyroperoxidase (Engler et al., 1982). This is the basis for the antithyroid as well as the thyroid tumor–inducing effect of these chemicals. Carbon tetrachloride, which is activated by cytochrome P450, destroys this enzyme as well as the neighboring microsomal membranes (Osawa et al., 1995). Several mitochondrial enzymes—including pyruvate dehydrogenase, succinate dehydrogenase, and cytochrome *c* oxidase—are convenient targets for nephrotoxic cysteine conjugates such as dichlorovinyl cysteine, because these conjugates are converted to electrophiles in the same organelle by mitochondrial cysteine conjugate b-lyase (Dekant et al., 1989). Reactive metabolites that are unable to find appropriate endogenous molecules in close proximity to their site of formation may diffuse until they encounter such reactants. For example, hard electrophiles such as the arylnitrenium ion metabolite of Λ-methyl-4-aminoazobenzene react readily with hard nucleophilic atoms in nucleic acids, and thus target DNA in the nucleus even though the electrophiles are produced in the cytoplasm.

Not all targets for chemicals contribute to the harmful effects. Thus, while carbon monoxide causes toxicity by binding to ferrohemoglobin, it also associates with the iron in cytochrome P450 with little or no consequence. Covalent binding of toxicants to various intracellular proteins, including enzymes and structural proteins, has been demonstrated, yet it is often uncertain which protein(s) is/are involved in binding that is toxicologically relevant (Cohen et al., 1997; Pumford and Halmes, 1997; Rombach and Hanzlik, 1999). Arylation of some hepatic mitochondrial proteins by acetaminophen might be causally related to the liver injury induced by this drug because the nonhepatotoxic regioisomer of acetaminophen does not readily bind covalently to these proteins (Cohen et al., 1997). In contrast, arylation of a number of hepatic cytoplasmic proteins by acetaminophen is likely to be inconsequential because a nonhepatotoxic regioisomer of this drug also arylates those proteins (Nelson and Pearson, 1990). Covalent binding to proteins without adverse consequences may even represent a form of detoxication by sparing toxicologically relevant targets. This principle is best exemplified by covalent binding of organophosphate insecticides to plasma cholinesterase, which is a significant protective mechanism, as it counteracts phosphorylation of acetylcholinesterase, the target molecule. Thus, to conclusively identify a target molecule as being responsible for toxicity, it should be demonstrated that the ultimate toxicant (1) reacts with the target and adversely affects its function, (2) reaches an effective concentration at the target site, and (3) alters the target in a way that is mechanistically related to the observed toxicity.

Types of Reactions

The ultimate toxicant may bind to the target molecules noncovalently or covalently and may alter it by hydrogen abstraction, electron transfer, or enzymatically.

Noncovalent Binding This type of binding can be due to apolar interactions or the formation of hydrogen and ionic bonds and is typically involved in the interaction of toxicants with targets such as membrane receptors, intracellular receptors, ion channels, and some enzymes. For example, such interactions are responsible for the binding of strychnine to the glycine receptor on motor neurons in the spinal cord, TCDD to the aryl hydrocarbon receptor, saxitoxin to sodium channels, phorbol esters to protein kinase C, and warfarin to vitamin K 2,3-epoxide reductase. Such forces also are responsible for the intercalation of chemicals such as acridine yellow and doxorubicin into the double helix of DNA. These chemicals are toxic because the steric arrangement of their atoms allows them to combine with complementary sites on the endogenous molecule more or less as a key fits into a lock. Noncovalent binding usually is reversible because of the comparatively low bonding energy.

Covalent Binding Being practically irreversible, covalent binding is of great toxicologic importance because it permanently alters endogenous molecules (Boelsterli, 1993). Covalent adduct formation is common with electrophilic toxicants such as nonionic and cationic electrophiles and radical cations. These toxicants react with nucleophilic atoms that are abundant in biological macromolecules, such as proteins and nucleic acids. Electrophilic atoms exhibit some selectivity toward nucleophilic atoms, depending on their charge-to- radius ratio. In general, soft electrophiles prefer to react with soft nucleophiles (low charge-to-radius ratio in both), whereas hard electrophiles react more readily with hard nucleophiles (high charge-to-radius ratio in both). Examples are presented in Table 3-3. Metal ions such as silver and mercury also are classified as soft electrophiles that prefer to react with soft nucleophiles and hard electrophiles such as lithium, calcium, and barium, which react preferentially with hard nucleophiles. Metals falling between these two extremes, such as chromium, zinc, and lead, exhibit universal reactivity with nucleophiles. The reactivity of an electrophile determines which endogenous nucleophiles can react with it and become a target.

Table 3-3 Examples of Soft and Hard Electrophiles and Nucleophiles

Neutral free radicals such as HO$^{\bullet}$, $^{\bullet}$NO$_2$, and Cl$_3$C$^{\bullet}$ also can bind covalently to biomolecules. The addition of Cl$_3$C$^{\bullet}$ to double-bonded carbons in lipids or to lipid radicals yields lipids containing chloromethylated fatty acids. The addition of hydroxyl radicals to DNA bases results in the formation of numerous products, including 8-hydroxypurines, 5-hydroxymethylpyrimidines, and thymine and cytosine glycols (Breen and Murphy, 1995).

Nucleophilic toxicants are in principle reactive toward electrophilic endogenous compounds. Such reactions occur infrequently because electrophiles are rare among biomolecules. Examples include the covalent reactions of amines and hydrazides with the aldehyde pyridoxal, a cosubstrate for decarboxylases. Carbon monoxide,

cyanide, hydrogen sulfide, and azide form coordinate covalent bonds with iron in various hemeproteins. Other nucleophiles react with hemoglobin in an electron-transfer reaction (see below).

Hydrogen Abstraction Neutral free radicals, such as those generated in reactions depicted in Fig. 3-4, can readily abstract H atoms from endogenous compounds, converting those compounds into radicals. Abstraction of hydrogen from thiols (R—SH) creates thiyl radicals (R—S •), which are precursors of other thiol oxidation products, such as sulfenic acids (R—SOH) and disulfides (R—S—S—R). Radicals can remove hydrogen from CH_2 groups of free amino acids or from amino acid residues in proteins and convert them to carbonyls. These carbonyls react with amines, forming cross-links with DNA or other proteins. Hydrogen abstraction from deoxyribose in DNA yields the C-4'-radical, the first step to DNA cleavage (Breen and Murphy, 1995). Abstraction of hydrogen from fatty acids produces lipid radicals and initiates lipid peroxidation. As depicted in Fig. 3-8, nitration of tyrosine residues in proteins purportedly involves H abstraction followed by covalent binding between the resultant tyrosyl radical and $^\bullet NO_2$ (Squadrito and Pryor, 1998).

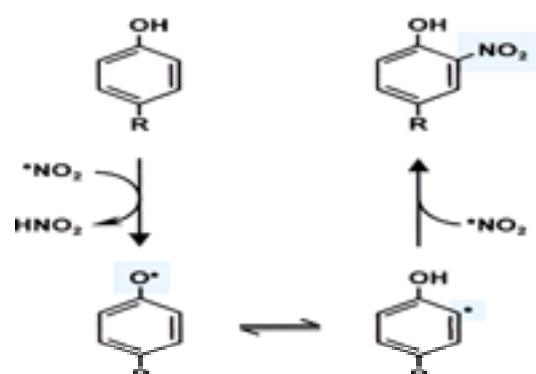

Figure 3-8. Formation of 3-nitrotyrosine residues in proteins by reaction with nitrogen dioxide ($^\bullet NO_2$).

($^\bullet NO_2$) is the nitrating species generated from $ONOO^-$ (Fig. 3-4). In addition, ($^\bullet NO_2$) is a contaminant in cigarette smoke, exhaust of gas engines and stoves, as well as the causative agent of "silo-filler's disease."

Electron Transfer Chemicals can oxidize Fe(II) in hemoglobin to Fe(III), producing methemoglobinemia. Nitrite can oxidize hemoglobin, whereas *N*-hydroxyl arylamines (such as dapsone hydroxylamine), phenolic compounds (such as 5-hydroxy primaquine), and hydrazines (such as phenylhydrazine) are cooxidized with oxyhemoglobin, forming methemoglobin and hydrogen peroxide (Coleman and Jacobus, 1993).

Enzymatic Reactions A few toxins act enzymatically on specific target proteins. For example, ricin induces hydrolytic fragmentation of ribosomes, blocking protein synthesis. Several bacterial toxins catalyze the transfer for ADP-ribose from NAD+ to specific proteins. For example, diphtheria toxin blocks the function of elongation factor 2 in protein synthesis and cholera toxin activates a G protein through such a mechanism. Snake venoms contain hydrolytic enzymes that destroy biomolecules.

In summary, most ultimate toxicants act on endogenous molecules on the basis of their chemical reactivity. Those with more than one type of reactivity may react by different mechanisms with various target molecules. For example, quinones may act as electron acceptors and initiate thiol oxidation or free radical reactions that lead to lipid peroxidation, buy they may also act as soft electrophiles and bind covalently to protein thiols. The lead ion acts as a soft electrophile when it forms coordinate covalent bonds with critical thiol groups in d-aminolevulinic acid dehydratase, its major target enzyme in heme synthesis (Goering, 1993). However, it behaves like a hard electrophile or an ion when it binds to protein kinase C or blocks calcium channels, substituting for the natural ligand Ca^{2+} at those target sites.

Effects of Toxicants on Target Molecules

Reaction of the ultimate toxicant with endogenous molecules may cause dysfunction or destruction; in the case of proteins, it may render them foreign (i.e., an antigen) to the immune system.

Dysfunction of Target Molecules Some toxicants activate protein target molecules, mimicking endogenous ligands. For example, morphine activates opiate receptors, clofibrate is an agonist on the peroxisome proliferator–activated receptor, and phorbol esters and lead ions stimulate protein kinase C.

More commonly, chemicals inhibit the function of target molecules. Several xenobiotics—such as atropine, curare, and strychnine—block neurotransmitter receptors by attaching to the ligand-binding sites or by interfering with the function of ion channels. Tetrotodoxin and saxitoxin, for example, inhibit opening of the voltage-activated sodium channels in the neuronal membrane, whereas DDT and the pyrethroid insecticides inhibit their closure. Some toxicants block ion transporters, others inhibit mitochon-drial electron transport complexes, and many inhibit enzymes. Chemicals that bind to tubulin (e.g., vinblastine, colchicine, paclitaxel, trivalent arsenic) or actin (e.g., cytochalasin B, phalloidin) impair the assembly (polymerization) and/or disassembly (depolymerization) of these cytoskeletal proteins.

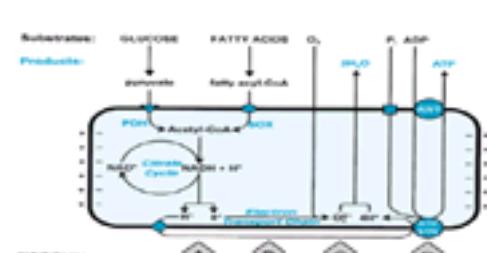
Protein function is impaired when conformation or structure is altered by interaction with the toxicant. Many proteins possess critical moities, especially thiol groups, that are essential for catalytic activity or assembly to macromolecular complexes. Proteins that are sensitive to covalent and/or oxidative modification of their thiol groups include the enzymes protein tyrosine phosphatases (Herrlich et al., 1998), glyceraldehyde 3-phosphate dehydrogenase (see Table 3-6), and pyruvate dehydrogenase (see Fig. 3-13), the Ca^{2+} pumps (see Fig. 3-14, Table 3-7), and the transcription factor AP-1, just to name a few. The activity of these and many other proteins is impaired by thiol-reactive chemicals, triggering aberrant signal transduction and/or impaired maintenance of the cell's energy and metabolic homeostasis. Protein tyrosine nitration (see Fig. 3-8) may alter also protein function or may interfere with signaling pathways that involve tyrosine kinases and phosphatases (Arteel et al., 1999).


Figure 3-13. ATP synthesis (oxidative phosphorylation) in mitochondria.

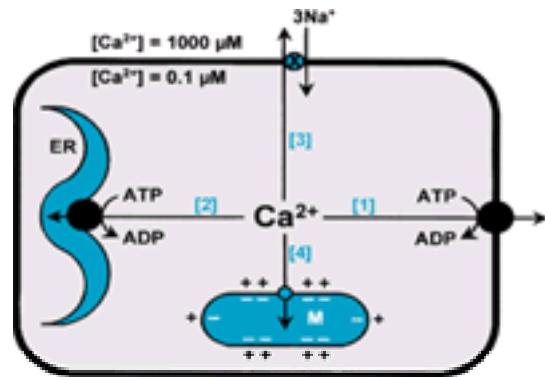
Arrows with roman numerals point to the ultimate sites of action of four categories of agents that interfere with oxidative phosphorylation (Table 3-6). For simplicity, this scheme does not indicate the outer mitochondrial membrane and that protons are extruded from the matrix space along the electron transport chain at three sites. bOX = beta-oxidation of fatty acids; e^- = electron; P_i = inorganic phosphate; ANT = adenine nucleotide translocator; ATP SYN= ATP synthase (F_0F_1ATPase).


Figure 3-14. Four mechanisms for the elimination of Ca^{2+} from the cytoplasm: Ca^{2+}-ATPase-mediated pumping into (1) the extracellular space as well as (2) the endoplasmic reticulum (ER) and ion-gradient–driven transport into (3) the extracellular space (by the Ca^{2+}/Na$^+$ exchanger) as well as (4) the mitochondria (M; by the Ca^{2+} uniporter).

Some chemicals that inhibit these mechanisms are listed in Table 3-7, group B.

Table 3-6 Agents Impairing Mitochondrial ATP Synthesis*

Table 3-7 Agents Causing Sustained Elevation of Cytosolic Ca^{2+}

Toxicants may interfere with the template function of DNA. The covalent binding of chemicals to DNA causes nucleotide mispairing during replication. For example, covalent binding of aflatoxin 8,9-oxide to *N*-7 of guanine results in pairing of the adduct-bearing guanine with adenine rather than cytosine, leading to the formation of an incorrect codon and the insertion of an incorrect amino acid into the protein. Such events are involved in the aflatoxin-induced mutation of the *ras* proto-oncogene and the *p53* tumor suppressor gene (Eaton and Gallagher, 1994). 8-Hydroxy-guanine and 8-hydroxyadenine are mutagenic bases produced by HO• that can cause mispairing with themselves as well as with neighboring pyrimidines, producing multiple amino acid substitutions (Breen and Murphy, 1995). Chemicals such as doxorubicin, that intercalate between stacked bases in the double-helical DNA, push adjacent base pairs apart, causing an even greater error in the template function of DNA by shifting the reading frame.

Destruction of Target Molecules In addition to adduct formation, toxicants alter the primary structure of endogenous molecules by means of cross-linking and fragmentation. Bifunctional electrophiles such as 2,5-hexanedione, carbon disulfide, acrolein, 4-hydroxynonenal, and nitrogen mustard alkylating agents cross-link cytoskeletal proteins, DNA, or DNA with proteins. Hydroxyl radicals also can induce cross-linking by converting these macromolecules into either reactive electrophiles (e.g., protein carbonyls), which react with a nucleophilic site in another macromolecule, or radicals, which react with each other. Cross-linking imposes both structural and functional constraints on the linked molecules.

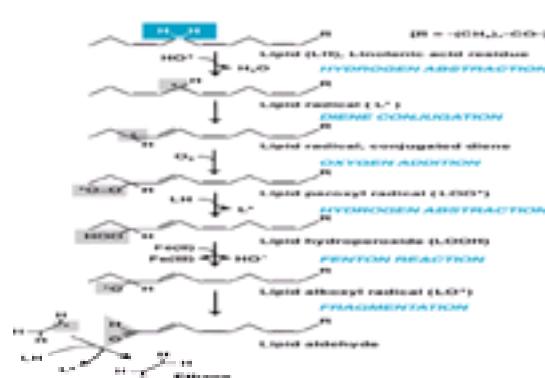
Some target molecules are susceptible to spontaneous degradation after chemical attack. Free radicals such as Cl$_3$COO• and HO• can initiate peroxidative degradation of lipids by hydrogen abstraction from fatty acids (Recknagel et al., 1989). The lipid radical (L•) formed is converted successively to lipid peroxyl radical (LOO•) by oxygen fixation, lipid hydroperoxide (LOOH) by hydrogen abstraction, and lipid alkoxyl radical (LO •) by the Fe(II)-catalyzed Fenton reaction. Subsequent fragmentation gives rise to hydrocarbons such as ethane and reactive aldehydes such as 4-hydroxynonenal and malondialdehyde (Fig. 3-9). Thus, lipid peroxidation not only destroys lipids in cellular membranes but also generates endogenous toxicants, both free radicals (e.g., LOO •, LO•) and electrophiles (e.g., 4-hydroxynonenal). These substances can readily react with adjacent molecules, such as membrane proteins, or diffuse to more distant molecules such as DNA.


Figure 3-9. Lipid peroxidation initiated by the hydroxyl radical (HO˙).

Many of the products, such as the radicals and the a,b-unsaturated aldehydes, are reactive, whereas others, such as ethane, are nonreactive but are indicators of

lipid peroxidation.

Apart from hydrolytic degradation by toxins and radiolysis, toxicant-induced fragmentation of proteins is not well documented. There are, however, examples for destruction of the prosthetic group in enzymes. For instance, cytochrome P450 converts allyl isopropyl acetamide into a reactive metabolite, which alkylates the heme moiety of the enzyme. This leads to loss of the altered heme and to porphyria (De Matteis, 1987). Aconitase is attacked by $ONOO^-$ at its $[4Fe-4S]^{2+}$ cluster, whose one Fe atom is genuinely labile (as is complexed to an inorganic sulfur and not to enzyme-bound cysteines like the others). As a result of the oxidant action of $ONOO^-$, the labile Fe is lost, inactivating the enzyme (Castro et al., 1994) and compromising the citric acid cycle where aconitase functions.

Several forms of DNA fragmentation are caused by toxicants. For instance, attack of DNA bases by $HO^\bullet$ can result in the formation of imidazole ring–opened purines or ring–contracted pyrimidines, which block DNA replication. Formation of a bulky adduct at guanine N-7 destabilizes the N-glycosylic bond, inducing depurination. Depurination results in apurinic sites that are mutagenic. Single-strand breaks typically are caused by hydroxyl radicals via abstraction of H from desoxyribose in DNA yielding the C-4' radical, followed by $O_2^{\bullet-}$ addition, Criegee rearrangement, and cleavage of the phosphodiester bond (Breen and Murphy, 1995). Multiple hydroxyl radical attacks on a short length of DNA, which occur after ionizing radiation, cause double-strand breaks that are typically lethal to the affected cell.

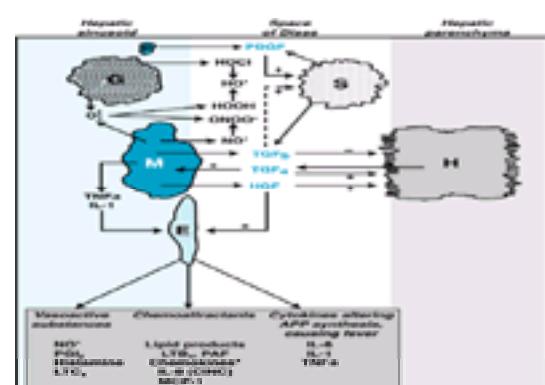
Neoantigen Formation While the covalent binding of xenobiotics or their metabolites is often inconsequential with respect to the function of the immune system, in some individuals these altered proteins evoke an immune response. Some chemicals (e.g., dinitrochlorobenzene, penicillin, nickel) may be sufficiently reactive to bind to proteins spontaneously. Others may obtain reactivity by autooxidation to quinones (e.g., urushiols, the allergens in poison ivy) or by enzymatic biotransformation (Park et al., 1998). For example, cytochrome P450 biotransforms halothane to an electrophile, trifluoroacetyl chloride, which binds as a hapten to various microsomal and cell surface proteins in the liver, inducing antibody production. The immune reaction is thought to be responsible for the hepatitis-like syndrome seen in sensitive patients. Drug-induced lupus and possibly many cases of drug-induced agranulocytosis are mediated by immune reactions triggered by drug-protein adducts. The causative chemicals are typically nucleophiles, such as aromatic amines (e.g., aminopyrine, clozapine, procainamide, and sulfonamides), hydrazines (e.g., hydralazine and isoniazid), and thiols (e.g., propylthiouracil, methimazole, and captopril). These substances can be oxidized by myeloperoxidase discharged from activated granulocytes or by the ROS/RNS such cells produce ($HO^\bullet$, $ONOO^-$, HOCl, see Fig. 3-22) to reactive metabolites that bind to the surface proteins of these cells, making them antigens (Uetrecht, 1992). Unfortunately, some proteins that bear an adduct can mimic some normal proteins, which thus also can be attacked by the antibodies.


Figure 3-22. Mediators of tissue repair and side reactions to tissue injury in liver: (1) growth factors promoting replacement of cells and the extracellular matrix; (2) mediators of inflammation, acute-phase protein (AAP) synthesis, and fever; and (3) cytotoxic mediators of inflammatory cells.

HGF= hepatocyte growth factor; PDGR= platelet-derived growth factor; TGF-a = transforming growth factor-alpha, TGF-b = transforming growth factor-beta; $NO^\bullet$ = nitric oxide; PGI_2 = prostacyclin; LTC_4 = leukotriene C_4; IL= interleukin; LTB_4 = leukotriene B_4; PAF = platelet-activating factor; CINC (the rat homolog of IL-8) = cytokine-induced neutrophil chemoattractant; MCP-1 = monocyte chemotactic protein; TNF = tumor necrosis factor. Cells presented are E = endothelial cells; G = granulocyte; H = hepatocyte; M = macrophage (Kupffer cell); S = stellate cell (also called perisinusoidal, Ito or fat-storing cell). *Rather than the endothelial cells, other stromal cells are the main sources of chemokines (e.g., stellate cells for MCP-1). Solid arrows represent effects of growth factors on cell division, whereas the dashed arrow shows the effect on extracellular matrix formation. Positive and negative signs indicate stimulation and inhibition, respectively. See text for further details.

Toxicity Not Initiated by Reaction with Target Molecules

Some xenobiotics do not or do not only interact with a specific endogenous target molecule to induce toxicity but instead alter the biological microenvironment (see step 2b in Fig. 3-1). Included here are (1) chemicals that alter H^+ ion concentrations in the aqueous biophase, such as acids and substances biotransformed to acids, such as methanol and ethylene glycol, as well as protonophoric uncouplers such as 2,4-dinitrophenol and pentachlorophenol, which dissociate their phenolic protons in the mitochondrial matrix, thus dissipating the proton gradient that drives ATP synthesis; (2) solvents and detergents that physicochemically alter the lipid phase of cell membranes and destroy transmembrane solute gradients that are essential to cell functions; and (3) other xenobiotics that cause harm merely by occupying a site or space. For example, some chemicals (e.g., ethylene glycol) form water-insoluble precipitates in the renal tubules. By occupying bilirubin binding sites on albumin, compounds such as the sulfonamides induce bilirubin toxicity (kernicterus) in neonates. Carbon dioxide displaces oxygen in the pulmonary alveolar space and causes asphyxiation.

STEP 3—CELLULAR DYSFUNCTION AND RESULTANT TOXICITIES

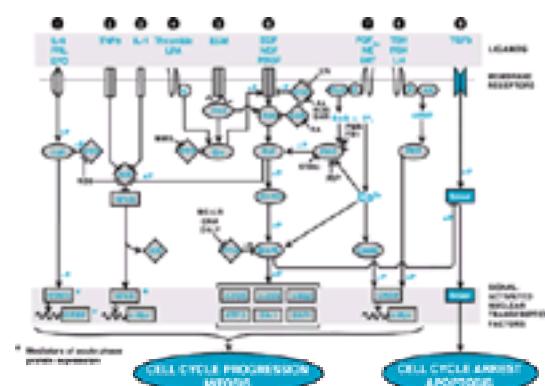
The reaction of toxicants with a target molecule may result in impaired cellular function as the third step in the development of toxicity (Fig. 3-1). Each cell in a multicellular organism carries out defined programs. Certain programs determine the destiny of cells—that is, whether they undergo division, differentiation (i.e., express proteins for specialized functions), or apoptosis. Other programs control the ongoing (momentary) activity of differentiated cells, determining whether they secrete more or less of a substance, whether they contract or relax, and whether they transport and metabolize nutrients at higher or lower rates. For regulations of these cellular programs, cells possess signaling networks (such as those shown in Fig. 3-11 and Fig. 3-12) that can be activated and inactivated by external signaling molecules. To execute the programs, cells are equipped with synthetic, metabolic, kinetic, transport, and energy-producing system as well as structural elements, organized into macromolecular complexes, cell membranes, and organelles, by which they maintain their own integrity (internal functions) and support the maintenance of other cells (external functions).


Figure 3-11. Signal transduction pathways from cell membrane receptors to signal-activated nuclear transcription factors that influence transcription of

genes involved in cell-cycle regulation.

The symbols of cell membrane receptors are numbered 1–9 and some of their activating ligands are indicated. Circles represent G proteins, oval symbols protein kinases, rectangles transcription factors, wavy lines genes, and diamond symbols inhibitory proteins, such as protein phosphatases (PTP, PP2A), the GTPase-activating protein GAP, and the inhibitory binding protein IbB. Arrowheads indicate stimulation or formation of second messengers (e.g., DAG, IP$_3$, cAMP, Ca^{2+}), whereas blunt arrows indicate inhibition. Phosphorylation and dephosphorylation are indicated by +P and –P, respectively. Abbreviations for interfering chemicals are printed in black (As = arsenite; CALY = calyculin A; FA = fatty acids; FB1 = fumonisin B; MC-LR = microcystin-LR; OKA = okadaic acid; MMS = methylmethane sulfonate; PMA = phorbol miristate acetate; ROS = reactive oxygen species; SHR = SH-reactive chemicals, such as iodoacetamide; STAU = staurosporin).

In the center of the depicted networks is the pathway activated by growth factors, such as EGF, that acts on a tyrosine kinase receptor (#6) which uses adaptor proteins (Shc, Grb2 and SOS; not shown) to convert the inactive GDP-bound Ras to active GTP-bound form, which in turn activates the MAP-kinase phosphorylation cascade (Raf, MAPKK, MAPK). The phosphorylated MAPK moves into the nucleus and phosphorylates transcription factors thereby enabling them to bind to cognate sequences in the promoter regions of genes to facilitate transcription. There are numerous interconnections between the signal transduction pathways. Some of these connections permit the use of the growth factor receptor (#6)-MAPK "highway" for other receptors (e.g., 4, 5, 7) to send mitogenic signals. For example, receptor (#4) joins in via its G protein b/g subunits and tyrosine kinase Src; the integrin receptor (#5), whose ligands are constituents of the extracellular matrix (ECM), possibly connects via G-protein Rho (not shown) and focal adhesion kinase (FAK); and the G-protein-coupled receptor (#7) via phospholipase C (PLC)-catalyzed formation of second messengers and activation of protein-kinase C (PKC). The mitogenic stimulus relayed along the growth factor receptor (#6)-MAPK axis can be amplified by, for example, the Raf-catalyzed phosphorylation of IkB, which unleashes NF-kB from this inhibitory protein, and by the MAPK-catalyzed inhibitory phosphorylation of Smad that blocks the cell-cycle arrest signal from the TGF-b receptor (#9). Activation of protein kinases (PKC, CaMK, MAPK) by Ca^{2+} can also trigger mitogenic signaling. Several xenobiotics that are indicated in the figure may dysregulate the signaling network. Some may induce cell proliferation either by activating mitogenic protein kinases (e.g., PKC), or inhibiting inactivating proteins, such as protein phosphatases (PTP, PP2A), GAP or IkB. Others, e.g., inhibitors of PKC, oppose mitosis and facilitate apoptosis.

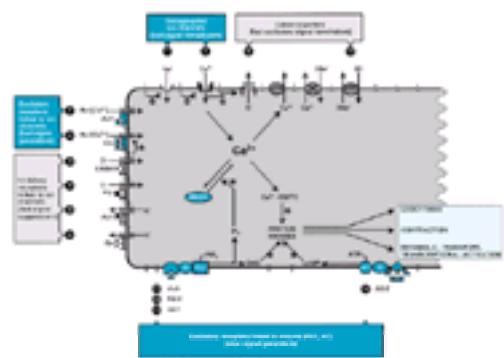
This scheme is oversimplified and tentative in several details. Virtually all components of the signaling network (e.g., G proteins, PKCs, MAPKs) are present in multiple, functionally different forms whose distribution may be cell specific. The pathways depicted are not equally relevant for all cells. In addition, these pathways regulating gene expression determine not only the fate of cells, but also control certain aspects of the ongoing cellular activity. For example, NF-kB induces synthesis of acute phase proteins.


Figure 3-12. Signaling mechanisms for neurotransmitters..

This simplified scheme depicts major cellular signaling mechanisms that are operational in many neurons and muscle and exocrine cells. Chemicals acting on the numbered elements are listed in Table 3-5. Fast signaling is initiated by the opening of ligand-gated Na^{+}/Ca^{2+} channels (1,2). The resultant cation influx decreases the inside negative potential (i.e., evokes depolarization) and thus triggers the opening of the voltage-gated Na^{+} and Ca^{2+} channels (7,8). As a second messenger, the influxed Ca^{2+} activates intracellular Ca^{2+}-binding proteins such as calmodulin (CM) and troponin C (TC), which, in turn, enhance the phosphorylation of specific proteins, causing activation of specific cellular functions. The signal is terminated by channels and transporters (e.g., 9,10) that remove cations from the cells and thus reestablish the inside negative resting potential (i.e., cause repolarization) and restore the resting Ca^{2+} level. Fast signaling can be suppressed by opening the ligand-activated Cl^{-} or K^{+} channels (3-6), which increases the inside negativity (i.e., induces hyperpolarization) and thus counteracts opening of the voltage-gated Na^{+} and Ca^{2+} channels (7,8). Signal transduction from other receptors (11–14) is slower because it involves enzymatic generation of second messengers: inositol 1,4,5-trisphosphate (IP$_3$) and diacylglycerol (DAG) by phospholipase C (PLC) and cyclic AMP (cAMP) by adenylyl cyclase (AC). These messengers influence cellular activities by activating protein kinases directly or by mobilizing Ca^{2+} from the sarcoplasmic or endoplasmic reticulum (SR and ER), as IP$_3$ does. Ach = acetylcholine; Glu = glutamate; GABA = g-aminobutyric acid; Gly = glycine; Op = opioid peptides; NE = norepinephrine; E = epinephrine; 5HT = 5-hydroxytryptamine; G = G protein; PIP$_2$ = phosphatidylinositol 4,5-bisphosphate. Encircled positive and negative signs indicate activation and inhibition, respectively.

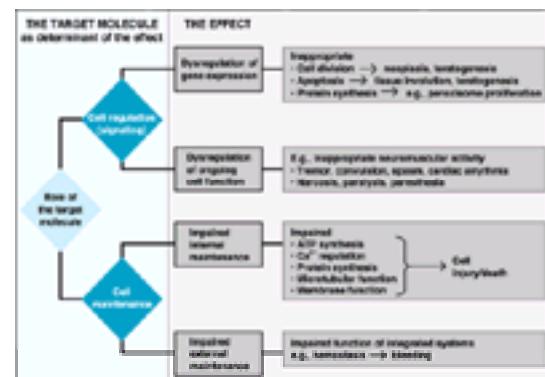
As outlined in Fig. 3-10, the nature of the primary cellular dysfunction caused by toxicants, but not necessarily the ultimate outcome, depends on the role of the target molecule affected. If the target molecule is involved in cellular regulation (signaling), dysregulation of gene expression and/or dysregulation of momentary cellular function occurs primarily. However, if the target molecule is involved predominantly in the cell's internal maintenance, the resultant dysfunction can ultimately compromise the survival of the cell. The reaction of a toxicant with targets serving external functions can influence the operation of other cells and integrated organ systems. The following discussion deals with these consequences.


Figure 3-10. The third step in the development of toxicity: alteration of the regulatory or maintenance function of the cell.

Toxicant-Induced Cellular Dysregulation

Cells are regulated by signaling molecules that activate specific cellular receptors linked to signal transducing networks that transmit the signals to the regulatory regions of genes and/or to functional proteins. Receptor activation may ultimately lead to (1) altered gene expression that increases or decreases the quantity of specific proteins and/or (2) a chemical modification of specific proteins, typically by phosphorylation, that activates or inhibits proteins. Programs controlling the destiny of cells primarily affect gene expression, whereas those regulating the ongoing activities primarily influence the activity of functional proteins; however, one

signal often evokes both responses because of branching and interconnection of signaling networks.

Dysregulation of Gene Expression Dysregulation of gene expression may occur at elements that are directly responsible for transcription, at components of the intracellular signal transduction pathway, and at the synthesis, storage, or release of the extracellular signaling molecules.

Dysregulation of Transcription Transcription of genetic information from DNA to mRNA is controlled largely by an interplay between transcription factors (TFs) and the regulatory or promoter region of genes. By binding to nucleotide sequences in this region, activated TFs facilitate the formation of the preinitiation complex, promoting transcription of the adjacent gene. Xenobiotics may interact with the promoter region of the gene, the TFs, or other components of the preinitiation complex. However, altered activation of TFs appears to be the most common modality. Functionally, two types of TFs are known: ligand-activated and signal-activated.

Many natural compounds, such as hormones (e.g., steroids, thyroid hormones) and vitamins (retinoids and vitamin D), influence gene expression by binding to and activating TFs (Table 3-4). Xenobiotics may mimic the natural ligands. For example, fibric acid–type lipid-lowering drugs and phthalate esters substitute for polyunsaturated fatty acids as ligands for the peroxisome proliferator-activated receptor (PPAR) (Poellinger et al., 1992), and Cd^{2+} substitutes for Zn^{2+}, the endogenous ligand of metal-responsive element-binding transcription factor (MTF-1) (Heuchel et al., 1994).

Table 3-4 Toxicants Acting on Ligand-Activated Transcription Factors

Natural or xenobiotic ligands may cause toxicity mediated by ligand-activated TFs when administered at extreme doses or at critical periods during ontogenesis (Table 3-4). Glucocorticoids induce apoptosis of lymphoid cells. While desirable in the treatment of lymphoid malignancies, this is an unwanted response in many other conditions. TCDD, a ligand of the aryl hydrocarbon receptor (AHR), produces thymic atrophy by causing apoptosis of thymocytes. Estrogens exert mitogenic effects in cells that express estrogen receptors, such as those found in the female reproductive organs, the mammary gland, and the liver. Estrogen-induced proliferation appears to be responsible for tumor formation in these organs during prolonged estrogen exposure (Green, 1992). It has been speculated that environmental xenoestrogens such as DDT, polychlorinated biphenyls, bisphenol A, and atrazine contribute to an increased incidence of breast cancer. Zearalenone, a myco-estrogen feed contaminant, causes vulval prolapse in swine, an example of an estrogen receptor–mediated proliferative lesion. The mitogenic and hepatic tumor-promoting effects of peroxysome proliferators is also receptor-mediated, because it is not observed in PPARa-null mice (Peters et al., 1998). Humans express PPARa at low levels and often in nonfunctional forms and thus, as opposed to rodents, do not exhibit hepatocellular and peroxisomal proliferation. Chemicals that act on ligand-activated TFs, such as glucocorticoids, TCDD, and retinoids, induce fetal malformations that may be regarded as inappropriate gene expression (Armstrong et al., 1992). Candidate target genes are the homeobox genes that determine the body plan during early ontogenesis.

Compounds that act on ligand-activated TFs can also change the pattern of cell differentiation by overexpressing various genes. For example, the PPAR-ligand fibric acid derivatives stimulate genes that encode peroxisomal enzymes and induce proliferation of peroxisomes in rodent liver (Green, 1992).

TCDD, phenobarbital, and pregnenolone 16a-carbonitrile (PCN) activate AHR, the constitutive androstane receptor (CAR), and the pregnane X receptor (PXR), respectively (Table 3-4), thereby exerting their well known cytochrome P450–inducing effects. Genes of other xenobiotic metabolizing enzymes are also activated by these chemicals. For example, TCDD increases the expression of cytochrome-P450 lAl, UDP-glucuronosyltransferase-1, and several subunits of mouse and rat glutathione *S*-transferase because the promoter region of their genes contains a dioxin (or xenobiotic) response element that is recognized by the TCDD-activated Ah receptor complexed with its nuclear translocator protein ARNT. In AHR-null mice, TCDD induces neither these enzymes nor the adverse effects listed in Table 3-4 (Gonzales and Fernandez-Salguero, 1998).

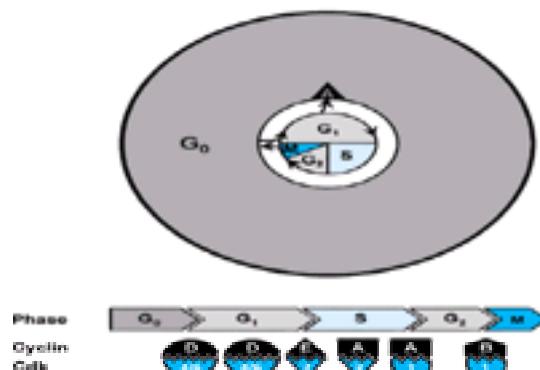
Dysregulation of Signal Transduction Extracellular signaling molecules, such as growth factors, cytokines, hormones, and neurotransmitters, can ultimately activate TFs utilizing cell surface receptors and intracellular signal transducing networks. Figure 3-11 depicts a simplified scheme for such networks and identifies some of the most important signal-activated TFs that control transcriptional activity of genes that influence cell cycle progression and thus determine the fate of cells. Among these TFs are the c-Fos and c-Jun proteins, which bind in dimeric combinations (called AP-1) to the tetradecanoylphorbol acetate (TPA) response element (TRE), for example, in the promoter of cyclin D gene. Another is the c-Myc protein, which, upon dimerizing with Max protein and binding to its cognate nucleotide sequence, transactivates cyclin D and E genes, among others. The cyclins, in turn, accelerate the cell division cycle by activating cyclin-dependent protein kinases (see Fig. 3-21 and Fig. 3-24). Mitogenic signaling molecules thus induce cellular proliferation. In contrast, TGF-b induces the expression of cyclin-dependent protein kinase inhibitor proteins (e.g., p27) that mediates its antimitotic effect (Johnson and Walker, 1999) (see Fig. 3-24).


Figure 3-21. The cell division cycle and the participating cyclins and cyclin-dependent protein kinases.

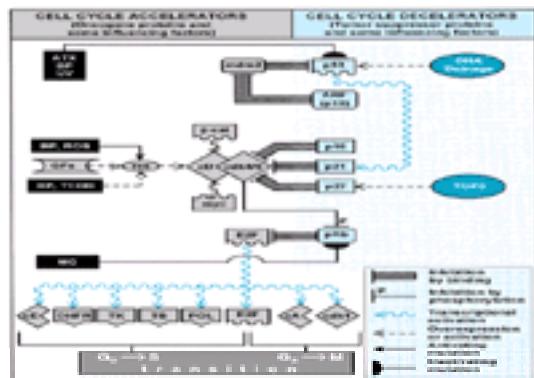
Areas representing phases of the cycle are meant to be proportional to the number of cells in each phase. Normally, most cells are in G_0 phase, a differentiated and quiescent state. After receiving signals to divide, they progress into the G_1 phase of the cell division cycle. G_0/G_1 transition involves activation of immediate early genes so that cells acquire replicative competence. Now increasingly responsive to growth factors, these cells progress to the phase of DNA synthesis (S). If this progression is blocked (e.g., by the accumulated p53 protein), the cells may undergo apoptosis (A). After DNA replication, the cells prepare further for mitosis in the G_2 phase. Mitosis (M) is the shortest phase of the cell cycle (approximately 40 min out of the 40-h-long cycle of hepatocytes) and most likely requires the largest energy expenditure per unit of time. The daughter cells produced may differentiate and enter into the pool of quiescent cells (G_0), substituting for those which had been lost. During the cycle, the levels of various cyclins surge (see figure). These proteins bind to and activate specific cyclin-dependent protein kinases (Cdk, see figure), which, in turn, phosphorylate and thus activate enzymes and other proteins required for DNA replication and cell division (Johnson and Walker, 1999) (see Fig. 3-24). After tissue necrosis, the number of cells entering the cell division cycle markedly increases at areas adjacent to the injury. The proportion of cells that are in S phase in a given period is reflected by the labeling index, whereas the percentage of cells under going mitosis is the mitotic index (see text).


Figure 3-24. Key regulatory proteins controlling the cell division cycle with some signaling pathways and xenobiotics affecting them.

Proteins on the left, represented by gray symbols, accelerate the cell cycle and are oncogenic if permanently active or expressed at high level. In contrast, proteins on the right, represented by blue symbols, decelerate or arrest the cell cycle and thus suppress oncogenesis, unless they are inactivated (e.g., by mutation).

Accumulation of cyclin D (cD) is a crucial event in initating the cell division cycle. cD activates cyclin-dependent protein kinases 4 and 6 (cdk4/6), which in turn phosphorylate the retinoblastoma protein (pRb) causing dissociation of pRb from transcription factor E2F (Johnson and Walker, 1999). Then the unleashed E2F is able to bind to and transactivate genes whose products are essential for DNA synthesis, such as dihydrofolate reductase (DHFR), thymidine kinase (TK), thymidylate synthetase (TS), and DNA polymerase (POL), or are regulatory proteins, such as cyclin E (cE), cyclin A (cA) and cyclin-dependent protein kinase 1 (cdk1), that promote further progression of the cell cycle. Expression of cD is increased, for example, by signals evoked by growth factors (GFs) via ras proteins and by transcription factors, such as myc and b-catenin (b-cat). Some carcinogens, e.g., benzpyrene (BP) and reactive oxygen species (ROS), may cause mutation of the *ras* gene that results in permanently active mutant *ras* protein, but BP as well as TCDD may also induce simple overexpression of normal *ras* protein.

Cell cycle progression is counteracted, for example, by pRb (which inhibits the function of E2F), by cyclin-dependent protein kinase inhibitors (such as p16, p21, and p27), by p53 (that transactivates the *p21* gene), and by ARF (also called p19 that binds to mdm2, thereby neutralizing the antagonistic effect of mdm2 on p53). Signals evoked by DNA damage and TGF-b will ultimately result in accumulation of p53 and p27 proteins, respectively, and deceleration of the cell cycle. In contrast, mutations that disable the tumor suppressor proteins facilitate cell cycle progression and neoplastic conversion and are common in human tumors. Aflatoxin B $_1$ (ATX), BP and UV light cause such mutations of the *p53* gene (Bennet et al., 1999), whereas *pRb* mutations occur invariably in methylcholanthrene (MC)-induced transplacental lung tumors in mice (Miller, 1999).

The signal from the cell surface receptors to the TFs is relayed by successive protein-protein interactions and protein phosphorylations. Growth factor receptors (item 6 in Fig. 3-11), exposed on the surface of all cells, are in fact phosphorylating enzymes (i.e., receptor protein tyrosine kinases). Their ligands induce them to phosphorylate themselves, which, in turn, enable these receptors to bind to adapter proteins through which they activate Ras. The active Ras sets in motion the mitogen-activated kinase (MAPK) cascade, involving serial phosphorylations of protein kinases, which finally reaches the TFs (Fig. 3-11). Thus, the activity of many signaling elements, ranging from the receptors through the kinases to the transcription factors, is affected by phosphorylation at specific serine, threonine, or tyrosine hydroxyl groups. These signal transducers are typically but not always activated by phosphorylation—that is catalyzed by protein kinases—and are usually inactivated by dephosphorylation, which is carried out by protein phosphatases.

Chemicals may cause aberrant signal transduction in a number of ways, most often by altering protein phosphorylation, occasionally by interfering with the GTPase activity of G proteins (e.g., Ras), by disrupting normal protein-protein interactions or by establishing abnormal ones, or by altering the synthesis or degradation of signaling proteins. Such interventions may ultimately influence cell cycle progression.

Chemically Altered Signal Transduction with Proliferative Effect Xenobiotics that facilitate phosphorylation of signal transducers often promote mitosis and tumor formation. Such are the phorbol esters and fumonisin B that activate protein kinase C (PKC). These chemicals mimic diacylglycerol (DAG), one of the physiologic activators of PKC (Fig. 3-11). The other physiologic PKC activator Ca $^{2+}$ is mimicked by Pb $^{2+}$, whose effect on PKCa is concentration-dependent: stimulatory at picomolar concentration, when Pb $^{2+}$ occupies only high-affinity binding sites on PKC, and inhibitory at micromolar concentration, where the low affinity sites are also occupied (Sun et al., 1999). Lead acetate does induce marked hepatocellular proliferation in rats. The activated PKC promotes mitogenic signaling at least in two ways: (1) by phosphorylating Raf, the first protein kinase in the MAPK pathway (Fig. 3-11), and (2) by phosphorylating a protein phosphatase that dephosphorylates the transcription factor c-Jun at specific sites (Thr 231, Ser 234, and Ser 249), thereby permitting its binding to DNA. Protein kinases may also be activated by interacting proteins that had been altered by a xenobiotic. For example, the TCDD-liganded AHR binds to MAPK. This may contribute to the TCDD-induced overexpression of cyclins and cyclin-dependent kinases in guinea pig liver (Ma and Babish, 1999).

Aberrant phosphorylation of proteins may result not only from increased phosphorylation by kinases but also from decreased dephosphorylation by phosphatases. Inhibition of phosphatases appears to be the underlying mechanism of the mitogenic effect of various chemicals, oxidative stress, and ultraviolet (UV) irradiation (Herrlich et al., 1999). Protein tyrosine phosphatases and dual-specificity phosphatases (i.e., enzymes that remove phosphate from phosphorylated tyrosine as well as serine and threonine residues) contain a catalytically active cysteine and are susceptible to inactivation by oxidation and covalent reaction with SH-reactive chemicals. Indeed, xenobiotics such as the SH-reactive iodoacetamide, the organometal compound tributyltin, arsenite, and oxidants (e.g., HOOH) cause phosphorylation of the epidermal growth factor (EGF) receptor (item 6 in Fig. 3-11) by interfering with the protein tyrosine phosphatase that would dephosphorylate and thus "silence" this receptor (Herrlich et al., 1999; Chen et al., 1998). Arsenite may also inactivate the dual-specificity phosphatase that dephosphorylates and "silences" certain MAPKs (JNK, p38), whereas methylmethane sulfonate (MMS) appears to inhibit a protein phosphatase that inactivates Src, a protein tyrosine kinase (Herrlich et al., 1999). The thiol oxidizing agent diamide (which increases phosphorylation of MAPKs) and phenolic antioxidants (which form phenoxyl radicals and increase c-Fos and c-Jun expression) (Dalton et al., 1999) may also act by incapacitating protein tyrosine phosphatases. Protein phosphatase 2A (PP2A) is the major soluble ser/thr phosphatase in cells and is likely responsible, at least in part, for reversing the growth factor–induced stimulation of MAPK, thereby keeping the extent and duration of MAPK activity under control (Goldberg, 1999). PP2A also removes an activating phosphate from a mitosis-triggering protein kinase (p34 ^{cdc2}). Several natural toxins are extremely potent inhibitors of PP2A; including the blue-green algae poison microcystin-LG and the dinoflagellate-derived okadaic acid (Toivola and Eriksson, 1999), which are tumor promoters in experimental animals subjected to prolonged low-dose exposure. It is to be noted, however, that acute high-dose exposure to microcystin induces severe liver injury, whereas such exposure to okadaic acid is the underlying cause of the diarrhetic shellfish poisoning. In these conditions, hyperphosphorylation of proteins other than those involved in proliferative signaling (e.g. hepatocellular microfilaments in microcystin poisoning) may be primarily responsible for the pathogenesis.

Apart from phosphatases, there are also inhibitory binding proteins that can keep signaling under control. Such is IkB, which binds to NF-kB, preventing its transfer into the nucleus and its function as a TF. Upon phosphorylation, IkB becomes degraded and NF-kB is set free. Because phosphorylation of IkB can be catalyzed by Raf, a protein kinase in the MAPK cascade (Fig. 3-11), and because the released NF-kB can transactivate the c-Myc gene, NF-kB is an important contributor to proliferative and prolife signaling. In addition, because NF-kB also targets the genes of several cytokines (e.g., TNF-a, IL-1b) and acute phase proteins (e.g., C-reactive protein, a1-acid glycoprotein), and because such cytokines acting on their receptors (items 2 and 3 in Fig. 3-11) also activate NF-kB, this TF plays a leading role also in inflammatory and acute phase reactions (Lee et al., 1998; Waddick and Uckun, 1999). IkB degradation and NF-kB activation can also be induced by oxidative stress, and it appears that peroxides are the reactive oxygen species (ROS) that mediate this effect (Dalson et al., 1999). Activated NF-kB probably contributes to the proliferative and inflammatory response to oxidative stress. NF-kB also protects cells from apoptosis by maintaining c-Myc transcription, which is required for survival (Waddick and Uckun, 1999), and by transactivating the genes of antiapoptotic IAP proteins, which inhibit caspases (Jäättelä, 1999). Another site from which aberrant mitogenic signals may originate is the GTP/GDP binding protein Ras, which is active in GTP-bound form but inactive in GDP-bound form. The activity of Ras is normally terminated via stimulation of its own GTPase activity by a GTPase-activating protein (GAP) (Fig. 3-11) that returns Ras into its inactive GDP-bound state. Fatty acids, which may accumulate, for example, in response to phospholipase A activation and exposure to peroxysome proliferators (Rose et al., 1999), inhibit GAP and can delay the turning off of Ras. As discussed in more detail later in the chapter, genotoxic carcinogens may mutate Ras, and if the mutation leads to a loss of its GTPase activity, this would result in a permanent signaling for the MAPK pathway—a condition that contributes to malignant transformation of the affected cell population.

Chemically Altered Signal Transduction with Antiproliferative Effect Downturning of increased proliferative signaling after cell injury may compromise replacement of

injured cells. This prediction has been made from a recent study on cultured Hepa 1-6 cells that exhibited the following, seemingly consequential alterations upon exposure to acetaminophen (follow the path in Fig. 3-11): inhibition of Raf ® diminished degradation of IkB ® diminished binding of NF-kB to DNA ® diminished expression of c-Myc mRNA (Boulares et al., 1999). Down-regulation of a normal mitogenic signal is a step away from survival and toward apoptosis. Indeed, staurosporin, an inhibitor of PKC, and gliotoxin, an inhibitor of IkB degradation (Waddick and Uckun, 1999), are potent apoptosis inducers. TGF-b and glucocorticoids increase IkB synthesis and, in turn, decrease NF-kB activation and c-Myc expression (Waddick and Uckun, 1999). These mechanisms may contribute to the apoptotic effect of TGF-b and glucocorticoids, the latter in lymphoid cells.

Dysregulation of Extracellular Signal Production Hormones of the anterior pituitary exert mitogenic effects on endocrine glands in the periphery by acting on cell surface receptors. Pituitary hormone production is under negative feedback control by hormones of the peripheral glands. Perturbation of this circuit adversely affects pituitary hormone secretion and, in turn, the peripheral gland. For example, xenobiotics that inhibit thyroid hormone production (e.g., the herbicide amitrole and the fungicide metabolite ethylenethiourea) or enhance thyroid hormone elimination (e.g., phenobarbital) reduce thyroid hormone levels and increase the secretion of thyroid-stimulating hormone (TSH) because of the reduced feedback inhibition. The increased TSH secretion stimulates cell division in the thyroid gland, which is responsible for the goiters or thyroid tumors caused by such toxicants (Chap. 21). Decreased secretion of pituitary hormone produces the opposite adverse affect, with apoptosis followed by involution of the peripheral target gland. For example, estrogens produce testicular atrophy in males by means of feedback inhibition of gonadotropin secretion. The low sperm count in workers intoxicated with the xenoestrogen chlordecone probably results from such a mechanism.

Dysregulation of Ongoing Cellular Activity Ongoing control of specialized cells is exerted by signaling molecules acting on membrane receptors that transduce the signal by regulating Ca^{2+} entry into the cytoplasm or stimulating the enzymatic formation of intracellular second messengers. The Ca^{2+} or other second messengers ultimately alter the phosphorylation of functional proteins, changing their activity and, in turn, cellular functions almost instantly. Toxicants can adversely affect ongoing cellular activity by disrupting any step in signal coupling.

Dysregulation of Electrically Excitable Cells Many xenobiotics influence cellular activity in excitable cells, such as neurons, skeletal, cardiac, and smooth muscle cells. Cellular functions such as the release of neurotransmitters and muscle contraction are controlled by transmitters and modulators synthesized and released by adjacent neurons. The major mechanisms that control such cells are shown schematically in Fig. 3-12, and chemicals that interfere with these mechanisms are listed in Table 3-5.

Table 3-5 Agents Acting on Signaling Systems for Neurotransmitters and Causing Dysregulation of the Momentary Activity of Electrically Excitable Cells Such as Neurons and Muscle Cells*

Altered regulation of neural and/or muscle activity is the basic mechanism of action of many drugs and is responsible for toxicities associated with drug overdosage, pesticides, and microbial, plant, and animal toxins (Herken and Hucho, 1992). As neurons are signal-transducing cells, the influence of chemicals on neurons is seen not only on the neuron affected by the toxicant but also on downstream cells influenced by the primary target. Thus, tetrodotoxin, which blocks voltage-gated Na^+ channels (item 7 in Fig. 3-12) in motor neurons, causes skeletal muscle paralysis. In contrast, cyclodiene insecticides, which block GABA receptors (item 3 in Fig. 3-12) in the central nervous system, induce neuronal excitation and convulsions (Narahashi, 1991).

Perturbation of ongoing cellular activity by chemicals may be due to an alteration in (1) the concentration of neurotransmitters, (2) receptor function, (3) intracellular signal transduction, or (4) the signal-terminating processes.

Alteration in Neurotransmitter Levels Chemicals may alter synaptic levels of neurotransmitters by interfering with their synthesis, storage, release, or removal from the vicinity of the receptor. The convulsive effect of hydrazides is due to their ability to decrease the synthesis of the inhibitory neurotransmitter GABA (Gale, 1992). Reserpine causes its several adverse effects by inhibiting the neuronal storage of norepinephrine, 5-hydroxytryptamine, and dopamine, thereby depleting these transmitters. Skeletal muscle paralysis caused by botulinum toxin is due to inhibition of acetylcholine release from motor neurons and the lacking stimulation of the acethylcholine receptors at the neuromuscular junction (receptor 1 in Fig. 3-12). In contrast, inhibition of acetylcholinesterase by organophosphate or carbamate insecticides or chemical warfare agents (e.g., soman) prevents the hydrolysis of acetylcholine, resulting in massive stimulation of cholinergic receptors (receptors 1, 5, and 10 in Fig. 3-12) and a cholinergic crisis (Table 3-5). Inhibition of the neuronal reuptake of norepinephrine by cocaine or tricyclic antidepressants is responsible for overexcitation of alpha$_1$-adrenergic receptors on vascular smooth muscles, resulting in nasal mucosal ulceration and myocardial infarction in heavy cocaine abusers, whereas overstimulation of beta$_1$-adrenergic receptors contributes to life-threatening arryhthmias. Similar cardiac complications may result from amphetamine abuse, because amphetamine enhances the release of norepinephrine from adrenergic neurons and competitively inhibits neuronal reuptake of this transmitter. A hypertensive crisis can occur with the combined use of tricyclic antidepressants and monoamine oxidase inhibitors, drugs that block different mechanisms of norepinephrine elimination (Hardman et al., 1995).

Toxicant–Neurotransmitter Receptor Interactions Some chemicals interact directly with neurotransmitter receptors, including (1) agonists that associate with the ligand-binding site on the receptor and mimic the natural ligand, (2) antagonists that occupy the ligand-binding site but cannot activate the receptor, (3) activators, and (4) inhibitors that bind to a site on the receptor that is not directly involved in ligand binding. In the absence of other actions, agonists and activators mimic, whereas antagonists and inhibitors block, the physiologic responses characteristic of endogenous ligands. For example, muscimol, a mushroom poison, is an agonist at the inhibitory GABA$_A$ receptor (item 3 in Fig. 3-12), whereas barbiturates, benzodiazepines, general anaesthetics, and alcohols are activators (Narahashi, 1991). Thus, all these agents cause inhibition of central nervous system activity, resulting in sedation, general anesthesia, coma, and ultimately blockade of the medullary respiratory center, depending on the dose administered. There are also similarities in the responses evoked by agonist/activators on excitatory receptors and those elicited by antagonists/inhibitors on inhibitory sites. Thus, glutamate receptor agonists and muscarinic receptor agonists cause neuronal hyperactivity in the brain and ultimately convulsions, as do inhibitors of GABA$_A$ receptor. It is also apparent that chemicals acting as agonists/activators on inhibitory receptors and those acting as antagonists/inhibitors on excitatory receptors may exert similar effects. Moreover, general anesthetic solvents induce general anesthesia not only by activating the inhibitory ligand-gated chloride-ion channels (i.e., GABA$_A$ and glycine receptors; see items 3 and 4, respectively, in Fig. 3-12) but also by inhibiting the excitatory ligand-gated cation channels (i.e., neuronal nicotinic acethylcholine receptor and glutamate receptors; see items 1 and 2, respectively, in Fig. 3-12) (Franks and Lieb, 1998; Perouansky et al., 1998). Because there are multiple types of receptors for each neurotransmitter, these receptors may be affected differentially by toxicants. For example, the neuronal nicotinic acetylcholine receptor is extremely sensitive to inhibition by lead ions, whereas the muscular nicotine receptor subtype is not (Oortgiesen et al., 1993). Other chemicals that produce neurotransmitter receptor–mediated toxicity are listed in Table 3-5.

Some sensory neurons have receptors that are stimulated by chemicals, such as the capsaicin receptor, which is a ligand-gated cation channel (Herken and Hucho, 1992). This receptor mediates the burning sensation of the tongue and reflex stimulation of the lacrimal gland associated with exposure to red pepper and other irritants. Lacrimators in tear gas, which are typically thiol-reactive chemicals, also stimulate these neurons, though their precise mode of action is unclear.

Toxicant–Signal Transducer Interactions Many chemicals alter neuronal and/or muscle activity by acting on signal-transduction processes. Voltage-gated Na^+ channels (item 7 in Fig. 3-12), which transduce and amplify excitatory signals generated by ligand-gated cation channels (receptors 1 and 2 in Fig. 3-12), are activated by a number of toxins derived from plants and animals (Table 3-5) as well as by synthetic chemicals such as DDT, resulting in overexcitation (Narahashi, 1992). In contrast, agents that block voltage-gated Na^+ channels (such as tetrodotoxin and saxitoxin) cause paralysis. The Na^+ channels are also important in signal transduction in sensory neurons; therefore, Na^+-channel activators evoke sensations and reflexes, whereas Na^+-channel inhibitors induce anesthesia. This explains

the reflex bradycardia and burning sensation in the mouth that follow the ingestion of monkshood, which contains the Na$^+$-channel activator aconitine, as well as the use of Na$^+$-channel inhibitors such as procaine and lidocaine for local anesthesia.

Toxicant–Signal Terminator Interactions The cellular signal generated by cation influx is terminated by removal of the cations through channels or by transporters (Fig. 3-12). Inhibition of cation export may prolong excitation, as occurs with the inhibition of Ca^{2+}-activated K$^+$ channels (item 9 in Fig. 3-12) by Ba^{2+}, which is accompanied by potentially lethal neuroexcitatory and spasmogenic effects. Glycosides from digitalis and other plants inhibit Na$^+$,K$^+$-ATPase (item 10 in Fig. 3-12) and thus increase the intracellular Na$^+$ concentration, which, in turn, decreases Ca^{2+} export by Ca^{2+}/Na$^+$ exchange (Fig. 3-12). The resultant rise in the intracellular concentration of Ca^{2+} enhances the contractility and excitability of cardiac muscle. Inhibition of brain Na$^+$,K$^+$-ATPase by chlordecone may be responsible for the tremor observed in chlordecone-exposed workers (Desaiah, 1982). Lithium salts, although used therapeutically, have the potential to produce hyperreflexia, tremor, convulsions, diarrhea, and cardiac arrhythmias (Hardman et al., 1995). Lithium also markedly potentiates cholinergically mediated seizures. A possible reason for these toxic effects is inefficient repolarization of neurons and muscle cells in the presence of Li$^+$. Whereas Li$^+$ readily enters these cells through Na$^+$ channels, contributing to the signal-induced depolarization, it is not a substrate for the Na$^+$,K$^+$ pump. Therefore, the cells fail to repolarize properly if a fraction of intracellular Na$^+$ is replaced by Li$^+$.

Failure of the Na$^+$,K$^+$ pump also is believed to contribute to the neuronal damage resulting from hypoxia, hypoglycemia, and cyanide intoxication. Inasmuch as 70 percent of the ATP produced in neurons is used to drive the Na$^+$,K$^+$ pump; cessation of ATP synthesis causes a cell to become or remain depolarized. The depolarization-induced release of neurotransmitters such as glutamate from such neurons is thought to be responsible for the hypoxic seizures and further amplification of neuronal injury by the neurotoxic actions of glutamate (Patel et al., 1993).

Dysregulation of the Activity of Other Cells While many signaling mechanisms also operate in nonexcitable cells, disturbance of these processes is usually less consequential. For example, rat liver cells possess alpha$_1$-adrenergic receptors (item 12 in Fig. 3-12) whose activation evokes metabolic changes, such as increased glycogenolysis and glutathione export, through elevation of intracellular Ca^{2+}, which may have toxicologic significance.

Many exocrine secretory cells are controlled by muscarinic acetylcholine receptors (item 11 in Fig. 3-12). Salivation, lacrimation, and bronchial hypersecretion after organophosphate insecticide poisoning are due to stimulation of these receptors. In contrast, blockade of these receptors contributes to the hyperthermia characteristic of atropine poisoning. Kupffer cells, resident macrophages in the liver, secrete inflammatory mediators (see Fig. 3-22) that can harm the neighboring cells. Because Kupffer cells possess glycine receptors, i.e., glycine-gated Cl$^-$ channels (item 4 in Fig. 3-12), the secretory function of these macrophages (e.g., secretion of inflammatory mediators) can be blocked by administration of glycine, which induces hyperpolarization via influx of Cl$^-$. Such intervention alleviates ethanol-induced liver injury (Yin et al., 1998).

The discovery that some sulfonamides produce hypoglycemia in experimental animals led to the development of oral hypoglycemic agents for diabetic patients. These drugs inhibit K$^+$ channels in pancreatic beta cells, inducing sequentially depolarization, Ca^{2+} influx through voltage-gated Ca^{2+} channels, and exocytosis of insulin (Hardman et al., 1995). The antihypertensive diazoxide acts in the opposite fashion on K$^+$ channels and impairs insulin secretion. While this effect is generally undesirable, it is exploited in the treatment of inoperable insulin-secreting pancreatic tumors.

Toxic Alteration of Cellular Maintenance

Numerous toxicants interfere with cellular maintenance functions. In a multicellular organism, cells must maintain their own structural and functional integrity as well as provide supportive functions for other cells. Execution of these functions may be disrupted by chemicals, resulting in a toxic response.

Impairment of Internal Cellular Maintenance: Mechanisms of Toxic Cell Death For survival, all cells must synthesize endogenous molecules; assemble macromolecular complexes, membranes, and cell organelles; maintain the intracellular environment; and produce energy for operation. Agents that disrupt these functions, especially the energy-producing function of mitochondria and protein synthesis controlling function of the genome, jeopardize survival and may cause toxic cell death.

There are three critical biochemical disorders that chemicals inflicting cell death may initiate, namely ATP depletion, sustained rise in intracellular Ca^{2+}, and overproduction of ROS and RNS. In the following discussion, these events and the chemicals that may cause them are individually characterized. Then it is pointed out how their concerted action may induce a bioenergetic catastrophe, culminating in necrosis. Finally, there follows a discussion of the circumstances under which the cell can avoid this disordered decay and how it can execute death by activating catabolic processes that bring about an ordered disassembly and removal of the cell, called apoptosis.

Primary Metabolic Disorders Jeopardizing Cell Survival: ATP Depletion, Ca^{2+} Accumulation, ROS/RNS Generation *Depletion of ATP* ATP plays a central role in cellular maintenance both as a chemical for biosynthesis and as the major source of energy. It is utilized in numerous biosynthetic reactions, activating endogenous compounds by phosphorylation and adenylation, and is incorporated into cofactors as well as nucleic acids. It is required for muscle contraction and polymerization of the cytoskeleton, fueling cellular motility, cell division, vesicular transport, and the maintenance of cell morphology. ATP drives ion transporters such as the Na$^+$,K$^+$-ATPase in the plasma membrane, the Ca^{2+}-ATPase in the plasma and the endoplasmic reticulum membranes, and H$^+$-ATPase in the membrane of lysosomes and neurotransmitter-containing vesicles. These pumps maintain conditions essential for various cell functions. For example, the Na$^+$ concentration gradient across the plasma membrane generated by the Na$^+$,K$^+$ pump drives Na$^+$-glucose and Na$^+$-amino acid cotransporters as well as the Na$^+$/Ca^{2+} antiporter, facilitating the entry of these nutrients and the removal of Ca^{2+}.

Chemical energy is released by hydrolysis of ATP to ADP or AMP. The ADP is rephosphorylated in the mitochondria by ATP synthase (Fig. 3-13). Coupled to oxidation of hydrogen to water, this process is termed *oxidative phosphorylation.* In addition to ATP synthase, oxidative phosphorylation requires the (1) delivery of hydrogen in the form of NADH to the initial electron transport complex; (2) delivery of oxygen to the terminal electron transport complex; (3) delivery of ADP and inorganic phosphate to ATP synthase; (4) flux of electrons along the electron transport chain to O$_2$, accompanied by ejection of protons from the matrix space across the inner membrane; and (5) return of protons across the inner membrane into the matrix space down an electrochemical gradient to drive ATP synthase (Fig. 3-13).

Several chemicals impede these processes, interfering with mitochondrial ATP synthesis (Commandeur and Vermeuien, 1990; Wallace and Starkow, 2000). These chemicals are divided into five groups (Table 3-6). Substances in class A interfere with the delivery of hydrogen to the electron transport chain. For example, fluoroacetate inhibits the citric acid cycle and the production of reduced cofactors. Class B chemicals such as rotenone and cyanide inhibit the transfer of electrons along the electron transport chain to oxygen. Class C agents interfere with oxygen delivery to the terminal electron transporter, cytochrome oxidase. All chemicals that cause hypoxia ultimately act at this site. Chemicals in class D inhibit the activity of ATP synthase, the key enzyme for oxidative phosphorylation. At this site, the synthesis of ATP may be inhibited in one of four ways: (1) direct inhibition of ATP synthase, (2) interference with ADP delivery, (3) interference with inorganic phosphate delivery, and (4) deprivation of ATP synthase from its driving force, the controlled influx of protons into the matrix space. Protonophoric chemicals (uncouplers) such as 2,4-dinitrophenol and pentachlorophenol import protons into the mitochondrial matrix, dissipating the proton gradient that drives the controlled influx of protons into the matrix, which, in turn, drives ATP synthase. Finally, chemicals causing mitochondrial DNA injury, and thereby impairing synthesis of specific proteins encoded by the mitochondrial genome (e.g., subunits of complex I and ATP synthase), are listed in group E. These include the dideoxynucleoside antiviral drugs used against AIDS, such as zidovudine. Table 3-6 lists other chemicals that impair ATP synthesis.

Impairment of oxidative phosphorylation is detrimental to cells because failure of ADP rephosphorylation results in the accumulation of ADP and its breakdown products as well as depletion of ATP. Accordingly, hepatocytes exposed to KCN and iodoacetate exhibit a rapid rise in cytosolic H$^+$ and Mg^{2+} as a result of the hydrolysis of adenosine di- and triphosphates (existing as Mg salts) and the release of phosphoric acid and Mg^{2+} (Herman et al., 1990). The increased conversion of pyruvate to lactate also may contribute to the acidosis. The lack of ATP compromises the operation of ATP-requiring ion pumps, leading to the loss of ionic and volume-regulatory controls (Buja et al., 1993). Shortly after intracellular acidosis and hypermagnesemia, liver cells exposed to KCN and iodoacetate exhibit a rise in intracellular Na$^+$, probably as a result of failure of the Na$^+$ pump, after which plasma membrane blebs appear. The intracellular phosphoric acidosis is beneficial for the cells presumably because the released phosphoric acid forms insoluble calcium phosphate, preventing the rise of cytosolic Ca^{2+}, with its deleterious consequences (see below). In addition, a low pH also directly decreases the activity of phospholipases and inhibits mitochondrial permeability transition (see later). Terminally, the intracellular pH rises, increasing phospholipase activity, and this contributes to irreversible membrane damage (i.e., rupture of the blebs) not only by degrading phospholipids but also by generating endogenous detergents such as lysophospholipids and free fatty acids. The lack of ATP aggravates this condition

because the reacylation of lysophospholipids with fatty acids is impaired.

Sustained Rise of Intracellular Ca^{2+} Intracellular Ca^{2+} levels are highly regulated (Fig. 3-14). The 10,000-fold difference between extracellular and cytosolic Ca^{2+} concentration is maintained by the impermeability of the plasma membrane to Ca^{2+} and by transport mechanisms that remove Ca^{2+} from the cytoplasm (Richter and Kass, 1991). Ca^{2+} is actively pumped from the cytosol across the plasma membrane and is sequestered in the endoplasmic reticulum and mitochondria (Fig. 3-14). Because they are equipped with a low-affinity transporter, the mitochondria play a significant role in Ca^{2+} sequestration only when the cytoplasmic levels rise into the micromolar range. Under such conditions, a large amount of Ca^{2+} accumulates in the mitochondria, where it is deposited as calcium phosphate.

Toxicants induce elevation of cytoplasmic Ca^{2+} levels by promoting Ca^{2+} influx into or inhibiting Ca^{2+} efflux from the cytoplasm (Table 3-7). Opening of the ligand- or voltage-gated Ca^{2+} channels or damage to the plasma membrane causes Ca^{2+} to move down its concentration gradient from extracellular fluid to the cytoplasm. Toxicants also may increase cytosolic Ca^{2+} inducing its leakage from the mitochondria or the endoplasmic reticulum. They also may diminish Ca^{2+} efflux through inhibition of Ca^{2+} transporters or depletion of their driving forces. Several chemicals that can cause a sustained rise in cytoplasmic Ca^{2+} levels are listed in Table 3-7. Sustained elevation of intracellular Ca^{2+} is harmful because it can result in (1) depletion of energy reserves, (2) dysfunction of microfilaments, (3) activation of hydrolytic enzymes, and (4) generation of ROS and RNS.

There are at least three mechanisms by which sustained elevations in intracellular Ca^{2+} unfavorably influence the cellular energy balance. First, high cytoplasmic Ca^{2+} levels cause increased mitochondrial Ca^{2+} uptake by the Ca^{2+} "uniporter," which, like ATP synthase, utilizes the inside negative mitochondrial membrane potential (DYm) as the driving force. Consequently, mitochondrial Ca^{2+} uptake dissipates DYm and inhibits the synthesis of ATP. Moreover, agents that oxidize mitochondrial NADH activate a transporter that extrudes Ca^{2+} from the matrix space (Richter and Kass, 1991). The ensuing continuous Ca^{2+} uptake and export ("Ca^{2+} cycling") by the mitochondria further compromise oxidative phosphorylation. Second, Ca^{2+} may also impair ATP synthesis by causing oxidative injury to the inner membrane by mechanisms described later. Third, a sustained rise in cytoplasmic Ca^{2+} not only impairs ATP synthesis but also increases ATP consumption by the Ca^{2+}-ATPases working to eliminate the excess Ca^{2+}.

A second mechanism by which an uncontrolled rise in cytoplasmic Ca^{2+} causes cell injury is microfilamental dissociation (Nicotera et al., 1992; Leist and Nicotera, 1997). The cellwide network of actin filaments maintains cellular morphology by attachment of the filaments to actin-binding proteins in the plasma membrane. An increase of cytoplasmic Ca^{2+} causes dissociation of actin filaments from a-actinin and fodrin, proteins that promote anchoring of the filament to the plasma membrane. This represents a mechanism leading to plasma membrane blebbing, a condition that predisposes the membrane to rupture.

A third event whereby high Ca^{2+} levels are deleterious to cells is activation of hydrolytic enzymes that degrade proteins, phospholipids, and nucleic acids (Nicotera et al., 1992; Leist and Nicotera, 1997). Many integral membrane proteins are targets for Ca^{2+}-activated neutral proteases, or calpains (Saido et al., 1994). Calpain-mediated hydrolysis of actin-binding proteins also may cause membrane blebbing. Indiscriminate activation of phospholipases by Ca^{2+} causes membrane breakdown directly and by the generation of detergents. Activation of a Ca^{2+}-Mg^{2+}-dependent endocuclease causes fragmentation of chromatin. Elevated levels of Ca^{2+} can lock topoisomerase II in a form that cleaves but does not religate DNA. In summary, intracellular hypercalcemia activates several process that interfere with the ability of cells to maintain their structural and functional integrity. The relative importance of these processes in vivo requires further definition.

Overproduction of ROS and RNS There are a number of xenobiotics that can directly generate ROS and RNS, such as the redox cyclers (Fig. 3-3) and the transition metals (Fig. 3-4). In addition, overproduction of ROS and RNS can be secondary to the intracellular hypercalcemia, as Ca^{2+} activates enzymes that generate ROS and/or RNS in the following ways:

1. Activation of the dehydrogenases in the citric acid cycle by Ca^{2+} accelerates the hydrogen output from the citrate cycle and, in turn, the flux of electrons along the electron transport chain (see Fig. 3-13). This, together with the suppressed ATP synthase activity (owing to the Ca^{2+}-induced uncoupling), increases the formation of O$_2^{-\bullet}$ by the mitochondrial electron transport chain.
2. Ca^{2+}-activated proteases proteolytically convert xanthine dehydrogenase into xanthine oxidase, whose byproducts are O$_2^{-\bullet}$ and HOOH.
3. Neurons and endothelial cells constitutively express NOS that is activated by Ca^{2+}. Given the extremely high reactivity of $^{\bullet}$NO with O$_2^{-\bullet}$, co-production of these radicals will inevitably lead to formation of ONOO$^-$, a highly reactive oxidant (Murphy, 1999) (Fig. 3-4). Moreover, ONOO$^-$ can increase its own formation by incapacitating the highly sensitive Mn-SOD, which would eliminate O$_2^{-\bullet}$, a precursor of ONOO$^-$.

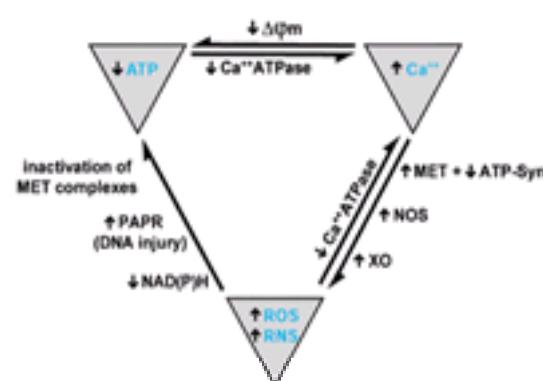
Interplay between the Primary Metabolic Disorders Spells Cellular Disaster The primary derailments in cellular biochemistry discussed above do not remain isolated but interact and amplify each other in a number of ways (Fig. 3-15):


Figure 3-15. Interrelationship between the primary metabolic disorders (ATP depletion, intracellular hypercalcemia, and overproduction of ROS/RNS) that ultimately cause necrosis or apoptosis.

See text for details. ATP-SYN = ATP synthase, MET = mitochondrial electron transport; NOS = nitric oxide synthase; PARP = poly(ADP-ribose) polymerase; ROS = reactive oxygen species; RNS = reactive nitrogen species; XO = xanthine oxidase; DYm = mitochondrial membrane potential.

1. Depletion of cellular ATP reserves deprives the endoplasmic and plasma membrane Ca^{2+} pumps of fuel, causing elevation of Ca^{2+} in the cytoplasm. With the influx of Ca^{2+} into the mitochondria, DYm declines, hindering ATP synthase.
2. As stated above, intracellular hypercalcemia facilitates formation of ROS and RNS, which oxidatively inactivate the thiol-dependent Ca^{2+} pump, which, in turn, aggravates the hypercalcemia.
3. The ROS and RNS can also drain the ATP reserves. $^{\bullet}$NO is a reversible inhibitor of cytochrome oxidase, NO+ (nitrosonium cation, a product of $^{\bullet}$NO) *S*-nitrosylates and thus inactivates glyceraldehyde 3-phosphate dehydrogenase, impairing glycolysis, whereas ONOO$^-$ irreversibly inactivates respiratory chain complexes I, II, III, and aconitase (by reacting with their Fe-S center) (Murphy, 1999). Therefore, $^{\bullet}$NO and ONOO$^-$ inhibit cellular ATP synthesis.
4. Furthermore, ONOO$^-$ can induce DNA single-strand breaks, which activate poly(ADP-ribose) polymerase (PARP) (Szabó, 1996). As part of the repair strategy, activated PARP transfers multiple ADP-ribose moieties from NAD$^+$ to nuclear proteins and PARP itself (D'Amours et al., 1999). Consumption of NAD$^+$ severely compromises ATP synthesis (see Fig. 3-13), whereas resynthesis of NAD$^+$ consumes ATP. Hence a major consequence of DNA damage by ONOO$^-$ is a cellular energy deficit (Murphy, 1999).

The chain of events and their contribution to the worsening metabolic conditions are somewhat cell-specific. For example, cyanide toxicity in neurons is associated with depolarization and glutamate release (Patel et al., 1993), followed by Ca^{2+} influx through voltage-gated as well as glutamate-gated channels (see items 8 and 12, respectively, in Fig. 3-12). As they express Ca^{2+}-activated NOS, neurons are also prone to generate "nitrosative stress," which affects not only themselves but perhaps more significantly the neighboring astrocytes (Szabó, 1996). In contrast, in cyanide- and iodoacetate-poisoned liver cells, the increase in cytoplasmic Ca^{2+} is

not an early event (Herman et al., 1990) and •NO formation is less likely involved. Nevertheless, the interplay of ATP depletion, intracellular hypercalcemia, and overproduction of ROS and RNS, involving multiple vicious cycles (Fig. 3-15), can progressively aggravate the biochemical disorder until it becomes a disaster.

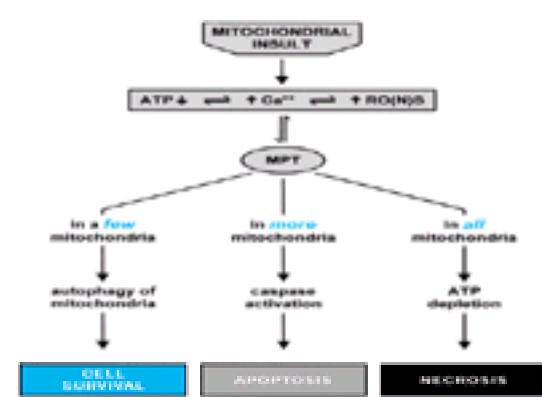
Mitochondrial Permeability Transition (MPT) and the Worst Outcome: Necrosis Mitochrondrial Ca^{2+} uptake, decreased DYm, generation of ROS and RNS, depletion of ATP, and consequences of the primary metabolic disorders (e.g., accumulation of inorganic phosphate, free fatty acids, and lysophosphatides) are all considered as causative factors of an abrupt increase in the mitochondrial inner-membrane permeability, termed MPT, believed to be caused by opening of a proteinaceous pore ("megachannel") that spans both mitochondrial membranes (Lemasters et al., 1998; Kroemer et al., 1998). As this pore is permeable to solutes of size <1500 Da, its opening permits free influx into the matrix space of protons, causing rapid and complete dissipation of DYm and cessation of ATP synthesis as well as osmotic influx of water, resulting in mitochondrial swelling. Ca^{2+} that had accumulated in the matrix space effluxes through the pore, flooding the cytoplasm. Such mitochondria are not only incapable of synthesizing ATP but even waste the remaining sources because depolarization of the inner membrane forces the ATP synthase to operate in the reverse mode, as an ATPase, hydrolyzing ATP. Then even glycolysis may become compromised by the insufficient ATP supply to the ATP-requiring glycolytic enzymes (hexokinase, phosphofructokinase). A complete bioenergetic catastrophe ensues in the cell if the metabolic disorders evoked by the toxic agent (such as one listed in Table 3-6 and Table 3-7) is so extensive that most or all mitochondria in the cell undergo MPT, causing depletion of cellular ATP (see Fig. 3-17). Degradative processes already outlined (e.g., oxidative and hydrolytic degradation of macromolecules and membranes as well as disintegration of intracellular solute and volume homeostasis) will go to completion, causing a complete failure in maintenance of cellular structure and functions and culminating in cell lysis or necrosis.


Figure 3-17. "Decision plan" on the fate of injured cell.

See the text for details. MPT = mitochondrial permeability transition; RO(N)S = reactive oxygen or nitrogen species.

An Alternative Outcome of MPT: Apoptosis The chemicals that adversely affect the cellular energy metabolism, Ca^{2+} homeostasis and redox state and ultimately cause necrosis, may also induce apoptosis, another form of demise. While the necrotic cell swells and lyses, the apoptotic cell shrinks; its nuclear and cytoplasmic materials condense, and then it breaks into membrane-bound fragments (apoptotic bodies) that are phagocytosed (Wyllie, 1997).

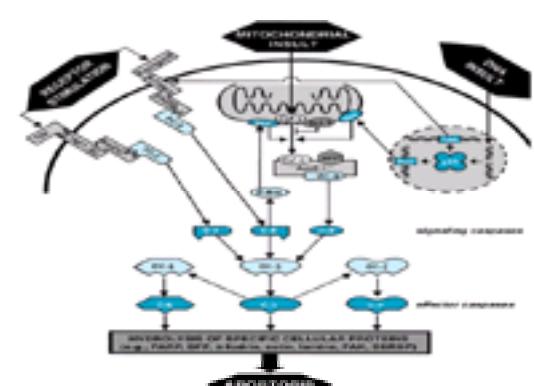
As discussed above, the multiple metabolic defects that a cell suffers in its way to necrosis are causal yet rather random in sequence. In contrast, the routes to apoptosis are ordered, involving cascade-like activation of catabolic processes that finally disassemble the cell. Many details of the apoptotic pathways have been uncovered in recent years, some of which are presented schematically in Fig. 3-16.


Figure 3-16. Apoptotic pathways initiated by mitochondrial insult, nuclear DNA insult and Fas or TNF receptor-1 stimulation.

The figure is a simplified scheme of three pathways to apoptosis. (1) Mitochondrial insult (see text) ultimately opens the permeability transition pore spanning both mitochondrial membranes and/or causes release of cytochrome c (Cyt c) from the mitochondria. Cyt c release is facilitated by Bax or Bid proteins and opposed by Bcl-2 protein. (2) DNA insult, especially double-strand breaks, activates p53 protein which increases the expression of Bax (that mediates Cyt c release) and the membrane receptor protein Fas. (3) Fas ligand or tumor necrosis factor binds to and activates their respective receptor, Fas and TNF1 receptor. These ligand-bound receptors and the released Cyt c interact with specific adapter proteins (i.e., FADD, RAIDD and Apaf-1) through which they proteolytically activate procaspases (PC) to active caspases (C). The latter in turn cleave and activate other proteins (e.g., the precursor of Bid, P-Bid) and PC-3, a main effector procaspase. The active effector caspase-3 activates other effector procaspases (PC-6, PC-7). Finally, C-3, C-6, and C-7 clip specific cellular proteins, whereby apoptosis occurs. These pathways are not equally relevant in all types of cells and other pathways, such as those employing TGF-b as an extracellular signaling molecule, and ceramide as an intracellular signaling molecule, also exist. DFF = DNA fragmentation factor; FAK = focal adhesion kinase; PARP = poly(ADP-ribose) polymerase; SREBP = sterol regulatory element binding protein.

It appears that most if not all chemical-induced cell death will involve the mitochondria, and the resulting mitochondrial dysfunction (such as Ca^{2+} accumulation, dissipation of DYm, overproduction of ROS/RNS) may ultimately trigger either necrosis or apoptosis, and that MPT is a crucial event in both. Another related event is release into the cytoplasm of cytochrome c (cyt c), a small hemoprotein that normally resides in the mitochondrial intermembrane space attached to the surface of inner membrane.

The significance of cyt c release is twofold (Cai et al., 1998): (1) As cyt c is the penultimate link in the mitochondrial electron transport chain, its loss will block ATP synthesis, increase formation of $O_2^{-•}$ (instead of O_2^{4-} as shown in Fig. 3-13), and potentially thrust the cell toward necrosis. (2) Simultaneously, the unleashed cyt c (and perhaps other proteins set free from the mitochondria) represents a signal or an initial link in the chain of events directing the cell to the apoptotic path (Fig. 3-16). Upon binding, together with ATP, to an adapter protein (Apaf-1), cyt c can induce proteolytic cleavage of the Apaf-1-bound latent procaspase-9 to active caspase-9.

Caspases are cysteine proteases (that is, they possess catalytically active cysteine) that clip proteins at specific asparagine residues (Nicholson and Thornberry, 1997). They reside in the cytoplasm in inactive forms, as procaspases, which are proteolytically converted to the active proteases. Some caspases (e.g., 2, 8, and 9) cleave and activate procaspases. Thereby these signaling caspases carry the activation wave to the so-called effector caspases (e.g., 3, 6, and 7), which clip specific cellular proteins, activating or inactivating them. It is the caspase-catalyzed hydrolysis of these specific proteins that accounts directly or indirectly for the morphologic and biochemical alterations in apoptotic cells. For example, proteolytic inactivation of PARP prevents futile DNA repair and wasting of ATP; hydrolytic activation of DNA fragmentation factor induces fragmentation of nuclear DNA; clipping of structural proteins (a-fodrin, actin, lamins) aids in disassembly of the cell; incapacitation of focal adhesion kinase (see Fig. 3-11) permits detachment of the cell from the extracellular matrix; and hydrolytic activation of sterol regulatory element–binding

proteins may contribute to accumulation of sterols and externalization of phosphatidylserine in the plasma membrane that identify the apoptotic cell to phagocytes.

The decisive mitochondrial events of cell death, i.e., MPT and release of cyt *c*, are controlled by the Bcl-2 family of proteins, which includes members that facilitate (e.g., Bax, Bad, Bid) and those that inhibit (e.g., Bcl-2, Bcl-XL) these processes. While the death-promoting members probably act directly in the mitochondrial membranes, their death-suppressor counterparts are thought to act predominantly by dimerizing with the death agonists and therefore neutralizing them. Thus, the relative amount of these antagonistic proteins functions as a regulatory switch between cell survival and death (Reed et al., 1998).

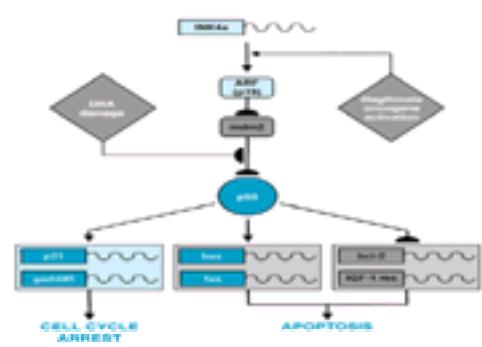
The proapoptotic Bax and Bid proteins also represent links whereby death programs initiated extramitochondrically, e.g., by DNA damage in the nucleus or by stimulation of Fas receptors at the cell surface, can engage the mitochondria into the apoptotic process (Green, 1998) (Fig. 3-16). DNA damage (evoked by ionizing and UV radiations, alkylating chemicals, doxorubicin (Adriamycin), and topoisomerase II inhibitors) induces stabilization and activation of p53 protein, a transcription factor, which increases expression of Bax protein (Bates and Vousden, 1998) (see also Fig. 3-25). As discussed further on, DNA damage is potentially mutagenic and carcinogenic, therefore apoptosis of cells with damaged DNA is an important self-defense of the body against oncogenesis. Furthermore, the antitumor drugs targeting the nuclear DNA exert their desirable toxic effects against tumor cells (and also their undesirable cytotoxic effects against rapidly dividing normal cells such as hematopoietic cells and small intestinal mucosal cells) by inducing apoptosis primarily via a p53-dependent mechanism. Stimulation of TNF receptor-1 or Fas can directly activate caspases, nevertheless Fas activation can also engage the mitochondria into the death program via caspase-mediated activation of Bid (Fig. 3-16). The Fas system is involved in cell-mediated cytotoxicity, as cytotoxic T lymphocytes express the Fas ligand that activates Fas in the membrane of potential target cells, such as those of the liver, heart, and the lung. The Fas system also mediates germ cell apoptosis in the testes of rodents exposed to mono-(2-ethylhexyl)phthalate or 2,5-hexanedione, the ultimate toxicant formed from hexane. These chemicals damage the microtubules in the Sertoli cells that normally nurse the germ cells. Unable to support the germ cells, Sertoli cells overexpress the Fas ligand to limit the number of germ cells (which upregulate their Fas receptor) by deleting them via apoptosis (Cohen et al., 1997; Lee et al., 1997).


Figure 3-25. The guardian of the genome: p53 tumor suppressor protein—its role and regulation.

The p53 protein is chiefly a gene transcription modulator. For example, it transactivates *p21* (or *waf1*) and *gadd45* genes whose products are inhibitors of cyclin–cyclin-dependent protein kinase complexes and arrest the cell cycle in G $_1$ and G$_2$ phases, respectively. p53 also transactivates the genes of pro-apoptotic proteins (e.g., bax and fas; see Fig. 3-16) and transrepresses the genes of anti-apoptotic proteins (e.g., bcl-2 and insulin-like growth factor-1 [IGF-1] receptor), whereby it promotes apoptosis. These (and other) p53-induced pro-apoptotic mechanisms may be cell specific, i.e., all are not necessarily occurring in the same cell at the same time.

The intracellular level and activity of p53 depends primarily on the presence of mdm2 protein, which inactivates p53 and promotes its proteosomal degradation. The influence of mdm2 on p53 may be disrupted by DNA damage (possibly via phosphorylation of p53) and by "illegitimate" oncogene activation. The latter results in overexpression of the ARF (or p19) protein, which in turn, binds to mdm2, releasing p53 from its inactivator mdm2. Both mechanisms thus stabilize p53 protein, thereby greatly increasing its abundance and activity.

By arresting division of cells with potentially mutagenic DNA damage and eliminating such cells, p53 protein counteracts neoplastic development. *p53*-null mice, like *ARF*-null mice, develop tumors with high incidence. Mutational inactivation of the p53 protein is thought to contribute to the carcinogenic effect of aflatoxin B $_1$, sunlight and cigarette smoke in humans. Overexpression of mdm2 can lead to constitutive inhibition of p53 and thereby promotes oncogenesis even if the *p53* gene is unaltered. See the text for more details.

Thus, apoptosis can be executed via multiple pathways, all involving caspase activation. The route preferred will depend among others on the initial insult (Fig. 3-16) as well as on the type and state of the cell. For example, T lymphocytes lacking the *Bax* gene can still undergo p53-dependent death in response to ionizing radiation, probably by increasing Fas expression (Fig. 3-16), whereas *Bax*-null fibroblasts cannot.

ATP Availability Determines the Form of Cell Death There are several common features in the process of apoptosis and necrosis. First of all, many xenobiotics—such as the hepatotoxin acetaminophen, 1,1-dichloroethylene, thioacetamide, and cadmium as well as the nephrotoxin ochratoxin—can cause both apoptosis and necrosis (Corcoran et al., 1994). Toxicants tend to induce apoptosis at low exposure levels or early after exposure at high levels, whereas they cause necrosis later at high exposure levels. In addition, induction of both forms of cell death by cytotoxic agents may involve similar metabolic disturbances and most importantly MPT (Lemasters et al., 1998; Kroemer et al., 1998; Quian et al., 1999), and blockers of the latter (e.g., cyclosporin A, Bcl-2 overexpression) prevent both apoptosis and necrosis. What determines, then, whether the injured cell undergoes apoptosis or necrosis—which, as emphasized further on, may have a significant impact on the surrounding tissue?

Recent findings suggest that the availability of ATP is critical in determining the form of cell death. In experimental models so different as Ca $^{2+}$-exposed hepatocytes, Fas-stimulated T lymphocytes, and HOOH-exposed endothelial cells, necrosis occurred instead of apoptosis when cells were depleted of ATP, but apoptosis took place rather than necrosis when ATP depletion was alleviated by providing substrates for ATP generation (Leist et al., 1997; Lemasters et al., 1998; Lelli et al., 1998).

Lemasters et al. (1998) used confocal microscopy to visualize mitochondria in cells exposed to an apoptogenic stimulus and found that MPT does not occur uniformly in all mitochondria. They proposed a model in which the number of mitochondria undergoing MPT (which probably depends on the degree of chemical exposure) determines the severity of cellular ATP depletion and, in turn, the fate of the cell. According to this model (Fig. 3-17), when only a few mitochondria develop MPT, they, and with them the proapoptotic signals (e.g., externalized cyt *c*), are removed by lysosomal autophagy. When MPT involves more mitochondria, the autophagic mechanism becomes overwhelmed and the released cyt *c* initiates caspase activation and apoptosis (Fig. 3-16). When MPT involves virtually all mitochondria, ATP becomes severely depleted for reasons discussed above. Lack of ATP prevents execution of the apoptotic program, which involves ATP-requiring steps, one of which is formation of the complex between Apaf-1, cyt *c*, and pocaspase-9 (Fig. 3-16). Then cytolysis occurs before the caspases come into action.

Induction of Cell Death by Unknown Mechanisms In addition to chemicals that ultimately injure mitochondria by disrupting oxidative phosphorylation and/or control of intracellular Ca^{2+}, there are toxicants that cause cell death by affecting other functions or structures primarily. Included here are (1) chemicals that directly damage the plasma membrane, such as lipid solvents, detergents, and venom-derived hydrolytic enzymes; (2) xenobiotics that damage the lysosomal membrane, such as aminoglycoside antibiotics and hydrocarbons binding to a $_{2u}$-globulin; (3) toxins that destroy the cytoskeleton, such as the microfilamental toxins phalloidin and cytochalasins and the microtubular toxins colchicine and 2,5-hexanedione; (4) the protein phosphatase inhibitor hepatotoxin microcystin, which causes hyperphosphorylation of microfilaments and other cellular proteins (Toivola and Eriksson, 1999); and (5) toxins that disrupt protein synthesis, such as a-amanitin and ricin.

The events leading to cell death after exposure to these chemicals are generally unknown. It is likely that cell death caused by these chemicals is ultimately mediated by impairment of oxidative phosphorylation, sustained elevation of intracellular Ca $^{2+}$, and/or overproduction of ROS/RNS and that it takes the form of necrosis if these processes are abrupt but apoptosis if they are protracted. For example, direct injury of the plasma membrane would lead rapidly to increased intracellular Ca $^{2+}$ levels. Neurofilamental toxins that block axonal transport cause energy depletion in the distal axonal segment. More subtle changes may also underlie the cell death. For

example, paclitaxel, an antimicrotubule agent, purportedly causes hyperphosphorylation and inactivation of Bcl-2, which favors opening the MPT pore (Fan, 1999).

Impairment of External Cellular Maintenance Toxicants also may interfere with cells that are specialized to provide support to other cells, tissues, or the whole organism. Chemicals acting on the liver illustrate this type of toxicity. Hepatocytes produce and release into the circulation a number of proteins and nutrients. They remove cholesterol and bilirubin from the circulation, converting them into bile acids and bilirubin glucuronides, respectively, for subsequent excretion into bile. Interruption of these processes may be harmful to the organism, the liver, or both. For example, inhibition of the hepatic synthesis of coagulation factors by coumarins does not harm the liver but may cause death by hemorrhage (Hardman et al., 1995). This is the mechanism of the rodenticidal action of warfarin. In the fasting state, inhibitors of hepatic gluconeogenesis such as hypoglycin may be lethal by limiting the supply of glucose to the brain. Similarly, Reye's syndrome, which is viewed as a hepatic mitochondrial injury caused by a combination of a viral disease (which may induce hepatic NOS) and intake of salicylate (which provokes MPT) (Fromenty and Pessayre, 1997; Lemasters et al., 1998), causes not only hepatocellular injury but also severe metabolic disturbances (hypoglycemia, hyperammonemia) that affect other organs as well. Chemical interference with the b-oxidation of fatty acids or the synthesis, assembly, and secretion of lipoproteins overloads the hepatocytes with lipids, causing hepatic dysfunction (Fromenty and Pessayre, 1997). a-Naphthylisothiocyanate causes separation of the intercellular tight junctions that seal bile canaliculi (Knell et al., 1987), impairing biliary secretion and leading to the retention of bile acids and bilirubin; this adversely affects the liver as well as the entire organism.

STEP 4 REPAIR OR DYSREPAIR

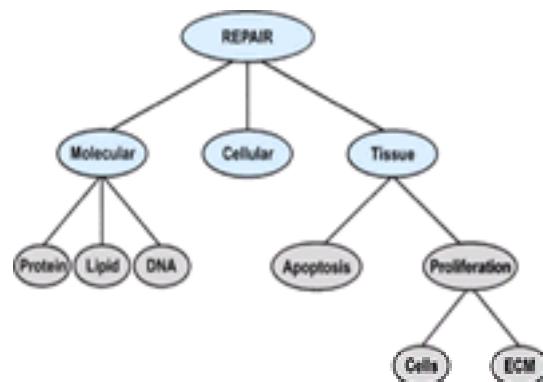
The fourth step in the development of toxicity is inappropriate repair (Fig. 3-1). As noted previously, many toxicants alter macromolecules, which, if not repaired, cause damage at higher levels of the biological hierarchy in the organism. Because repair influences the progression of toxic lesions, mechanisms of repair are categorized in Fig. 3-18 and discussed below in detail.


Figure 3-18. Repair mechanisms.

Dysfunction of these mechanisms results in dysrepair, the fourth step in the development of numerous toxic injuries. ECM = extracellular matrix.

Molecular Repair

Damaged molecules may be repaired in different ways. Some chemical alterations, such as oxidation of protein thiols and methylation of DNA, are simply reversed. Hydrolytic removal of the molecule's damaged unit or units and insertion of a newly synthesized unit or units often occur with chemically altered DNA and peroxidized lipids. In some instances, the damaged molecule is totally degraded and resynthesized. This process is time-consuming but unavoidable in cases such as the regeneration of cholinesterases after organophosphate intoxication.

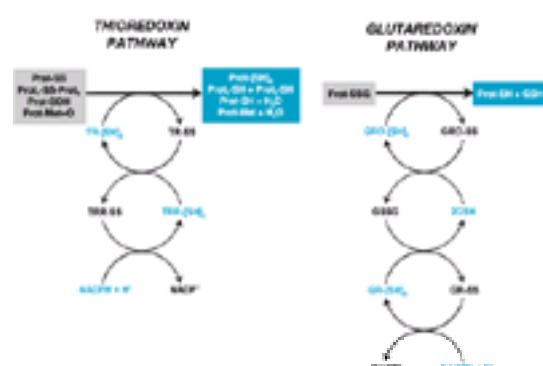
Repair of Proteins Thiol groups are essential for the function of numerous proteins, such as receptors, enzymes, cytoskeletal proteins, and TFs. Oxidation of protein thiols (Prot-SHs) to protein disulfides (Prot-SS, Prot$_1$-SS-Prot$_2$), protein-glutathione mixed disulfides, and protein sulfenic acids (Prot-SOH) as well as oxidation of methionine in proteins to methionine sulfoxide can be reversed by enzymatic reduction (Fernando et al., 1992; Gravina and Mieyal, 1993; Maskovitz et al., 1999) (Fig. 3-19). The endogenous reductants are thioredoxin and glutaredoxin, small, ubiquitous proteins with two redox-active cysteines in their active centers. Because the catalytic thiol groups in these proteins are oxidized, they are recycled by reduction with NADPH generated by glucose-6-phosphate dehydrogenase and 6-phosphogluconate dehydrogenase in the pentose phosphate pathway.


Figure 3-19. Repair of proteins oxidized at their thiol groups.

Protein disulfides (Prot-SS, Prot$_1$-SS-Prot$_2$), protein sulfenic acids (Prot-SOH) and protein methionine sulfoxides (Prot-Met=O) are reduced by thioredoxin (TR-[SH]$_2$) with methionine sulfoxide reductase catalyzing the latter process. Protein-glutathione mixed disulfides (Prot-SSG) are reduced by glutaredoxin (GRO-[SH]$_2$), which is also called thioltransferase. The figure also indicates how TR-[SH]$_2$ and GRO-[SH]$_2$ are regenerated from their disulfides (TR-SS and GRO-SS, respectively). In the mitochondria, TR-SS also can be regenerated by the dithiol dihydrolipoic acid, a component of the pyruvate- and a-ketoglutarate dehydrogenase complexes. GSH = glutathione; GSSG = glutathione disulfide; GR-[SH]$_2$ and GR-SS = glutathione reductase (dithiol and disulfide forms, respectively); TRR-[SH]$_2$ and TRR-SS = thioredoxin reductase (dithiol and disulfide forms, respectively).

Repair of oxidized hemoglobin (methemoglobin) occurs by means of electron transfer from cytochrome b_5, which is then regenerated by a NADH-dependent cytochrome b_5 reductase (also called methemoglobin reductase). Soluble intracellular proteins are susceptible to denaturation by physical or chemical insults. Molecular chaperones such as the heat-shock proteins are synthesized in large quantities in response to protein denaturation and are important in the refolding of altered proteins (Morimoto, 1993). Damaged proteins can be eliminated also by proteolytic degradation. For example, the immunogenic trifluoroactylated proteins that are formed in the liver during halothane anesthesia are degraded by lysosomal proteases (Cohen et al., 1997). Although the ATP/ubiquitin–dependent proteolytic system is specialized in controlling the level of regulatory proteins (e.g., p53, IkB, cyclins), it can also eliminate damaged or mutated intracellular proteins (Hershko and Ciechanover, 1998). These proteins are first conjugated with ubiquitin, allowing their recognition by proteasomes—large protease complexes in the cytosol that proteolytically degrade them. Removal of damaged and aggregated proteins is especially critical in the eye lens for maintenance of its transparency. Erythrocytes have ATP-independent, nonlysosomal proteolytic enzymes that rapidly and selectively degrade proteins denatured by HO $^•$ (Davies, 1987).

Repair of Lipids Peroxidized lipids are repaired by a complex process that operates in concert with a series of reductants as well as with glutathione peroxidase and reductase (Fig. 3-20). Phospholipids containing fatty acid hydroperoxides are preferentially hydrolyzed by phospholipase A2, with the peroxidized fatty acids replaced

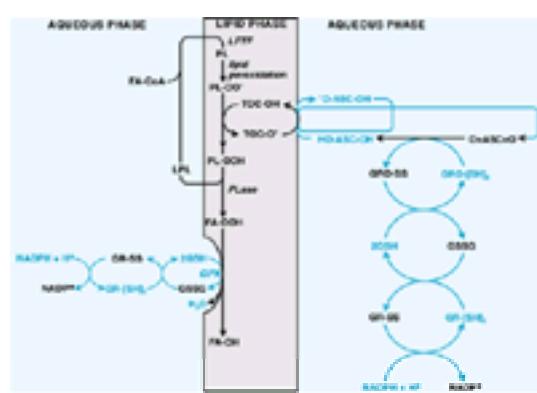
by normal fatty acids (van Kuijk et al., 1987). Again, NADPH is needed to "repair" the reductants that are oxidized in the process.


Figure 3-20. Repair of peroxidized lipids.

Phospholipid peroxyl radicals (PL-OO$^{\bullet}$) formed as a result of lipid peroxidation (Fig. 3-9) may abstract hydrogen from alpha-tocopherol (TOC-OH) and yield phospholipid hydroperoxide (PL-OOH). From the latter, the fatty acid carrying the hydroperoxide group is eliminated via hydrolysis catalyzed by phospholipase (PLase), yielding a fatty acid hydroperoxide (FA-OOH) and a lysophospholipid (LPL). The former is reduced to a hydroxy-fatty acid (FA-OH) by glutathione peroxidase (GPX), utilizing glutathione (GSH), whereas the latter is reacylated to phospholipid (PL) by lysophosphatide fatty acyl-coenzyme A transferase (LFTF), utilizing long-chain fatty acid-coenzyme A (FA-CoA). The figure also indicates regeneration of TOC-OH by ascorbic acid (HO-ASC-OH), regeneration of ascorbic acid from dehydroascorbic acid (O=ASC=O) by glutaredoxin (GRO-[SH]$_2$), and reduction of the oxidized glutaredoxin (GRO-SS) by GSH. Oxidized glutathione (GSSG) is reduced by glutathione reductase (GR-[SH]$_2$), which is regenerated from its oxidized form (GR-SS) by NADPH, the ultimate reductant. Most NADPH is produced during metabolism of glucose via the pentose phosphate shunt. TOC-O$^{\bullet}$ = tocopheroxyl radical; $^{\bullet}$O-ASC-OH = ascorbyl radical.

Repair of DNA Despite its high reactivity with electrophiles and free radicals, nuclear DNA is remarkably stable, in part because it is packaged in chromatin and because several repair mechanisms are available to correct alterations (Sancar and Sancar, 1988). The mitochondrial DNA, however, lacks histones and efficient repair mechanisms and therefore is more prone to damage.

Direct Repair Certain covalent DNA modifications are directly reversed by enzymes such as DNA photolyase, which cleaves adjacent pyrimidines dimerized by UV light. Inasmuch as this chromophore-equipped enzyme uses the energy of visible light to correct damage, its use is restricted to light-exposed cells. Minor adducts, such as methyl groups, attached to the O^6 position of guanine are removed by O^6-alkylguanine-DNA-alkyltransferase (Pegg and Byers, 1992). While repairing the DNA, this alkyltransferase destroys itself, transferring the adduct onto one of its cysteine residues. This results in its inactivation and eventual degradation. Thus, like glutathione, which is depleted during detoxication of electrophiles, O^6-alkylguanine-DNA-alkyltransferase is consumed during the repair of DNA.

Excision Repair Base excision and nucleotide excision are two mechanisms for removing damaged bases from DNA (Chap. 8 and Chap. 9). Lesions that do not cause major distortion of the helix typically are removed by base excision, in which the altered base is recognized by a relatively substrate-specific DNA-glycosylase that hydrolyzes the N-glycosidic bond, releasing the modified base and creating an apurinic or apyrimidinic (AP) site in the DNA. For example, 8-hydroxyguanine (8-OH-Gua), a major mutagenic product of oxidative stress, is removed from the DNA by specific 8-OH-Gua DNA glycosylase. The AP site is recognized by the AP endonuclease, which hydrolyzes the phosphodiester bond adjacent to the abasic site. After its removal, the abasic sugar is replaced with the correct nucleotide by a DNA polymerase and is sealed in place by a DNA ligase.

Bulky lesions such as adducts produced by aflatoxins or aminofluorene derivatives and dimers caused by UV radiation are removed by nucleotide-excision repair. An ATP-dependent nuclease recognizes the distorted double helix and excises a number of intact nucleotides on both sides of the lesion together with the one containing the adduct. The excised section of the strand is restored by insertion of nucleotides into the gap by DNA polymerase and ligase, using the complementary strand as a template. This phenomenon, designated "unscheduled DNA synthesis," can be detected by the appearance of altered deoxynucleosides in urine. Excision repair has a remarkably low error rate of less than 1 mistake in 10^9 bases repaired.

Poly(ADP-ribose)polymerase (PARP) appears to be an important contributor in excision repair. Upon base damage or single-strand break, PARP binds to the injured DNA and becomes activated. The active PARP cleaves NAD$^+$ to use the ADP-ribose moiety of this cofactor for attaching long chains of polymeric ADP-ribose to nuclear proteins, such as histones. Because one ADP-ribose unit contains two negative charges, the poly(ADP-ribosyl)ated proteins accrue negativity and the resultant electrorepulsive force between the negatively charged proteins and DNA causes decondensation of the chromatin structure. It is hypothesized that PARP-mediated opening of the tightly packed chromatin allows the repair enzymes to access the broken DNA and fix it. Thereafter, poly(ADP-ribose) glycohydrolase gains access to the nucleus from its perinuclear localization and reverses the PARP-mediated modification of nuclear proteins (D'Amours et al., 1999). Other features of PARP that are relevant in toxicity—such as destruction of PARP by caspases during apoptosis as well as the significance of NAD$^+$ (and consequently ATP) wasting by PARP in necrosis—have been discussed earlier in this chapter.

Surveillance for damage by repair systems is not equally vigilant on the two DNA strands, and repair rates are not uniform for all genes (Scicchitano and Hanawalt, 1992). Actively transcribed genes are more rapidly repaired than are nontranscribed genes, and lesions in the transcribed strand that block RNA polymerase are more rapidly repaired than are lesions in the nontranscribed or coding strand. A protein termed *transcription-repair coupling factor* in *Escherichia coli* recognizes and displaces the RNA polymerase that has stalled at a DNA lesion, allowing access by the excision repair enzymes to the damage (Selby and Sancar, 1993).

Recombinational (or Postreplication) Repair Recombinational repair occurs when the excision of a bulky adduct or an intrastrand pyrimidine dimer fails to occur before DNA replication begins (Sancar and Sancar, 1988). At replication, such a lesion prevents DNA polymerase from polymerizing a daughter strand along a sizable stretch of the parent strand that carries the damage. The replication results in two homologous ("sister") yet dissimilar DNA duplexes: one that has a large postreplication gap in its daughter strand and an intact duplex synthesized at the opposite leg of the replication fork. This intact sister duplex is utilized to complete the postreplication gap in the damaged sister duplex. This is accomplished by recombination ("crossover") of the appropriate strands of the two homologous duplexes. After separation, the sister duplex that originally contained the gap carries in its daughter strand a section originating from the parent strand of the intact sister, which in turn carries in its parent strand a section originating from the daughter strand of the damaged sister. This strand recombination explains the phenomenon of "sister chromatid exchange," which is indicative of DNA damage corrected by recombinational repair. This process also repairs double breaks, which can also be repaired by the so-called DNA nonhomologous end-joining system that ligates DNA ends and employs several proteins including DNA-dependent protein kinase. A combination of excision and recombinational repairs occurs in restoration of DNA with interstrand cross-links. The process of recombinational repair at the molecular level has been partially characterized in *E. coli*. Much less is known about this process in eukaryotes.

Cellular Repair A Strategy in Peripheral Neurons

Repair of damaged cells is not a widely applied strategy in overcoming cellular injuries. In most tissues, injured cells die, with the survivors dividing to replace the lost cells. A notable exception is nerve tissue, because mature neurons have lost their ability to multiply. In peripheral neurons with axonal damage, repair does occur and requires macrophages and Schwann cells. Macrophages remove debris by phagocytosis and produce cytokines and growth factors, which activate Schwann cells to proliferate and transdifferentiate from myelinating operation mode into a growth-supporting mode. Schwann cells play an indispensable role in promoting axonal regeneration by increasing their synthesis of cell adhesion molecules (e.g., N-CAM), by elaborating extracellular matrix proteins for base membrane construction, and by producing an array of neurotrophic factors (e.g., nerve growth factor, glial–cell line–derived growth factor) and their receptors (Fu and Gordon, 1997). While comigrating with the regrowing axon, Schwann cells physically guide as well as chemically lure the axon to reinnervate the target cell.

In the mammalian central nervous system, axonal regrowth is prevented by growth inhibitory glycoproteins (e.g., NI 35, myelin-associated glycoprotein) and chondroitin sulfate proteoglycans produced by the oligodendrocytes and by the scar produced by astrocytes (Johnson, 1993). Thus, damage to central neurons is irreversible but is compensated for in part by the large number of reserve nerve cells that can take over the functions of lost neurons. For example, in Parkinson's

disease, symptoms are not observed until there is at least an 80 percent loss of nigrostriatal neurons.

Tissue Repair

In tissues with cells capable of multiplying, damage is reversed by deletion of the injured cells and regeneration of the tissue by proliferation. The damaged cells are eliminated by apoptosis or necrosis.

Apoptosis: An Active Deletion of Damaged Cells Apoptosis initiated by cell injury can be regarded as tissue repair for two reasons, the first of which is that it may intercept the process leading to necrosis, as discussed earlier (see Fig. 3-17). Necrosis is a more harmful sequala than apoptosis for the tissue in which the injured cell resides. A cell destined for apoptosis shrinks; its nuclear and cytoplasmic materials condense, and then it breaks into membrane-bound fragments (apoptotic bodies) that are phagocytosed (Bursch et al., 1992). During necrosis, cells and intracellular organelles swell and disintegrate with membrane lysis. While apoptosis is orderly, necrosis is a disorderly process that ends with cell debris in the extracellular environment. The constituents of the necrotic cells attract aggressive inflammatory cells, and the ensuing inflammation amplifies cell injury (see further on). With apoptosis, dead cells are removed without inflammation. Second, apoptosis may intercept the process leading to neoplasia by eliminating the cells with potentially mutagenic DNA damage. This function of apoptosis is discussed in more detail in the final section of this chapter.

It must be emphasized, however, that apoptosis of damaged cells has a full value as a tissue repair process only for tissues that are made up of constantly renewing cells (e.g., the bone marrow, the respiratory and gastrointestinal epithelium, and the epidermis of the skin), or of conditionally dividing cells (e.g., hepatic and renal parenchymal cells), because in these tissues the apoptotic cells are readily replaced. The value of apoptosis as a tissue repair strategy is markedly lessened in organs containing nonreplicating and nonreplaceable cells, such as the neurons, cardiac muscle cells, and female germ cells, because deletion of such cells, if extensive, can cause a deficit in the organ's function.

Proliferation: Regeneration of Tissue Tissues are composed of various cells and the extracellular matrix. Tissue elements are anchored to each other by transmembrane proteins. Cadherins allow adjacent cells to adhere to one other, whereas connexins connect neighboring cells internally by association of these proteins into tubular structures (gap junctions). Integrins link cells to the extracellular matrix. Therefore, repair of injured tissues involves not only regeneration of lost cells and the extracellular matrix but also reintegration of the newly formed elements. In parenchymal organs such as liver, kidney, and lung, various types of cells are involved in the process of tissue restoration. Nonparenchymal cells of mesenchymal origin residing in the tissue, such as resident macrophages and endothelial cells, and those migrating to the site of injury, such as blood monocytes, produce factors that stimulate parenchymal cells to divide and stimulate some specialized cells (e.g., the stellate cells in the liver) to synthesize extracellular matrix molecules.

Replacement of Lost Cells by Mitosis Soon after injury, cells adjacent to the damaged area enter the cell division cycle (Fig. 3-21). Enhanced DNA synthesis is detected experimentally as an increase in the labeling index, which is the proportion of cells that incorporate administered ^{3}H-thymidine or bromodeoxyuridine into their nuclear DNA during the S phase of the cycle. Also, mitotic cells can be observed microscopically. As early as 2 to 4 h after administration of a low dose of carbon tetrachloride to rats, the mitotic index in the liver increases dramatically, indicating that cells already in the G$_2$ phase progress rapidly to the M phase. The mitotic activity of the hepatocytes culminates at 36 to 48 h, after a full transit through the cycle, indicating that quiescent cells residing in G$_0$ enter and progress to mitosis (M). Peak mitosis of nonparenchymal cells occurs later, after activation and replication of parenchymal cells (Burt, 1993). In some tissues, such as intestinal mucosa and bone marrow, stem cells first divide to provide self-renewal and then differentiate to replace more mature cells lost through injury. Stem cells are also located in the liver, in the bile ductules. In toxic liver injury, when hepatocyte replication is impaired, the stem cells proliferate to form the so-called oval cells, which can differentiate into both hepatocytes and biliary epithelial cells (Fausto, 2000). In an ozone-exposed lung, the nonciliated Clara cells and type II pneumocytes undergo mitosis and terminal differentiation to replace, respectively, the damaged ciliated bronchial epithelial cells and type I pneumocytes (Mustafa 1990).

Sequential changes in gene expression occur in the cells that are destined to divide. Early after injury, intracellular signaling turns on, as indicated by activation of protein kinases (e.g., the MAP kinase homolog JNK) as well as transcription factors (e.g., NF-kB, AP-1, C/EBP; see Fig. 3-11), and expression of numerous genes are increased (Fausto, 2000). Among these so-called immediate-early genes are those that code for transcription factors such as c-*fos*, c-*jun* and c-*myc* as well as cytokine-like secreted proteins (Mohn et al., 1991; Zawaski et al., 1993). These primary gene products amplify the initial gene-activation process by stimulating other genes directly or through cell surface receptors and the coupled transducing networks (Fausto and Webber, 1993). A few hours later the so-called delayed-early genes are expressed, such as the Bcl-X$_L$,which encodes an antiapoptotic protein from the Bcl-2 family (see Fig. 3-16), followed by the genes whose products regulate the cell-division cycle (Fausto, 2000). Not only genes for the cell cycle accelerator proteins (e.g., cyclin D and mdm2; see Fig. 3-24), but also genes whose products decelerate the cell cycle (e.g., p53 and p21; see Fig. 3-24) become temporarily overexpressed, suggesting that this duality keeps tissue regeneration precisely regulated. Thus, genetic expression is reprogrammed so that DNA synthesis and mitosis gain priority over specialized cellular activities. For example, as a result of dedifferentiation, regenerating hepatocytes underexpress cytochrome P450 and hepatic stellate cells cease to accumulate fat and vitamin A.

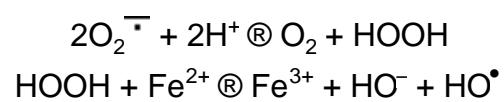
It has been speculated that the regenerative process is initiated by the release of chemical mediators from damaged cells. The nonparenchymal cells, such as resident macrophages and endothelial cells, are receptive to these chemical signals and produce a host of secondary signaling molecules, cytokines, and growth factors that promote and propagate the regenerative process (Fig. 3-22). The cytokines TNF-a and IL-6 purportedly promote transition of the quiescent cells into cell cycle ("priming"), whereas the growth factors, especially the hepatocyte growth factor (HGF) and transforming growth factor-a (TGF-a), initiate the progression of the "primed" cells in the cycle toward mitosis (Fausto, 2000). Despite its name, neither the formation nor the action of HGF is restricted to the liver. It is produced by resident macrophages and endothelial cells of various organs—including liver, lung, and kidney—and in a paracrine manner activates receptors on neighboring parenchymal cells (Fig. 3-22). In rats intoxicated with carbon tetrachloride, the synthesis of HGF in hepatic and renal nonparenchymal cells increases markedly (Noji et al., 1990) and HGF levels in blood rise rapidly (Lindroos et al., 1991). The communication between parenchymal and nonparenchymal cells during tissue repair is mutual. For example, TGF-a, a potent mitogen produced by regenerating hepatocytes, acts both as an autocrine and a paracrine mediator on liver cells as well as on adjacent nonparenchymal cells (Fig. 3-22).

Besides mitosis, cell migration also significantly contributes to restitution of certain tissues. The mucosa of the gastrointestinal tract is an important barrier; therefore replacement of mortally injured epithelial cells is an urgent need. Cells of the residual epithelium rapidly migrate to the site of injury as well as elongate and thin to reestablish the continuity of the surface even before this could be achieved by cell replication. Mucosal repair is dictated not only by growth factors and cytokines operative in tissue repair elsewhere but also by specific factors such as trefoil peptides that are associated with the mucous layer of the gastrointestinal tract and become overexpressed at sites of mucosal injury (Podolsky, 1999).

Replacement of the Extracellular Matrix The extracellular matrix is composed of proteins, glycosaminoglycans, and the glycoprotein and proteoglycan glycoconjugates (Gressner, 1992). In liver, these molecules are synthesized by stellate or fat storing cells located in the space of Disse, between the hepatic sinusoid and the hepatocytes (Fig. 3-22). The stellate cells become activated during liver regeneration, undergoing mitosis and major phenotypic changes. The latter changes include not only increased synthesis and secretion of extracellular matrix constituents but also loss of fat and vitamin A content and expression of actin. Thus, resting stellate cells become transdifferentiated into myofibroblast-like contractile and secretory cells. Activation of stellate cells is mediated chiefly by two growth factors—platelet-derived growth factor (PDGF) and transforming growth factor-b (TGF-b) (Fig. 3-22). Both may be released from platelets (that accumulate and degranulate at sites of injury) and later from the activated stellate cells themselves. The main sources of TGF-b, however, are the neighboring tissue macrophages residing in the hepatic sinusoids (Gressner, 1992). A dramatic increase in TGF-b mRNA levels in Kupffer cells is observed with in situ hybridization after carbon tetrachloride–induced hepatic necrosis (Burt, 1993). Proliferation of stellate cells is induced by the potent mitogen PDGF, whereas TGF-b acts on the stellate cells to stimulate the synthesis of extracellular matrix components, including collagens, fibronectin, tenascin, and proteoglycans. This effect of TGF-b is mediated through activation of JNK (a MAPK homolog) and not through the transcription factor Smad proteins, that relay the signal for the anti-proliferative and pro-apoptotic effects of TGF-b (see Fig. 3-11). TGF-b also plays a central role in extracellular matrix formation in other tissues. In the kidney and the lung, for example, TGF-b targets the mesangial cells and the septal fibroblasts, respectively (Border and Ruoslahti, 1992). Remodeling of the extracellular matrix is aided by matrix metalloproteinases, which hydrolyase specific components of the matrix, as well as by tissue inhibitors of matrix metalloproteinases. The former group of these proteins originates from various types of nonparenchymal cells, including inflammatory cells; however, their inhibitors are mainly produced by stellate cells (Arthur et al., 1999).

The way in which tissue regeneration is terminated after repair is unclear, but the gradual dominance of TGF-b, which is a potent antimitogen and apoptogen, over mitogens is a contributing factor in the termination of cell proliferation. Extracellular matrix production may be halted by products of the proliferative response that bind and inactivate TGF-b. The proteoglycan decorin and the positive acute phase protein alpha$_2$-macroglobulin are examples of such products (Gressner, 1992).

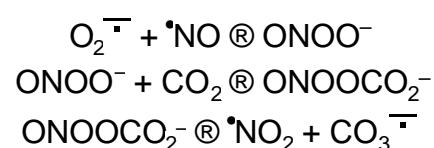
Side Reactions to Tissue Injury In addition to mediators that aid in the replacement of lost cells and the extracellular matrix, resident macrophages and endothelial cells activated by cell injury also produce other mediators that induce ancillary reactions with uncertain benefit or harm tissues (Fig. 3-22). Such reactions include

inflammation, altered production of acute-phase protein, and generalized reactions such as fever.


Inflammation Cells and Mediators Alteration of the microcirculation and accumulation of inflammatory cells are the hallmarks of inflammation. These processes are largely initiated by resident macrophages secreting cytokines such as TNF-a and interleukin-1 (IL-1) in response to tissue damage (Baumann and Gauldie, 1994) (Fig. 3-22). These cytokines, in turn, stimulate neighboring stromal cells, such as the endothelial cells and fibroblasts, to release mediators that induce dilation of the local microvasculature and cause permeabilization of capillaries. Activated endothelial cells also facilitate the egress of circulating leukocytes into the injured tissue by releasing chemoattractants and expressing cell-adhesion molecules, which are cell surface glycoproteins (Jaeschke, 1997). One group of cell-adhesion molecules, called selectins, located on the membrane of endothelial cells, interact with their ligands on the surface of leukocytes, thereby slowing down the flow of these cells and causing them to "roll" on the capillary surface. Subsequently a stronger interaction (adhesion) is established between the endothelial cells and leukocytes with participation of intercellular adhesion molecules (e.g., ICAM-1) expressed on the endothelial cell membrane and integrins expressed on the membrane of leukocytes. This interaction is also essential for the subsequent transendothelial migration of leukocytes. This is facilitated by gradients of chemoattractants that induce expression of leukocyte integrins. Chemoattractants originate from various stromal cells and include chemotactic cytokines (or chemokines), such as the monocyte chemotactic protein-1 (MCP-1) and IL-8 (whose rat homolog is the cytokine-induced neutrophil chemoattractant or CINC), as well as lipid-derived compounds, such as platelet-activating factor (PAF) and leukotriene B $_4$ (LTB$_4$). Ultimately all types of cells in the vicinity of injury express ICAM-1, thus promoting leukocyte invasion; the invading leukocytes also synthesize mediators, thus propagating the inflammatory response. Production of most inflammatory mediators is induced by signaling, turned on by TNF-a and IL-1, which results in activation of transcription factors, notably NF-kB and C/EBP (Poli, 1998) (see Fig. 3-11). Genes of many of the proteins mentioned above (e.g., selectins, ICAM-1, MCP-1, IL-8) and below (e.g., inducible nitric oxide synthase, acute phase proteins) as well as the genes of TNF-a and IL-1 themselves contain binding sites for the NF-kB (Lee and Burckart, 1998).

Inflammation Produces Reactive Oxygen and Nitrogen Species Macrophages, as well as leukocytes, recruited to the site of injury undergo a respiratory burst, producing free radicals and enzymes (Weiss and LoBuglio, 1982) (Fig. 3-22). Free radical are produced in the inflamed tissue in three ways, each of which involves a specific enzyme: NAD(P)H oxidase, nitric oxide synthase, or myeloperoxidase.

During the respiratory burst, membrane-bound NAD(P)H oxidase is activated in both macrophages and granulocytes and produces superoxide anion radical ($O_2^{\cdot-}$) from molecular oxygen:

$$NAD(P)H + 2O_2 \circledR NAD(P)^+ + H^+ + 2O_2^{\cdot-}$$


The $O_2^{\cdot-}$ can give rise to the hydroxyl radical (HO$^{\cdot}$) in two sequential steps: The first is spontaneous or is catalyzed by superoxide dismutase, and the second, the Fenton reaction, is catalyzed by transition metal ions (see also Fig. 3-4):

$$2O_2^{\cdot-} + 2H^+ \circledR O_2 + HOOH$$
$$HOOH + Fe^{2+} \circledR Fe^{3+} + HO^- + HO^{\cdot}$$

Macrophages, but not granulocytes, generate another cytotoxic free radical, nitric oxide ($^{\cdot}NO$). This radical is produced from arginine by nitric oxide synthase (Wang et al., 1993), which is inducible in macrophages by bacterial endotoxin and the cytokines IL-1 and TNF:

$$L\text{-arginine} + O_2 \circledR L\text{-citrulline} + {}^{\cdot}NO$$

Subsequently, $O_2^{\cdot-}$ and $^{\cdot}NO$, both of which are products of activated macrophages, can react with each other, yielding peroxynitrite anion; upon reaction with carbon dioxide, this decays into two radicals, nitrogen dioxide and carbonate anion radical (Fig. 3-4):

$$O_2^{\cdot-} + {}^{\cdot}NO \circledR ONOO^-$$
$$ONOO^- + CO_2 \circledR ONOOCO_2^-$$
$$ONOOCO_2^- \circledR {}^{\cdot}NO_2 + CO_3^{\cdot-}$$

Granulocytes, but not macrophages, discharge the lysosomal enzyme myeloperoxidase into engulfed extracellular spaces, the phagocytic vacuoles (Wang et al., 1993). Myeloperoxidase catalyzes the formation of hypochlorous acid (HOCl), a powerful oxidizing agent, from hydrogen peroxide (HOOH) and chloride ion:

$$HOOH + H^+ + Cl^- \circledR HOH + HOCl$$

Like HOOH, HOCl can form HO$^{\cdot}$ as a result of electron transfer from Fe^{2+} or from $O_2^{\cdot-}$ to HOCl:

$$HOCl + O_2^{\cdot-} \circledR O_2 + Cl^- + HO^{\cdot}$$

All these reactive chemicals, as well as the discharged lysosomal proteases, are destructive products of inflammatory cells. Although these chemicals exert antimicrobial activity at the site of microbial invasion, at the site of toxic injury they can damage the adjacent healthy tissues and thus contribute to propagation of tissue injury (see "Tissue Necrosis," below). Moreover, in some chemically induced injuries, inflammation plays the leading role. For example, a-naphthyl-isothiocyanate (ANIT), a cholestatic chemical, causes neutrophil- dependent hepatocellular damage. ANIT apparently acts on bile duct epithelial cells, causing them to release chemoattractants for neutrophil cells, which upon invading the liver, injure hepatocytes (Hill et al., 1999). Kupffer cell activation, TNF-a release, and subsequent inflammation are also prominent and causative events in galactosamine-induced liver injury in rats (Stachlewitz et al., 1999).

Altered Protein Synthesis: Acute-Phase Proteins Cytokines released from macrophages and endothelial cells of injured tissues also alter protein synthesis, predominantly in the liver (Baumann and Gauldie, 1994) (Fig. 3-18). Mainly IL-6 but also IL-1 and TNF act on cell surface receptors and increase or decrease the transcriptional activity of genes encoding certain proteins called positive and negative acute-phase proteins, respectively, utilizing primarily the transcription factors NF-kB, C/EBP, and STAT (Poli, 1998; see Fig. 3-12). Many of the hepatic acute-phase proteins, such as C-reactive protein, are secreted into the circulation, and their elevated levels in serum are diagnostic of tissue injury, inflammation, or neoplasm. Increased sedimentation of red blood cells, which is also indicative of these conditions, is due to enrichment of blood plasma with positive acute-phase proteins such as fibrinogen.

Apart from their diagnostic value, positive acute-phase proteins may play roles in minimizing tissue injury and facilitating repair. For example, many of them, such as alpha$_2$-macroglobulin and alpha$_1$-antiprotease, inhibit lysosomal proteases released from the injured cells and recruited leukocytes. Haptoglobin binds hemoglobin in blood, metallothionein complexes metals in the cells, heme oxygenase oxidizes heme to biliverdin, and opsonins facilitate phagocytosis. Thus, these positive acute-phase proteins may be involved in the clearance of substances released upon tissue injury.

Negative acute-phase proteins include some plasma proteins, such as albumin, transthyretin, and transferrin, as well as several forms of cytochrome P450 and glutathione *S*-transferase (Buetler, 1998). Because the latter enzymes play important roles in the toxication and detoxication of xenobiotics, the disposition and toxicity of chemicals may be altered markedly during the acute phase of tissue injury.

Although the acute-phase response is phylogenetically preserved, some of the acute-phase proteins are somewhat species-specific. For example, during the acute phase of tissue injury or inflammation, C-reactive protein and serum amyloid A levels dramatically increase in humans but not in rats, whereas the concentrations of alpha$_1$-acid glycoprotein and alpha$_2$-macroglobulin increase markedly in rats but only moderately in humans.

Generalized Reactions Cytokines released from activated macrophages and endothelial cells at the site of injury also may evoke neurohormonal responses. Thus IL-1, TNF, and IL-6 alter the temperature set point of the hypothalamus, triggering fever. IL-1 possibly also mediates other generalized reactions to tissue injury, such as hypophagia, sleep, and "sickness behavior" (Rothwell, 1991). In addition, IL-1 and IL-6 act on the pituitary to induce the release of ACTH, which in turn stimulates

the secretion of cortisol from the adrenals. This represents a negative feedback loop because corticosteroids inhibit cytokine gene expression.

When Repair Fails

Although repair mechanisms operate at molecular, cellular, and tissue levels, for various reasons they often fail to provide protection against injury. First, the fidelity of the repair mechanisms is not absolute, making it possible for some lesions to be overlooked. However, repair fails most typically when the damage overwhelms the repair mechanisms, as when protein thiols are oxidized faster than they can be reduced. In other instances, the capacity of repair may become exhausted when necessary enzymes or cofactors are consumed. For example, alkylation of DNA may lead to consumption of O^6-alkylguanine-DNA-alkyltransferase (Pegg and Byers, 1992), and lipid peroxidation can deplete alpha-tocopherol. Sometimes the toxicant-induced injury adversely affects the repair process itself. Thus, after exposure to necrogenic chemicals, mitosis of surviving cells may be blocked and restoration of the tissue becomes impossible (Soni and Mehendale, 1998). Finally, some types of toxic injuries cannot be repaired effectively, as occurs when xenobiotics are covalently bound to proteins. Thus, toxicity is manifested when repair of the initial injury fails because the repair mechanisms become overwhelmed, exhausted, or impaired or are genuinely inefficient.

It is also possible that repair contributes to toxicity. This may occur in a passive manner, for example, if excessive amounts of NAD$^+$ are cleaved by PARP when this enzyme assists in repairing broken DNA strands, or when too much NAD(P)H is consumed for the repair of oxidized proteins and endogenous reductants. Either event can compromise oxidative phosphorylation, which is also dependent on the supply of reduced cofactors (see Fig. 3-13), thus causing or aggravating ATP depletion that contributes to cell injury. Excision repair of DNA and reacylation of lipids also contribute to cellular deenergization and injury by consuming significant amounts of ATP. However, repair also may play an active role in toxicity. This is observed after chronic tissue injury, when the repair process goes astray and leads to uncontrolled proliferation instead of tissue remodeling. Such proliferation of cells may yield neoplasia whereas overproduction of extracellular matrix results in fibrosis.

Toxicity Resulting from Dysrepair

Like repair, dysrepair occurs at the molecular, cellular, and tissue levels. Some toxicities involve dysrepair at an isolated level. For example, hypoxemia develops after exposure to methemoglobin-forming chemicals if the amount of methemoglobin produced overwhelms the capacity of methemoglobin reductase. Because this repair enzyme is deficient at early ages, neonates are especially sensitive to chemicals that cause methemoglobinemia. Formation of cataracts purportedly involves inefficiency or impairment of lenticular repair enzyme, such as the endo- and exopeptidases, which normally reduce oxidized crystalline and hydrolyze damaged proteins to their constituent amino acids. Dysrepair also is thought to contribute to the formation of Heinz bodies, which are protein aggregates formed in oxidatively stressed and aged red blood cells. Defective proteolytic degradation of the immunogenic trifluoroacetylated proteins may make halothane-anesthetized patients victims of halothane hepatitis.

Several types of toxicity involve failed and/or derailed repairs at different levels before they become apparent. This is true for the most severe toxic injuries, such as tissue necrosis, fibrosis, and chemical carcinogenesis.

Tissue Necrosis As discussed above, several mechanisms may lead to cell death. Most or all involve molecular damage that is potentially reversible by repair mechanisms. If repair mechanisms operate effectively, they may prevent cell injury or at least retard its progression. For example, prooxidant toxicants cause no lipid fragmentation in microsomal membranes until alpha-tocopherol is depleted in those membranes. Membrane damage ensues when this endogenous antioxidant, which can repair lipids containing peroxyl radical groups (Fig 3-20), becomes unavailable (Scheschonka et al., 1990). This suggests that cell injury progresses toward cell necrosis if molecular repair mechanisms are inefficient or the molecular damage is not readily reversible.

Progression of cell injury to tissue necrosis can be intercepted by two repair mechanisms working in concert: apoptosis and cell proliferation. As discussed above, injured cells can initiate apoptosis, which counteracts the progression of the toxic injury. Apoptosis does this by preventing necrosis of injured cells and the consequent inflammatory response, which may cause injury by releasing cytotoxic mediators. Indeed, the activation of Kupffer cells, the source of such mediators in the liver, by the administration of bacterial lipopolysaccharide (endotoxin) greatly aggravates the hepatotoxicity of galactosamine. In contrast, when the Kupffer cells are selectively eliminated by pretreatment of rats with gadolinium chloride, the necrotic effect of carbon tetrachloride is markedly alleviated (Edwards et, al., 1993). Blockade of Kupffer cell function with glycine (via the inhibitory glycine receptor; see item 4 in Fig. 3-12) also protects the liver from alcohol-induced injury (Yin et al., 1998).

Another important repair process that can halt the propagation of toxic injury is proliferation of cells adjacent to the injured cells. This response is initiated soon after cellular injury. A surge in mitosis in the liver of rats administered a low (nonnecrogenic) dose of carbon tetrachloride is detectable within a few hours. This early cell division is thought to be instrumental in the rapid and complete restoration of the injured tissue and the prevention of necrosis. This hypothesis is corroborated by the finding that in rats pretreated with chlordecone, which blocks the early cell proliferation in response to carbon tetrachloride, a normally nonnecrogenic dose of carbon tetrachloride causes hepatic necrosis (Soni and Mehendale, 1998). The sensitivity of a tissue to injury and the capacity of the tissue for repair are apparently two independent variables, both influencing the final outcome of the effect of injurious chemical—that is, whether tissue restitution ensues with survival or tissue necrosis occurs with death. For example, variations in tissue repair capacity among species and strains of animals appear to be responsible for certain variations in the lethality of hepatotoxicants (Soni and Mehandale, 1998).

It appears that the efficiency of repair is an important determinant of the dose-response relationship for toxicants that cause tissue necrosis. Following chemically induced liver injury, the intensity of tissue repair increases up to a threshold dose, restraining injury, whereupon it is inhibited, allowing unrestrained progression of injury (Soni and Mehendale, 1998). Impaired signaling to mitosis (see Fig. 3-11) caused by high concentrations of acetaminophen may account for lagging repair of the liver damaged by this drug (Boulares et al., 1999), but maintenance of DNA synthesis, mitotic machinery, and energy supply may also be impaired at high-dose chemical exposures. That is, tissue necrosis is caused by a certain dose of a toxicant not only because that dose ensures sufficient concentration of the ultimate toxicant at the target site to initiate injury but also because that quantity of toxicant causes a degree of damage sufficient to compromise repair, allowing for progression of the injury. Experimental observations with hepatotoxicants indicate that apoptosis and cell proliferation are operative with latent tissue injury caused by low (nonnecrogenic) doses of toxicants but are inhibited with severe injury induced by high (necrogenic) doses. For example, 1,1-dichloroethylene, carbon tetrachloride, and thioacetamide all induce apoptosis in the liver at low doses but cause hepatic necrosis after high-dose exposure (Corcoran et al., 1994). Similarly, there is an early mitotic response in the liver to low-dose carbon tetrachloride, but this response is absent after administration of the solvent at necrogenic doses (Soni and Mehendale, 1998). This suggests that tissue necrosis occurs because the injury overwhelms and disables the repair mechanisms, including (1) repair of damaged molecules, (2) elimination of damaged cells by apoptosis, and (3) replacement of lost cells by cell division.

Fibrosis Fibrosis is a pathologic condition characterized by excessive deposition of an extracellular matrix of abnormal composition. Hepatic fibrosis, or cirrhosis, results from chronic consumption of ethanol or intoxication with hepatic necrogens such as carbon tetrachloride and iron. Pulmonary fibrosis is induced by drugs such as bleomycin and amiodarone and prolonged inhalation of oxygen or mineral particles. Doxorubicin may cause cardiac fibrosis, whereas exposure to ionizing radiation induces fibrosis in many organs. Most of these agents generate free radicals and cause chronic cell injury.

Fibrosis is a specific manifestation of dysrepair of the injured tissue. As discussed above, cellular injury initiates a surge in cellular proliferation and extracellular matrix production, which normally ceases when the injured tissue is remodeled. If increased production of extracellular matrix is not halted, fibrosis develops.

The cells that manufacture the extracellular matrix during tissue repair (e.g., stellate cells in liver, fibroblasts-like cells in lungs and skin) are the ones that overproduce the matrix in fibrosis. These cells are controlled and phenotypically altered ("activated") by cytokines and growth factors secreted by nonparenchymal cells, including themselves (see Fig. 3-22). TGF-b appears to be the major mediator of fibrogenesis, although other factors, such as TNF and platelet-derived growth factor, are also involved (Border and Ruoslahti, 1992). Indeed, subcutaneous injection of TGF-b induces local fibrosis, whereas TGF-b antagonists such as anti-TGF-b immunoglobulin and decorin ameliorate experimental fibrogenesis. In several types of experimental fibrosis and in patients with active liver cirrhosis, overexpression of TGF-b in affected tissues has been demonstrated. The increased expression of TGF-b is a common response mediating regeneration of the extracellular matrix after an acute injury. However, while TGF-b production ceases when repair is complete, this does not occur when tissue injury leads to fibrosis. Failure to halt TGF-b overproduction could be caused by continuous injury or a defect in the regulation of TGF-b.

The fibrotic action of TGF-b is due to (1) stimulation of the synthesis of individual matrix components by specific target cells and (2) inhibition of matrix degradation by decreasing the synthesis of matrix metalloproteinases and increasing the level of tissue inhibitors of metalloproteinases (Burt, 1993; Arthur et al., 1999). Interestingly, TGF-b induces transcription of its own gene in target cells, suggesting that the TGF-b produced by these cells can amplify in an autocrine manner the production of the extracellular matrix. This positive feedback may facilitate fibrogenesis (Border and Ruoslahti, 1992).

Fibrosis involves not only excessive accumulation of the extracellular matrix but also changes in its composition. The basement membrane components, such as collagen IV and laminin, as well as the fibrillar type collagens (collagen I and III), which confer rigidity to tissues, increase disproportionately, during fibrogenesis (Gressner, 1992).

Fibrosis is detrimental in a number of ways:

1. The scar compresses and may ultimately obliterate the parenchymal cells and blood vessels.
2. Deposition of basement membrane components between the capillary endothelial cells and the parenchymal cells presents a diffusional barrier which contributes to malnutrition of the tissue cells.
3. An increased amount and rigidity of the extracellular matrix unfavorably affect the elasticity and flexibility of the whole tissue, compromising the mechanical function of organs such as the heart and lungs.
4. Furthermore, the altered extracellular environment is sensed by integrins. Through these transmembrane proteins and the coupled intracellular signal transducing networks (see Fig. 3-11) fibrosis may modulate several aspects of cell behavior, including polarity, motility, and gene expression (Burt, 1993; Raghow, 1994).

Carcinogenesis Chemical carcinogenesis involves insufficient function of various repair mechanisms, including (1) failure of DNA repair, (2) failure of apoptosis, and (3) failure to terminate cell proliferation.

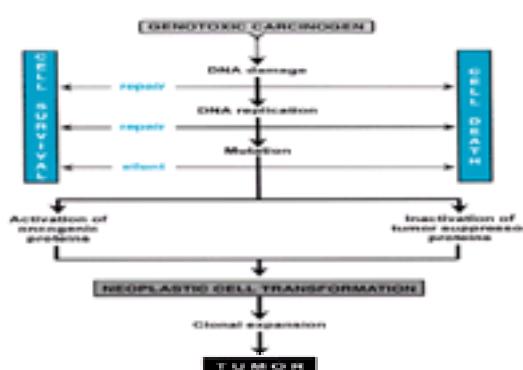
Failure of DNA Repair: Mutation, the Initiating Event in Carcinogenesis. Chemical and physical insults may induce neoplastic transformation of cells by genotoxic and nongenotoxic mechanisms. Chemicals that react with DNA may cause damage such as adduct formation, oxidative alteration, and strand breakage (Fig. 3-23). In most cases, these lesions are repaired or injured cells are eliminated. If neither event occurs, a lesion in the parental DNA strand may induce a heritable alteration, or mutation, in the daughter strand during replication. The mutation may remain silent if it does not alter the protein encoded by the mutant gene or if the mutation causes an amino acid substitution that does not affect the function of the protein. Alternatively, the genetic alteration may be incompatible with cell survival. The most unfortunate scenario for the organism occurs when the altered genes express mutant proteins that reprogram cells for multiplication. When such cells undergo mitosis, their descendants also have a similar propensity for proliferation. Moreover, because enhanced cell division increases the likelihood of mutations, these cells eventually acquire additional mutations that may further increase their growth advantage over their normal counterparts. The final outcome of this process is a nodule, followed by a tumor consisting of transformed, rapidly proliferating cells (Fig. 3-23).


Figure 3-23. The process of carcinogenesis initiated by genotoxic carcinogens (see text for explanation).

The critical role of DNA repair in preventing carcinogenesis is attested by the human heritable disease xeroderma pigmentosum. Affected individuals exhibit deficient excision repair and a greatly increased incidence of sunlight-induced skin cancers. Cells from these patients are also hypersensitive to DNA-reactive chemicals, including aflatoxin B_I, aromatic amines, polycyclic hydrocarbons, and 4-nitroquinoline-1-oxide (Lehmann and Dean, 1990). Also, mice with ablated PARP gene are extremely sensitive to g-rays and *N*-methylnitrosourea and show genomic instability, as indicated by increases in the levels of both sister chromatid exchanges and chromatid breaks following DNA damage (D'Amours et al., 1999).

A small set of cellular genes are the targets for genetic alterations that initiate neoplastic transformations. Included are proto-oncogenes and tumor-suppressor genes (Barrett, 1992).

Mutation of Proto-oncogenes Proto-oncogenes are highly conserved genes encoding proteins that stimulate the progression of cells through the cell cycle (Smith et al., 1993). The products of proto-oncogenes include (1) growth factors; (2) growth factor receptors; (3) intracellular signal transducers such as G proteins, protein kinases, cyclins, and cyclin-dependent protein kinases; and (4) nuclear transcription factors. Figure 3-24 depicts several proto-oncogene products that are closely involved in initiating the cell-division cycle. The legend of that figure outlines some important details on the function of these proteins and their interaction with tumor suppressor proteins (to be discussed below). Transient increases in the production or activity of proto-oncogene proteins are required for regulated growth, as during embryogenesis, tissue regeneration, and stimulation of cells by growth factors or hormones. In contrast, permanent activation and/or overexpression of these proteins favors neoplastic transformation. One mechanism whereby genotoxic carcinogens induce neoplastic cell transformation is by producing an activating mutation of a proto-oncogene. Such a mutation is so named because the altered gene (then called an *oncogene*) encodes a permanently active protein that forces the cell into the division cycle. An example of mutational activation of an oncogene protein is that of the Ras proteins.

Ras proteins represent a family of G-proteins with GTP/GDP binding capacity as well as GTPase activity (Anderson et al., 1992). They are localized on the inner surface of the plasma membrane and function as crucial mediators in responses initiated by growth factors (see Fig. 3-11 and Fig. 3-24). Ras is located downstream from growth factor receptors and nonreceptor protein tyrosine kinases and upstream from mitogen-activated protein kinase (MAPK) cascade whose activation finally upregulates the expression of cyclin D and initiates the mitotic cycle (Fig. 3-24). In this pathway, Ras serves as a molecular switch, being active in the GTP-bound form and inactive in the GDP-bound form. Some mutations of the *ras* gene (e.g., a point mutation in codon 12) dramatically lowers the GTPase activity of the protein. This in turn locks Ras in the permanently active GTP-bound form. Continual rather than signal-dependent activation of Ras can lead eventually to uncontrolled proliferation and transformation. Indeed, microinjection of Ras-neutralizing monoclonal antibodies into cells blocks the mitogenic action of growth factors as well as cell transformation by several oncogenes. Numerous carcinogenic chemicals induce mutations of ras proto-oncogenes that lead to constitutive activation of Ras proteins (Anderson et al., 1992). These include *N*-methyl-*N*-nitrosourea, polycyclic aromatic hydrocarbons, benzidine, aflatoxin B_I, and ionizing radiation. Most of these agents induce point mutations by transversion of G_{35} to T in codon 12.

While mutation-induced constitutive activation of oncogene proteins is a common mechanism in chemical carcinogenesis, overexpression of such proteins also can contribute to neoplastic cell transformation. This may result from (1) sustained transactivation of the promoter region of a proto-oncogene (e.g., the promoter of *ras* gene by TCDD- or benzpyrene-ligated Ah receptor; Ramos et al., 1998), (2) an alteration of the regulatory region of proto-oncogenes (e.g., by hypomethylation or translocation) and (3) amplification of the proto-oncogene (Anderson et al., 1992). Gene amplification (i.e., the formation more than one copy) may be initiated by DNA strand breaks, and therefore often observed after exposure to ionizing radiation

Mutation of Tumor-Suppressor Genes Tumor-suppressor genes encode proteins that inhibit the progression of cells in the division cycle. Figure 3-24 depicts such proteins, which include, for example, cyclin-dependent protein kinase inhibitors (e.g., p16, p21, and p27), transcription factors (e.g., p53) that transactivate genes encoding cyclin-dependent protein kinase inhibitors, and proteins (e.g., pRb) that block transcription factors involved in DNA synthesis and cell division. Uncontrolled proliferation can occur when the mutant tumor-suppressor gene encodes a protein that cannot suppress cell division. Inactivating mutations of specific tumor suppressor genes in germ cells are responsible for the inherited predisposition to cancer, as in familial retinoblastoma, Wilms' tumor, familial polyposis, and Li-Fraumeni syndrome (Gennett et al., 1999). Mutations of tumor-suppressor genes in somatic cells contribute to nonhereditary cancers. The best-known tumor suppressor gene involved in both spontaneous and chemically induced carcinogenesis is p53.

The p53 tumor suppressor gene encodes a 53,000-dalton protein with multiple functions (Fig. 3-25). Acting as a transcription factor, the p53 protein (1) transactivates

genes whose products arrest the cell cycle (e.g., p21 and gadd 45) or promote apoptosis (e.g., bax and fas receptor) and (2) represses genes that encode antiapoptotic proteins (e.g., bcl-2 and IGF1 receptor) (Asker et al., 1999; Bennett et al., 1999). DNA damage and illegitimate expression of oncogenes (e.g., c-*myc*) stabilizes the p53 protein, causing its accumulation (Fig. 3-25). The accumulated p53 induces cell cycle arrest (permitting DNA repair) or even apoptosis of the affected cells. Thus, p53 eliminates cancer-prone cells from the replicative pool, counteracting neoplastic transformation (Fig. 3-23); therefore it is commonly designated as guardian of the genome.

Indeed, cells that have no p53 are a million times more likely to permit DNA amplification than are cells with a normal level of the suppressor gene. Furthermore, genetically engineered mice with the p53 gene deleted develop cancer by 6 to 9 months of age. These observations attest to the crucial role of the p53 tumor-suppressor gene in preventing carcinogenesis.

Mutations in the p53 gene are found in 50 percent of human tumors and in a variety of induced cancers. The majority are "missense mutations" that change an amino acid and result in a faulty or altered protein (Bennett et al., 1999). The faulty p53 protein forms a complex with endogenous wild-type p53 protein and inactivates it. Thus, the mutant p53 not only is unable to function as a tumor suppressor protein but also prevents tumor suppression by the wild-type p53. Moreover, some observations suggest that the mutant p53 can actively promote cell proliferation, much as an oncogene protein does.

Different carcinogens cause different mutations in the p53 tumor-suppressor gene. An example is the point mutation in codon 249 from AGG to AGT, which changes amino acid 249 in the p53 protein from arginine to serine. This mutation predominates in hepatocellular carcinomas in individuals in regions where food is contaminated with aflatoxin B_1 (Bennett et al., 1999). Because aflatoxin B_1 induces the transversion of G to T in codon 249 of the p53 tumor-suppressor gene in human hepatocytes (Aguilar et al., 1993), it appears likely that this mutation is indeed induced by this mycotoxin. Although the detected mutation in patients presumably contributes to the hepatocarcinogenicity of aflatoxin B_1 in humans, it is not required for aflatoxin B_1 induced hepatocarcinogenesis in rats, as rats do not show this aberration in the transformed liver cells.

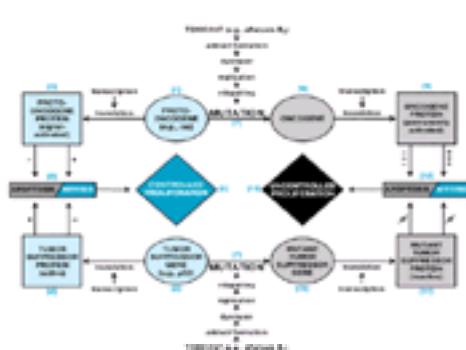
Cooperation of Proto-oncogenes and Tumor-Suppressor Genes in Carcinogenesis The accumulation of genetic damage in the form of (1) mutant proto-oncogenes (which encode activated proteins) and (2) mutant tumor-suppressor genes (which encode inactivated proteins) is the main driving force in the transformation of normal cells with controlled proliferative activity to malignant cells with uncontrolled proliferative activity. Because the number of cells in a tissue is regulated by a balance between mitosis and apoptosis, the uncontrolled proliferation results from perturbation of this balance (Fig. 3-26).


Figure 3-26. A model of cooperation between a proto-oncogene (1) and a tumor suppressor gene (2) before and after mutation.

The model shows that the normal proteins encoded by the cellular proto-oncogenes and the tumor suppressor genes [(3) and (4), respectively] reciprocally influence mitosis and apoptosis (5) and thus ensure controlled cell proliferation (6). However, the balance between the effects of these two types of proteins is offset by a toxicant-induced mutation of their genes (7) if the mutant prot-oncogene (oncogene) (8) encodes a constitutively (i.e., permanently) active oncogene protein (9) and the mutant tumor suppressor gene (10) encodes an inactive tumor suppressor protein (11). Under this condition, the effect of the oncogene protein on mitosis and apoptosis is unopposed (12), resulting in uncontrolled proliferation. Such a scenario may underlie the carcinogenicity of aflatoxin B_1, which can induce mutations in *ras* proto-oncogenes and the *p53* tumor suppressor gene (see text for details). Positive and negative signs represent stimulation and inhibition, respectively; Ø means "no effect."

Failure of Apoptosis: Promotion of Mutation and Clonal Growth In response to DNA damage caused by UV or gamma irradiation or genotoxic chemicals, the levels of p53 protein in cells increase dramatically (5- to 60-fold) (Levine et al., 1994). As discussed above, the high p53 protein levels block the progression of cells in the G1 phase and allow DNA repair to occur before replication or induce cell death by apoptosis (Fig. 3-25). Consequently, apoptosis eliminates cells with DNA damage, preventing mutation, the initiating event in carcinogenesis.

Preneoplastic cells, or cells with mutations, have much higher apoptotic activity than do normal cells (Bursch et al., 1992). Therefore apoptosis counteracts clonal expansion of the initiated cells and tumor cells. In fact, facilitation of apoptosis can induce tumor regression. This occurs when hormone-dependent tumors are deprived of the hormone that promotes growth and suppresses apoptosis. This is the rationale for the use of tamoxifen, an antiestrogen, and gonadotropin-releasing hormone analogs to combat hormone-dependent tumors of the mammary gland and the prostate gland, respectively (Bursch et al., 1992).

Thus, the inhibition of apoptosis is detrimental because it facilitates both mutations and clonal expansion of preneoplastic cells. Indeed, inhibition of apoptosis plays a role in the pathogenesis of human B-cell lymphomas. In this malignancy, chromosomal translocation brings together the bcl-2 gene and the immunoglobulin heavy-chain locus, resulting in aberrantly increased bcl-2 gene expression. The overexpressed bcl-2 protein, after binding to and inactivating the proapoptotic bax protein (see Fig. 3-16), overrides programmed cell death. Increased levels of bcl-2 are not limited to B-cell lymphoma but are detected in half of the human cancers, and a high bcl-2/bax ratio in a tumor is a marker for poor prognosis (Jäättelä, 1999). Besides bcl-2, other antiapoptotic proteins may also contribute to progression of neoplasia. These include specific heat-shock proteins (Hsp), such as Hsp 70 and 27, as well as a family of "inhibitor of apoptosis proteins" (IAP) that inhibit effector caspases 3 and 7 (see Fig. 3-16). Survivin, a member of the IAP family, is expressed in all cancer cells but not in adult differentiated cells (Jäättelä, 1999).

Inhibition of apoptosis is one mechanism by which phenobarbital, a tumor promoter, promotes clonal expansion of preneoplastic cells. This has been demonstrated in rats given a single dose of Λ-nitrosomorpholine followed by daily treatments with phenobarbital for 12 months to initiate and promote, respectively, neoplastic transformation in liver (Schulte-Hermann et al., 1990). From 6 months onward, phenobarbital did not increase DNA synthesis and cell division in the preneoplastic foci, yet it accelerated foci enlargement. The foci grow because phenobarbital lowers apoptotic activity, allowing the high cell replicative activity to manifest itself. The peroxisome proliferator nafenopin, a nongenotoxic hepatocarcinogen, also suppresses apoptosis in primary rat hepatocyte cultures (Bayly et al., 1994), supporting the hypothesis that this mechanism may play a role in the hepatocarcinogenicity of peroxisome proliferators in rodents.

Failure to Terminate Proliferation: Promotion of Mutation, Proto-Oncogene Expression, and Clonal Growth Enhanced mitotic activity, whether it is induced by oncogenes inside the cell or by external factors such as xenobiotic or endogenous mitogens, promotes carcinogenesis for a number of reasons.

1. First, the enhanced mitotic activity increases the probability of mutations. This is due to activation of the cell-division cycle, which invokes a substantial shortening of the GI phase. Thus, less time is available for the repair of injured DNA before replication, increasing the chance that the damage will yield a mutation. Although repair still may be feasible after replication, postreplication repair is error-prone. In addition, activation of the cell-division cycle increases the proportion of cells that replicate their DNA at any given time. During replication, the amount of DNA doubles and the DNA becomes unpacked, greatly increasing the effective target size for DNA-reactive mutagenic chemicals.
2. During increased proliferation, proto-oncogenes are overexpressed. These overproduced proto-oncogene proteins may cooperate with oncogene proteins to facilitate the neoplastic transformation of cells. In addition, enhanced mitotic activity indirectly enhances the transcriptional activity of proto-oncogenes and oncogenes by allowing less time for DNA methylation, which occurs in the early postreplication period. Methylation takes place at C_5 of specific cytosine residues in the promoter region of genes and decreases the transcription of genes by inhibiting the interaction of transcription factors with the promoter region. Nonexpressed genes are fully methylated. Hypomethylation of DNA, in contrast, enhances gene expression and may result in overexpression of proto-oncogenes and oncogenes. A "methyl-deficient diet" and ethionine, which deplete *S*-adenosyl-methionine, induce hypomethylation of DNA and cancer,

confirming the role of DNA hypomethylation in carcinogenesis (Poirier, 1994).

3. Another mechanism by which proliferation promotes the carcinogenic process is through clonal expansion of the initiated cells to form nodules (foci) and tumors.

4. Finally, cell-to-cell communication through gap junctions and intercellular adhesion through cadherins are temporarily disrupted during proliferation (Yamasaki et al., 1993). Lack of these junctions contributes to the invasiveness of tumor cells. Several tumor promoters, such as phenobarbital, phorbol esters, and peroxisome proliferators, decrease gap junctional intercellular communication. It has been hypothesized that this contributes to neoplastic transformation. It is unclear, however, whether diminished gap junctional communication plays a significant causative role in carcinogenesis or is merely a symptom of cell proliferation.

Nongenotoxic Carcinogens: Promoters of Mitosis and Inhibitors of Apoptosis A number of chemicals cause cancer by altering DNA and inducing a mutation. However, other chemicals do not alter DNA or induce mutations yet induce cancer after chronic administration (Barrett, 1992). These chemicals are designated *nongenotoxic* or *epigenetic carcinogens* and include (1) xenobiotic mitogens (e.g., phenobarbital, phorbol esters, DDT, peroxisomal proliferators, and some other chemicals that promote mitogenic signaling (see Fig. 3-11); (2) endogenous mitogens such as growth factors (e.g., TGF-a) and hormones with mitogenic action on specific cells [e.g., estrogens on mammary gland or liver cells, TSH on the follicular cells of the thyroid gland, and luteinizing hormone (LH) on Leydig cells in testes]; and (3) chemicals that, when given chronically, cause sustained cell injury (such as chloroform and *d*-limonene). Because several of these chemicals promote the development of tumors after neoplastic transformation has been initiated by a genotoxic carcinogen, they are referred to as *tumor promoters*. Despite the initial belief that promoters are unable to induce tumors by themselves, studies suggest that they can do so after prolonged exposure.

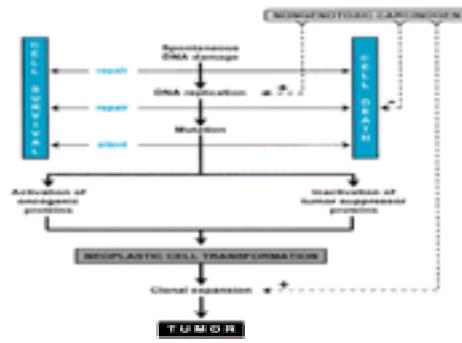
Nongenotoxic carcinogens cause cancer by promoting carcinogenesis initiated by genotoxic agents or spontaneous DNA damage (Fig. 3-27). Spontaneous DNA damage, some of which gives rise to mutation, commonly occurs in normal cells (Barrett, 1992). It is estimated that in human cells, 1 out of 10^8 to 10^{10} base pairs suffers spontaneous mutation. Genotoxic carcinogens increase the frequency 10- to 1000-fold. Nongenotoxic carcinogens also increase the frequency of spontaneous mutations through a mitogenic effect and by the mechanisms discussed earlier. In addition, nongenotoxic carcinogens, by inhibiting apoptosis, increase the number of cells with DNA damage and mutations. Both enhanced mitotic activity and decreased apoptotic activity brought about by nongenotoxic carcinogens expand the population of transformed cells, promoting cancer development. In summary, nongenotoxic carcinogens appear to act by enhancing cell division and/or inhibiting apoptosis.


Figure 3-27. The process of carcinogenesis promoted by nongenotoxic carcinogens.

Positive and negative signs represent stimulation and inhibition, respectively. See text for explanation.

It is easy to recognize that even epigenetic carcinogens of the cytotoxic type act in this manner. As discussed in the section on tissue repair, cell injury evokes the release of mitogenic growth factors such as HGF and TGF-a from tissue macrophages and endothelial cells. Thus, cells in chronically injured tissues are exposed continuously to endogenous mitogens. Although these growth factors are instrumental in tissue repair after acute cell injury, their continuous presence is potentially harmful because they may ultimately transform the affected cells into neoplastic cells. This view is supported by findings with transgenic mice that overexpress TGF-a. These animals exhibit hepatomegaly at a young age, and 80 percent develop tumors by 12 months (Fausto and Webber, 1993). Mitogenic cytokines secreted by Kupffer cells are apparently involved in hepatocyte proliferation and, possibly, tumor formation induced by peroxysome proliferators in rats (Rose et al., 1999).

It is important to realize that even epigenetic carcinogens can exert a genotoxic effect, although indirectly. For example, chemicals causing chronic cell injury evoke a prolonged inflammatory response, with the free radicals produced by the inflammatory cells causing DNA injury in adjacent cells. Similarly, phorbol esters are not only potent mitogens but also activators of leukocytes, which release DNA-reactive free radicals during their respiratory burst (Weiss and LoBuglio, 1982).

CONCLUSIONS

This overview systematically surveys the mechanisms of the potential events that follow toxicant exposure and contribute to toxicity. This approach is also useful in the search for mechanisms responsible for (1) selective toxicity, that is, differences in the sensitivity to toxicants of various organisms, such as different species and strains of animals, organs, and cells, and (2) alteration of toxicity by exogenous factors such as chemicals and food and physiologic or pathologic conditions such as aging and disease. To identify the mechanisms that underlie selective toxicity or alterations in toxicity, all steps where variations might occur must be considered systematically. Selective or altered toxicity may be due to different or altered (1) exposure; (2) delivery, thus resulting in a different concentration of the ultimate toxicant at the target site; (3) target molecules; (4) biochemical processes triggered by the reaction of the chemical with the target molecules; (5) repair at the molecular, cellular, or tissue level; or (6) mechanisms such as circulatory and thermoregulatory reflexes by which the affected organism can adapt to some of the toxic effects.

In this chapter, a simplified scheme has been used to give an overview of the development of toxicity (Fig. 3-1). In reality, the route to toxicity can be considerably more diverse and complicated. For example, one chemical may yield several ultimate toxicants, one ultimate toxicant may react with several types of target molecules, and reaction with one type of target molecule may have a number of consequences. Thus, the toxicity of one chemical may involve several mechanisms which can interact with and influence each other in an intricate manner.

This chapter has emphasized the significance of the chemistry of a toxicant in governing its delivery to and reaction with the target molecule as well as the importance of the biochemistry, molecular and cell biology, immunology, and physiology of the affected organism in its response to the action of the toxicant. An organism has mechanisms that (1) counteract the delivery of toxicants, such as detoxication; (2) reverse the toxic injury, such as repair mechanisms; and (3) offset some dysfunctions, such as adaptive responses. Thus, toxicity is not an inevitable consequence of toxicant exposure because it may be prevented, reversed, or compensated for by such mechanisms. Toxicity develops if the toxicant exhausts or impairs the protective mechanisms and/or overrides the adaptability of biological systems.

RISK ASSESSMENT

Elaine M. Faustman and Gilbert S. Omenn

INTRODUCTION AND HISTORICAL CONTEXT

Toxicologic research and toxicity testing conducted and interpreted by toxicologists constitute the scientific core of an important activity known as risk assessment for chemical exposures. For decades, the American Conference of Governmental Industrial Hygienists (ACGIH) has set threshold limit values for occupational exposures and the U.S. Food and Drug Administration (FDA) has established acceptable daily intakes for pesticide residues and food additives. In 1958, the U.S. Congress instructed the FDA in the Delaney clause to prohibit the addition to the food supply of all substances found to cause cancer in animals or humans. Pragmatically, this policy allowed food sources that had nondetectable levels of these additives to be declared "safe." As advances in analytic chemistry revealed that "nondetects" were not equivalent to "not present," regulatory agencies were forced to develop "tolerance levels" and "acceptable risk levels." Risk assessment methodologies blossomed in the 1970s (Albert, 1994).

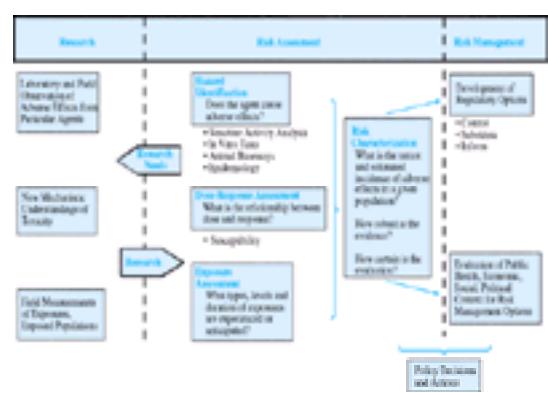
Together with the federal regulatory agencies, the White House Office of Science and Technology Policy developed a framework for regulatory decision making (Calkins et al., 1980; ILRG, 1979). The National Research Council then detailed the steps of hazard identification, dose–response assessment, exposure analysis, and characterization of risks (NRC, 1983) in *Risk Assessment in the Federal Government: Managing the Process* (widely known as "The Red Book"). This framework has evolved into the scheme shown in Fig. 4-1, providing a consistent framework for risk assessment across agencies. Figure 4-1 now shows a modified risk framework with bidirectional arrows showing an ideal situation where mechanistic research feeds directly into risk assessments and critical data uncertainty drives research. Initially, attention was focused on cancer risks; in recent years, noncancer endpoints have been examined with similar methods. Continuing advances in toxicology, epidemiology, exposure assessment, biologically based modeling of adverse responses, and modeling of variability and uncertainty have led to improvements in risk assessment. Nevertheless, public policy objectives often require extrapolations that go far beyond the observation of actual effects and reflect different tolerance for risks, generating controversy.


Figure 4-1. Risk assessment/risk management framework.

This framework shows in blue the four key steps of risk assessment: hazard identification, dose-response assessment, exposure assessment, and risk characterization. It shows an interactive, two-way process where research needs from the risk assessment process drive new research, and new research findings modify risk assessment outcomes. (Adapted from NRC, 1983; 1994; Calkins, 1980; Faustman, 1996; Gargas, 1999.)

The 1990 Amendments to the U.S. Clean Air Act led to two far-reaching reports triggered by Congressional action to force action on section 112, "Hazardous Air Pollutants." During the previous 20 years only seven substances had been regulated under this section of the law (vinyl chloride, asbestos, benzene, radionuclides, mercury, arsenic, and beryllium), using chemical-by-chemical risk-based analyses, largely because the statute required that the exposure standard provide an "ample margin of safety" below a no-effect level, which was widely agreed to be zero for carcinogens. Congress mandated an entirely new program to control 189 named hazardous air pollutants from point sources with maximum available control technology during the 1990s, to be followed over the next decade with determination of any unacceptable residual risks by methods informed by the mandated reports.

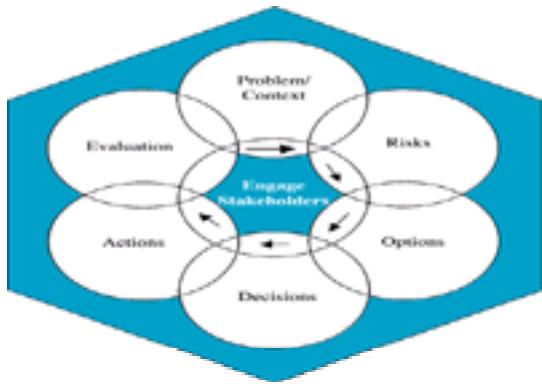
In 1994, the National Academy of Sciences report entitled *Science and Judgment in Risk Assessment* captured in its title the combination of qualitative and quantitative approaches essential to effective assessment of risks (NRC, 1994). This report discusses in detail the challenges and provides approaches for incorporating new scientific findings into the risk assessment process. It also highlights approaches to deal with uncertainty when insufficient scientific information is available. Following up on many of the challenges, the Presidential/Congressional Commission on Risk Assessment and Risk Management (Risk Commission, 1997) formulated a comprehensive framework that is being applied widely. The two crucial concepts are (1) putting each environmental problem or issue into public health and/or ecological context and (2) proactively engaging the relevant stakeholders, often affected or potentially affected community groups, from the very beginning of the six-stage process shown in Fig. 4-2. Particular exposures and potential health effects must be evaluated across sources and exposure pathways and in light of multiple endpoints, not just one chemical, in one environmental medium (air, water, soil, food, products), for one health effect at a time—the general approach up to the present. A similar framework has been utilized by the Health and Safety Executive Risk Assessment Policy Unit of the United Kingdom (HSE, 2000).


Figure 4-2. Risk management framework for environmental health from the U.S. Commission on Risk Assessment and Risk Management, "Omenn Commission."

The framework comprises six stages: (1) formulating the problem in a broad public health context; (2) analyzing the risks; (3) defining the options; (4) making risk-reduction decisions; (5) implementing those actions; and (6) evaluating the effectiveness of the actions taken. Interactions with stakeholders are critical and thus have been put at the center of the framework. (Omenn 1996; Risk Commission, 1997; Charnley, 1997; Ohanian, 1997.)

DEFINITIONS

Risk assessment is the systematic scientific characterization of potential adverse health effects resulting from human exposures to hazardous agents or situations (NRC, 1983, 1994; Omenn and Faustman, 2000). *Risk* is defined as the probability of an adverse outcome. The term *hazard* is used in the United States and Canada to refer to intrinsic toxic properties, whereas internationally this term is defined as the probability of an adverse outcome. Risk assessment requires qualitative information about the strength of the evidence and the nature of the outcomes—as well as quantitative assessment of the exposures, host susceptibility factors, and potential magnitude of the risk—and then a description of the uncertainties in the estimates and conclusions. The objectives of risk assessment are outlined in Table 4-1. Analogous approaches are applied to ecologic risks (NRC, 1993a).

Table 4-1 Objectives of Risk Assessment

The phrase *characterization of risk* may better reflect the combination of qualitative and quantitative analysis. Unfortunately, many toxicologists, public health practitioners, environmentalists, and regulators tend to equate risk assessment with quantitative risk assessment, generating a number (or a number with uncertainty bounds) for an overly precise risk estimate and then ignoring crucial information about the mechanism of effect across species, inconsistent findings across studies, multiple variable health effects, and means of avoiding or reversing the effects of exposures.

Risk management refers to the process by which policy actions are chosen to control hazards identified in the risk assessment/risk characterization stage of the six-stage framework (Fig. 4-2). Risk managers consider scientific evidence and risk estimates—along with statutory, engineering, economic, social, and political factors—in evaluating alternative options and choosing among those options (Risk Commission, 1997). (Chapter 34 discusses approaches to regulatory options.)

Risk communication is the challenging process of making risk assessment and risk management information comprehensible to community groups, lawyers, local elected officials, judges, business people, labor, and environmentalists (Morgan, 1993; Sandman, 1993; NRC, 1996; Fischhoff et al., 1996). A crucial, too- often neglected requirement for communication is listening to the fears, perceptions, priorities, and proposed remedies of these "stakeholders." Often these people have important inputs for various stages of the process, as illustrated in volume 1 of the Risk Commission reports (1997). Sometimes the decision makers and stakeholders simply want to know the "bottom line": is a substance or a situation "safe" or not? Others will be keenly interested in knowing why the risk estimates are uncertain and may be well prepared to challenge underlying assumptions about context and methodology. *Risk perception* is discussed at the end of this chapter.

DECISION MAKING

Risk management decisions are reached under diverse statutes in the United States (Table 4-2).

Table 4-2 Major Toxic Chemical Laws in the United States by Responsible Agency

Some statutes specify reliance on risk alone, while others require a balancing of risks and benefits of the product or activity (Table 4-1). Risk assessments provide a valuable framework for priority setting within regulatory and health agencies, in the chemical development process within companies, and in resource allocation by environmental organizations. Similar statutes and regulatory regimes have been developed in many other countries and through such international organizations as the International Programme for Chemical Safety (IPCS) of the World Health Organization (WHO). Currently, there are significant efforts toward the harmonization of testing protocols and then the assessment of risks and standards.

A major challenge for risk assessment, risk communication, and risk management is to work across disciplines to demonstrate the biological plausibility and clinical

significance of the conclusions from epidemiologic, lifetime animal, short-term in vitro and in vivo, and structure-activity studies of chemicals thought to have potential adverse effects. Biomarkers of exposure, effect, or individual susceptibility can link the presence of a chemical in various environmental compartments to specific sites of action in target organs and to host responses (NRC, 1989a, 1989b, 1992a, 1992b). Mechanistic investigations of the actions of specific chemicals can help us penetrate the "black box" approach of simply counting tumors, for example, in exposed animals in routine bioassays. Greater appreciation of the mechanisms and extent of individual variation in susceptibility among humans can improve protection of subgroups of susceptible people and better relate findings in animals to the characterization of risk for humans. Individual behavioral and social risk factors may be critically important both to the risk and the reduction of risk. Finally, public and media attitudes toward local polluters, other responsible parties, and relevant government agencies may lead to what has been labeled "the outrage factor" (Sandman, 1993), greatly influencing the communication process and the choices for risk management.

HAZARD IDENTIFICATION

Assessing Toxicity of Chemicals—Introduction

In many cases, toxicity information for chemicals is limited. For example, the Environmental Protection Agency (EPA) recently evaluated high-production-volume (HPV) chemicals (those produced in excess of 1 million lb/year) to ascertain the availability of chemical hazard data. Their study found that for 43 percent of these HPV chemicals, there were no publicly available studies for any of the basic toxicity endpoints (acute and chronic systemic toxicity, developmental/reproductive toxicity, genotoxicity/mutagenicity, ecotoxicity, and environmental fate). Only 7 percent of the HPV chemicals had a complete set of publicly available studies for these endpoints (EPA, 1998a). International efforts such as the Organization for Economic Development's screening information data set (OECD/SIDS) program are addressing many of these data needs, highlighted by the Environment Defense Fund in the book *Toxic Ignorance* (Roe et al., 1997). Data requirements for specific agents can vary greatly by compound type and applicable regulatory statutes. Table 4-3 shows requirements and 1997 costs for one example class of agents, pesticides (Stevens, 1997; 40 CFR 158.340; EPA, 1998c, 2000b). It also illustrates current international efforts to harmonize these testing guidelines by listing the new harmonized 870 test guidelines (EPA, 2000b). Increasing attention has been focused on this class of chemicals and reviews of available toxicity tests have shown the need for additional developmental neurobehavioral assessments (Makris et al., 1998). In summary, these critical data gaps in evaluating compounds have refocused attention on identifying new approaches that are both informative and cost and time efficient (NRC, 2000).

Table 4-3 EPA/FIFRA Requirement for Hazard Evaluation of Pesticides

Assessing Toxicity of Chemicals—Methods

Structure/Activity Relationships Given the cost of $1 to $2 million and the 3 to 5 years required for testing a single chemical in a lifetime rodent carcinogenicity bioassay, initial decisions on whether to continue development of a chemical, to submit premanufacturing notice (PMN), or to require additional testing may be based largely on structure/activity relationships (SARs) and limited short-term assays.

An agent's structure, solubility, stability, pH sensitivity, electrophilicity, volatility, and chemical reactivity can be important information for hazard identification. Historically, certain key molecular structures have provided regulators with some of the most readily available information on the basis of which to assess hazard potential. For example, 8 of the first 14 occupational carcinogens were regulated together by the Occupational Safety and Health Administration (OSHA) as belonging to the aromatic amine chemical class. The EPA Office of Toxic Substances relies on structure/activity relationships to meet deadlines to respond to premanufacturing notice for new chemical manufacture under the Toxic Substances Control Act (TSCA). Structural alerts such as *N*-nitroso or aromatic amine groups, amino azo dye structures, or phenanthrene nuclei are clues to prioritize agents for additional evaluation as potential carcinogens. The limited database of known developmental toxicants limits SARs to a few chemical classes, including chemicals with structures related to those of valproic acid, retinoic acid, and glycol ethers (NRC, 2000). For example, a report on developmentally toxic valproic acid derivatives relates their toxicity to activation of peroxisomal proliferation (Lampen et al., 1999).

Structure-activity relationships have been used for assessment of complex mixtures. A prominent application has been EPA's reassessment of risks associated with 2,3,7,8-tetrachlorodibenzo-*p*-dioxin *(TCDD)* and related chlorinated and brominated dibenzo-*p*-dioxins, dibenzofurans, and planar biphenyls, using toxicity equivalence factors (TEFs), based on induction of the aryl-hydrocarbon (Ah) receptor (EPA, 1994b). The estimated toxicity of environmental mixtures containing these chemicals was calculated as the sum of the product of the concentration of each multiplied by its TEF value. The World Health Organization has organized efforts to reach international consensus on TEFs used for polychlorinated biphenyls (PCBs), polychlorinated dibenzo-*p*-dioxins (PCDDs), and polychlorinated dibenzofurans (PCDFs) for both humans and wildlife (Van den Berg et al., 1998). EPA has issued new nomenclature for TEFs as part of their dioxin reassessment (www.epa.gov/ncea/dioxin.htm). However, it is difficult to predict activity across chemical classes and especially across multiple toxic endpoints using a single biological response. For these TEFs to be valid , all of the endpoints of toxicity must be mediated by the Ah receptor, yet direct measurement of activated Ah receptors in target human tissues is not currently feasible. Compounds within these complex mixtures can compete for the same receptor; thus, TEFs can be overly conservative. Many complex chemical/physical interactions are not easily understood and may be over-simplified. In draft proposals from EPA, cytochrome P450-1A2 (CYP1A2) activity or epidermal growth factor (EGF) receptor concentrations are proposed as activity surrogates across structurally related dioxin-like compounds for modeling mutation and growth rates.

Computerized SAR methods have given disappointing results in the National Toxicology Program (NTP) 44-chemical rodent carcinogenicity prediction challenge (Ashby and Tennant, 1994; Omenn et al., 1995). Much more focused efforts are those of pharmaceutical companies successfully using three-dimensional (3D) molecular modeling approaches to design ligands (new drugs) that can sterically fit into "receptors of interest." The basis for this strategy is pharmacophore mapping, 3D searching and molecular design, and establishment of 3D quantitative structure–activity relationships (Diener, 1997; Martin, 1993).

In Vitro and Short-Term Tests The next approach for hazard identification comprises in vitro or short-term tests, ranging from bacterial mutation assays performed entirely in vitro to more elaborate short-term tests such as skin-painting studies in mice or altered rat liver–foci assays conducted in vivo. For example, EPA mutagenicity guidelines call for assessment of reverse mutations using the Ames *Salmonella typhimurium* assay; forward mutations using mammalian cells, mouse lymphoma L5178Y, Chinese hamster ovary, or Chinese hamster lung fibroblasts; and in vivo cytogenetics assessment (bone marrow metaphase analysis or micronucleus tests). Chapter 8 discusses uses of these assays for identifying chemical carcinogens and Chap. 9 describes in detail various assays of genetic and mutagenic endpoints. Other assays evaluate developmental toxicity (NRC, 2000; Lewandowski et al., 2000; Brown et al., 1995; Whittaker and Faustman, 1994; Schwetz, 1993; Faustman, 1988), reproductive toxicity (Shelby et al., 1993; Harris et al., 1992; Gray, 1988), neurotoxicity (Costa, 2000; Atterwill et al., 1992), and immunotoxicity (Chap. 12). Less information is available on the extrapolation of these tests results for noncancer risk assessment than for the mutagenicity or carcinogenicity endpoints; however, mechanistic information obtained in these systems has been applied to risk assessment (NRC, 2000; Abbott et al., 1992; EPA, 1994a; Leroux et al., 1996). Overall, progress in developing new in vitro assays has been slow and frustrating.

The Interagency Coordinating Committee on the Validation of Alternative Methods (ICCVAM) of the National Toxicology Program (NTP) has reinvigorated the validation process in the United States as a result of Public Law 103-43 and has put forth recommendations for various short-term/in vitro assays, such as the cell-free corrosivity test, and recommendations for the mouse local lymph node assay for assessing chemical potential to elicit allergic contact dermatitis (NIEHS, 1999). A current review of the frog embryo teratogenicity assay in *Xenopus* (FETAX) by this group is under way.

The validation and application of short-term assays is particularly important to risk assessment because such assays can be designed to provide information about mechanisms of effects; moreover, they are fast and inexpensive compared with lifetime bioassays (McGregor et al., 1999). The NTP rodent carcinogenicity prediction challenge gave promising results for at least the prediction of genotoxic carcinogens; a second round with the next 30 chemicals that entered NTP rodent bioassays has been less successful (Ashby and Tennant, 1994). Validation of in vitro assays, like other kinds of tests, requires determination of their sensitivity (ability to identify true carcinogens), specificity (ability to recognize noncarcinogens as noncarcinogens), and predictive value for the toxic endpoint under evaluation. The societal costs of relying on such tests, with false positives (noncarcinogens classified as carcinogens) and false negatives (true carcinogens not detected) are the subject of a value-of-information model for the testing aspects of risk assessment and risk management (Lave and Omenn, 1986; Omenn and Lave, 1988). (See section below on linking information from hazard identification assessments.)

Current efforts to improve our ability to utilize short-term tests for carcinogenicity prediction include use of multivariate analysis with logistic regression (Kodell et al., 1999) and increased attention to improving the mechanistic basis of short-term testing. Examples of this approach include the several knockout transgenic mouse models proposed for use as shorter-term in vivo assays to identify carcinogens and currently under evaluation by NTP (Nebert and Duffy, 1997; Tennant et al., 1999). A TG.AC transgenic mouse carrying a *V-Ha-ras* gene construct has been shown to develop papillomas and malignant tumors in response to carcinogens and tumor-promoting compounds but is nonresponsive to noncarcinogens. A heterozygous p53 (+/–) mouse with one inactivated allele for p53 gene has been reported to have high sensitivity and specificity. Multiple transgenic assays are under evaluation (Robinson, 1998).

The primary use of short-term tests continues to be for mechanistic evaluations. In that context, results from short-term assays have impacted risk assessments. For example, evidence of nonmutagenicity in both in vitro and in vivo short-term assays continues to play an essential role, allowing regulators to consider nonlinear cancer risk assessment paradigms (EPA, 1999b).

New assay methods from molecular and developmental biology for developmental toxicity risk assessment that acknowledge the highly conserved nature of developmental pathways across species should accelerate use of a broader range of model organisms and assay approaches for noncancer risk assessments (NRC, 2000).

Animal Bioassays The use of animal bioassay data is a key component of the hazard identification process. A basic premise of risk assessment is that chemicals that cause tumors in animals can cause tumors in humans. All human carcinogens that have been adequately tested in animals produce positive results in at least one animal model. Thus, "although this association cannot establish that all agents and mixtures that cause cancer in experimental animals also cause cancer in humans, nevertheless, in the absence of adequate data on humans, it is biologically plausible and prudent to regard agents and mixtures for which there is sufficient evidence of carcinogenicity in experimental animals as if they presented a carcinogenic risk to humans" (IARC, 1994; 2000)—a reflection of the "precautionary principle." In general, the most appropriate rodent bioassays are those that test exposure pathways of most relevance to predicted or known human exposure pathways. Bioassays for reproductive and developmental toxicity and other noncancer endpoints have a similar rationale.

Consistent features in the design of standard cancer bioassays include testing in two species and both sexes, with 50 animals per dose group and near lifetime exposure. Important choices include the strains of rats and mice, the number of doses, and dose levels [typically 90, 50, and 10 to 25 percent of the maximally tolerated dose (MTD)], and the details of the required histopathology (number of organs to be examined, choice of interim sacrifice pathology, etc.). Positive evidence of chemical carcinogenicity can include increases in number of tumors at a particular organ site, induction of rare tumors, earlier induction (shorter latency) of commonly observed tumors, and/or increases in the total number of observed tumors.

However, there are serious problems with the rodent bioassay as a "gold standard" for prediction of human carcinogenicity risk (Risk Commission, 1997; Rodericks et al., 1997; McClain, 1994; Rice et al., 1999; Capen et al., 1999). Tumors may be increased only at the highest dose tested, which is usually at or near a dose that causes systemic toxicity (Ames and Gold, 1990). Second, even without toxicity, the high dose may trigger different events than do low-dose exposures. Table 4-4 presents some mechanistic details about rodent tumor responses that are no longer thought to be directly predictive of cancer risk for humans. Table 4-4 gives examples of both qualitative and quantitative considerations useful for determining relevance of rodent tumor responses for human risk evaluations. An example of qualitative considerations is the male rat kidney tumor observed following exposure to chemicals that bind to a_{2u}-globulin (e.g., unleaded gasoline, 1,4-dichlorobenzene, D-limonene). The a_{2u}-globulin is a male rat-specific low-molecular-weight protein not found in female rats, humans, or other species, including mice and monkeys.

Table 4-4 Examples of Mechanistic Considerations for Carcinogens: Explanation for Special Cases of Rodent Bioassay Data Lacking Relevance for Human Risk Evaluation

Table 4-4 also illustrates quantitative considerations important for determining human relevance of animal bioassay information. For example, doses of compounds so high as to exceed solubility in the urinary tract outflow lead to tumors of the urinary bladder in male rats following crystal precipitation and local irritation leading to hyperplasia. Such precipitates are known to occur following saccharin or nitriloacetic acid exposure. The decision to exclude saccharin from the NTP list of suspected human carcinogens reaffirms the nonrelevance of such high-dose responses for likely human exposure considerations (Neumann and Olin, 1995; NTP, 2000). A gross overloading of the particle clearance mechanism of rat lungs via directly administered particles, as was seen in titanium dioxide (TDO) exposures, resulted in EPA's delisting TDO as a reportable toxicant for the Clean Air Act Toxic Release Inventory (Oberdörster, 1995; EPA, 1988).

Other rodent responses not likely to be predictive for humans include localized forestomach tumors after gavage. Ethyl acrylate, which produces such tumors, was delisted on the basis of extensive mechanistic studies (NTP, 2000). In general, for risk assessment, it is desirable to use the same route of administration as the likely exposure pathway in humans to avoid such extrapolation issues. Despite the example of forestomach tumors, tumors in unusual sites—like the pituitary gland, the eighth cranial nerve, or the Zymbal gland—should not be dismissed as irrelevant, since organ-organ correlation is often lacking (NRC, 1994).

Rats and mice give concordant positive or negative results in only 70 percent of bioassays, so it is unlikely that rodent/human concordance would be higher (Lave et al., 1988). Haseman and Lockhart (1993) concluded that most target sites in cancer bioassays showed a strong correlation (65 percent) between males and females—especially for forestomach, liver, and thyroid tumors—so they suggested, for efficiency, that bioassays could rely on a combination of male rats and female mice. Even when concordant positive results are observed, there can still be very great differences in potency, as is observed in aflatoxin-induced tumors in rats and mice. In this example, an almost 100,000-fold difference in susceptibility to aflatoxin B$_1$ (AFB$_1$)-induced liver tumors is seen between the sensitive rat and trout species versus the more resistant mouse strains. Genetic differences in the expression of cytochrome P450 and glutathione-*S*-transferases explain most of these species differences and suggest that humans may be as sensitive to AFB$_1$-induced liver tumors as rats (Eaton and Gallagher, 1994).

Critical problems exist in using the hazard identification data from rodent bioassays for quantitative risk assessments. This is because of the limited dose–response data available from these rodent bioassays and nonexistent response information for environmentally relevant exposures. Results thus have traditionally been extrapolated from a dose–response curve in the 10 to 100 percent biologically observable tumor response range down to 10^{-6} risk estimates (upper confidence limit) or to a benchmark or reference dose-related risk.

Addition of investigations of mechanisms and assessment of multiple noncancer endpoints into the bioassay design represent important enhancements of lifetime bioassays. It is feasible and desirable to tie these bioassays together with mechanistically oriented short-term tests and biomarker and genetic studies in epidemiology (Perera et al., 1991; Perera and Weinstein, 2000). In the example of AFB$_1$ induced liver tumors, AFB$_1$-DNA adducts have proved to be an extremely useful biomarker. A highly linear relationship was observed between liver tumor incidence (in rats, mice, and trout) and AFB$_1$-DNA adduct formation over a dose range of 5 orders of magnitude (Eaton and Gallagher, 1994). Such approaches may allow for an extension of biologically observable phenomena to doses lower than those leading to frank tumor development and help to address the issues of extrapolation over multiple orders of magnitude to predict response at environmentally relevant doses.

Use of Epidemiologic Data in Risk Assessment The most convincing line of evidence for human risk is a well-conducted epidemiologic study in which a positive association between exposure and disease has been observed (NRC, 1983). Epidemiologic studies are essentially opportunistic. Studies begin with known or presumed exposures, comparing exposed versus nonexposed individuals, or with known cases, compared with persons lacking the particular diagnosis. Table 4-5 shows examples of epidemiologic study designs and provides clues on types of outcomes and exposures evaluated. There are important limitations. When the study is exploratory, hypotheses are often weak. Exposure estimates are often crude and retrospective, especially for conditions with long latency before clinical manifestations appear. Generally, there are multiple exposures, especially when a full week or a lifetime is considered. There is always a trade-off between detailed information on relatively few persons and very limited information on large numbers of persons. Contributions from lifestyle factors, such as smoking and diet, are a challenge to sort out. Humans are highly outbred, so the method must consider variation in susceptibility among those who are exposed. The expression of results in terms of odds ratios, relative risks, and confidence intervals may be unfamiliar to nonepidemiologists. Finally, the caveats self-effacing epidemiologists often cite may discourage risk managers and toxicologists!

Table 4-5 Example of Three Types of Epidemiological Study Designs

Nevertheless, human epidemiology studies provide very useful information for hazard identification and sometimes quantitative information for data characterization. Several good illustrations of types of epidemiological studies and their interpretation for toxicological evaluation are given in Checkoway (1994) and Gamble and Battigelli (1991). Three major types of epidemiology study designs are available: cross-sectional studies, cohort studies and case-control studies, as detailed in Table 4-5. Cross sectional studies survey groups of humans to identify risk factors (exposure) and disease but are not useful for establishing cause and effect. Cohort studies evaluate individuals selected on the basis of their exposure to an agent under study. Thus, based on exposure status, these individuals are monitored for development of disease. These prospective studies monitor over time individuals who initially are disease-free to determine the rates at which they develop disease. In case-control studies subjects are selected on the basis of disease status: disease cases and matched cases of disease free individuals. Exposure histories of the two groups are compared to determine key consistent features in their exposure histories. All case-control studies are retrospective studies.

Epidemiologic findings are judged by the following criteria: strength of association, consistency of observations (reproducibility in time and space), specificity (uniqueness in quality or quantity of response), appropriateness of temporal relationship (did the exposure precede responses?), dose–responsiveness, biological plausibility and coherence, verification, and analogy (biological extrapolation) (Hill, 1965). In addition, epidemiologic study designs should be evaluated for their power of detection, appropriateness of outcomes, verification of exposure assessments, completeness of assessing confounding factors, and general applicability of the outcomes to other populations at risk. Power of detection is calculated using study size, variability, accepted detection limits for endpoints under study, and a specified significance level. (See Healey, 1987, for calculation formulas or computer programs such as EPI-INFO; Dean et al., 1995; or EGRET, 1994, for determination of experimental power of detection.)

Recent advances from the human genome project, increased sophistication and molecular biomarkers, and improved mechanistic bases for epidemiologic hypotheses have allowed epidemiologists to get within the "black box" of statistical associations and move forward our understanding of biological plausibility and clinical relevance. "Molecular epidemiology" is a new focus of human studies where improved molecular biomarkers of exposure, effect, and susceptibility have allowed investigators to more effectively link molecular events in the causative disease pathway. Implications of these improvements for risk assessment are tremendous, as they provide an improved biological basis for extrapolation across the diversity of human populations and allow for improved cross-species comparisons with rodent bioassay information. The biological plausibility of epidemiologic associations will be increased remarkably by the use of biomarkers of exposure, effects, and susceptibility (Perera, et al., 1991; Perera and Weinstein, 2000; Omenn, 2000).

Integrating Qualitative Aspects of Risk Assessment

Qualitative assessment of hazard information should include a consideration of the consistency and concordance of findings. Such assessment should include a determination of the consistency of the toxicologic findings across species and target organs, an evaluation of consistency across duplicate experimental conditions, and the adequacy of the experiments to detect the adverse endpoints of interest.

The National Toxicology Program uses several categories to classify bioassay results, with the category *clear evidence of carcinogenicity* describing bioassays where dose-related increases in malignant or combined malignant and benign neoplasms are seen across all doses, or at least significant increases in two of the four species/sex test groups. NTP's evaluation guidelines specify the additional categories of *some, equivocal, no evidence,* and *inadequate study.*

Qualitative assessment of animal or human evidence is done by many agencies, including the EPA and International Agency for Research on Cancer (IARC). Similar evidence classifications have been used for both the animal and human evidence categories by both agencies. These evidence classifications have included levels of sufficient, limited, inadequate, and no evidence (EPA, 1994a) or *evidence suggesting lack of carcinogenicity* (IARC, 1994; 2000). EPA has also included a specific *no data* category.

These evidence classifications are used for overall weight-of-evidence carcinogenicity classification schemes. Although differing group number or letter categories are used, striking similarities exist between these approaches. EPA's newly proposed changes to their risk assessment guidelines for carcinogenic substances include changes in how likelihood categories are used, with references to categories described as *known, likely,* or *not likely* to be carcinogenic to humans. A category representing a *cannot evaluate* level includes *inadequate data, incomplete or inconclusive data,* and *no data* categories.

In this section we have discussed approaches for evaluating cancer endpoints. Similar weight-of-evidence approaches have been proposed for reproductive risk assessment (refer to *sufficient* and *insufficient evidence* categories in EPA proposed guidelines for reproductive risk in EPA, 1996c). The Institute for Evaluating Health Risks defined an "evaluation process" by which reproductive and developmental toxicity data can be consistently evaluated and integrated to ascertain their relevance for human health risk assessment (Moore et al., 1995). Application of such carefully deliberated approaches for assessing noncancer endpoints should help avoid the tendency to list chemicals as yes or no (positive or negative) without human relevancy information.

For many years there has been an information-sharing process aimed at harmonization of chemical testing regimes and clinical trials methodologies, so that data might be accepted in multiple countries that are members of the Organization for Economic Cooperation and Development (OECD). The United Nations Conference on the Environment in Rio de Janeiro, Brazil, in 1992, established harmonization of risk assessment as one of its goals, with a coordinating role for the International

Programme on Chemical Safety. The negotiation in 1994 of the General Agreement on Trade and Tariffs (GATT) and establishment of the World Trade Organization makes harmonization of various aspects of testing, risk assessment, labeling, registration, and standards important elements in trade, not just in regulatory science. Moolenaar (1994) summarized the carcinogen risk assessment methodologies used by various countries as a basis for regulatory actions. He tabulated the risk characterization, carcinogen identification, risk extrapolation, and chemical classification schemes of EPA, U.S. Department of Health and Human Services (DHHS), IARC, ACGIH, Australia, the European Economic Community (EEC), Germany, Netherlands, Norway, and Sweden. The approach of EPA to estimate an upper bound to human risk is unique; all other countries estimate human risk values based on expected incidence of cancer from the exposures under review. The United Kingdom follows a case-by-case approach to risk evaluations for both genotoxic and nongenotoxic carcinogens, with no generic procedures. Denmark, EEC, the United Kingdom (UK), and the Netherlands all divide carcinogens into genotoxic and nongenotoxic agents and use different extrapolation procedures for each. Norway does not extrapolate data to low doses, using instead the TD_{50} to divide category I carcinogens into tertiles by potency. The UK, EEC, and Netherlands all treat nongenotoxic chemical carcinogens as threshold toxicants. A "no observed adverse effect level" (NOAEL) and safety factor are used to set acceptable daily intakes (ADIs). The revised EPA guidelines for cancer risk assessment now propose applying benchmark dose-like methods and consideration of mode-of-action data, which will move the United States toward a more harmonized approach for risk approaches (EPA, 1999).

RISK CHARACTERIZATION

Quantitative considerations in risk assessment include dose—response assessment, exposure assessment, variation in susceptibility, and characterization of uncertainty. For dose–response assessment, varying approaches have been proposed for threshold versus nonthreshold endpoints. Traditionally, threshold approaches have been applied for assessment of noncancer endpoints, and nonthreshold approaches have been used for cancer endpoints. Each approach and its inherent assumptions is discussed below, as are recent efforts to harmonize these approaches.

In general, human exposure data for prediction of human response are quite limited; thus, animal bioassay data have primarily served as the basis for most quantitative risk assessments. However, the risk assessor is normally interested in low environmental exposures of humans, which are well below the experimentally observable range of responses from animal assays. Thus, methods of extrapolation from high dose to low dose and animal risk to human risk are required and make up a major aspect of dose–response assessment.

Dose–Response Assessment

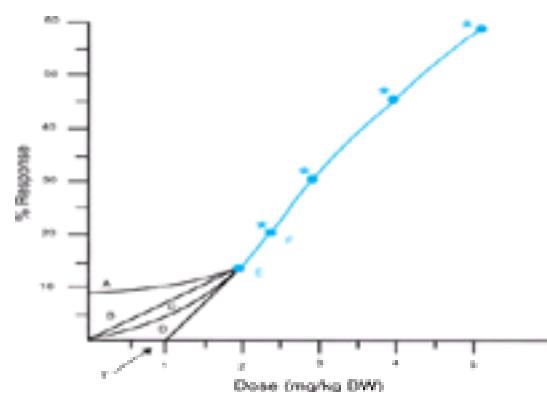
The fundamental basis of the quantitative relationships between exposure to an agent and the incidence of an adverse response is the dose–response assessment. Analysis of dose–response relationships must start with the determination of the critical effects to be quantitatively evaluated. EPA has issued toxicity specific guidelines that are useful in identifying such critical effects (for developmental toxicity, see EPA, 1991b; reproductive toxicity, EPA, 1996c; neurotoxicity, EPA, 1995; cancer, EPA, 1994b, 1996a, 1999). It is usual practice to choose the data sets with adverse effects occurring at the lowest levels of exposure; the "critical" adverse effect is defined as the significant adverse biological effect that occurs at the lowest exposure level (Barnes and Dourson, 1988). Approaches for characterizing threshold dose–response relationships include identification of NOAELs or "lowest observed adverse effect levels" (LOAELs). On the dose–response curve illustrated in Fig. 4-3, the threshold, indicated with a T, represents the dose below which no additional increase in response is observed. The NOAEL is identified as the highest non-statistically significant dose tested; in this example it is point E, at 2 mg/kg body weight. Point F is the LOAEL (2.5 mg/kg body weight), as it is the lowest dose tested with a statistically significant effect.


Figure 4-3. Dose–response curve.

This figure is designed to illustrate a typical dose-response curve with "•'s" indicating the biologically determined responses. Statistical significance of these responses is indicated with a 3 symbol. The threshold dose is shown by T, a dose below which no change in biological response occurs. Point E represents the highest non-statistically significant response point, hence it is the "no observed adverse effect level" (NOAEL) for this example. Point F is the "lowest observed adverse response level" (LOAEL). Curves A to D show possible options for extrapolating the dose-response relationship below the lowest biologically observed data point, E.

In general, animal bioassays are constructed with sufficient numbers of animals to detect low-level biological responses at the 10 percent response range. The risk assessor should always understand the biological significance of the responses being evaluated in order to put such statistical observations in context. *Significance* thus usually refers to both biological and statistical criteria (Faustman et al., 1994) and is dependent upon the number of dose levels tested, the number of animals tested at each dose, and background incidence of the adverse response in the nonexposed control groups. The NOAEL should not be perceived as risk-free, as several reports have shown that the response of NOAELs for continuous endpoints averages 5 percent risk, and NOAELs based on quantal endpoints can be associated with risk of greater than 10 percent (Faustman, et al., 1994, Allen et al., 1994a, 1994b).

As described in Chap. 2, approaches for characterizing dose–response relationships include identification of effect levels such as LD_{50} (dose producing 50 percent lethality), LC_{50} (concentration producing 50 percent lethality), ED_{10} (dose producing 10 percent response), as well as NOAELs (no observed adverse effect levels).

NOAELs have traditionally served as the basis for risk assessment calculations, such as reference doses or acceptable daily intake values. References doses (RfDs) or concentrations (RfCs) are estimates of a daily exposure to an agent that is assumed to be without adverse health impact on the human population. The ADIs are acceptable daily intake values used by WHO for pesticides and food additives to define "the daily intake of chemical, which during an entire lifetime appears to be without appreciable risk on the basis of all known facts at that time" (WHO, 1962) (Dourson et al., 1985). Reference doses (first introduced in Chap. 2) and ADI values typically are calculated from NOAEL values by dividing by uncertainty (UF) and/or modifying factors (MF) (EPA, 1991a; (Dourson and DeRosa, 1991; Dourson and Stara, 1983).

$$RfD = NOAEL / (UF * MF)$$
$$ADI = NOAEL / (UF * MF)$$

In principle, dividing by these factors allows for interspecies (animal-to-human) and intraspecies (human-to-human) variability with default values of 10 each. An additional uncertainty factor can be used to account for experimental inadequacies—for example, to extrapolate from short-exposure-duration studies to a situation more relevant for chronic study or to account for inadequate numbers of animals or other experimental limitations. If only a LOAEL value is available, then an additional 10-fold factor commonly is used to arrive at a value more comparable to a NOAEL. Allen et al. (1994) have shown for developmental toxicity endpoints that application of the 10-fold factor for LOAEL-to-NOAEL conversion is too large. Traditionally, a safety factor of 100 would be used for RfD calculations to extrapolate from a well-conducted animal bioassay (10-fold factor animal to human) and to account for human variability in response (10-fold factor human-to-human variability).

Modifying factors can be used to adjust the uncertainty factors if data on mechanisms, pharmacokinetics, or relevance of the animal response to human risk justify such modification. For example, if there is kinetic information suggesting that rat and human metabolism are very similar for a particular compound, producing the same active target metabolite, then—rather than using a 10-fold uncertainty factor to divide the NOAEL from the animal toxicity study to obtain a human relevant RfD—a factor of 3 for that uncertainty factor might be used. Of particular recent interest is the new extra 10-fold Food Quality and Protection Act (FQPA) factor, added

to ensure protection of infants and children (EPA, 1996b). Under this law an additional uncertainty factor is added to ensure protection of children's health; it is currently being used for determining allowable pesticide chemical residues. This factor is designed to take into account potential pre- and postnatal toxicity and to overcome the incompleteness of toxicity and exposure data (FQPA; PL 104-170). Illustrative discussions on how such a legislatively mandated uncertainty factor might be applied are available from EPA (1999) and from Schardein and Scialli (1999) for chlorpyrifos as an example compound.

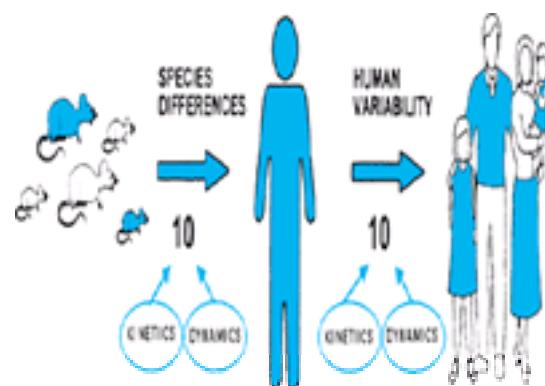
Recent efforts have focused on using data-derived factors to replace the 10-fold uncertainty factors traditionally used in calculating RfDs and ADIs. Such efforts have included reviewing the human pharmacologic literature from published clinical trials (Silverman et al., 1999) and developing human variability databases for a large range of exposures and clinical conditions (Hattis et al., 1999a, 1999b; Hattis and Silver, 1994). Toward this goal, Renwick has separated the intra-and interspecies uncertainty factors into two components: toxicokinetic (TK) and toxicodynamic (TD) aspects (Renwick, 1991; 1999; Johnson et al., 1997). Figure 4-4 shows these distinctions. A key advantage of this approach is that it provides a structure for incorporating scientific information on specific aspects of the overall toxicologic process into the reference dose calculations; thus, relevant data can replace a portion of the overall "uncertainty" surrounding these extrapolations. Initially Renwick proposed a factor of 4 for the TK and a factor of 2.5 for the TD component for both the interspecies and inter-individual factors (Renwick and Walker, 1993). However, subsequent evaluations have supported the revised WHO (1994) guidance, which retains the 4.0- and 2.5-fold factors for the TK and TD interspecies components but changes both the inter-individual TK and TD factors to 3.2. Such changes highlight the flexibility of this approach to incorporate new conclusions and even compound-specific data (Renwick and Lazarus, 1998).


Figure 4-4. Toxicokinetic (TK) and toxicodynamic (TD) considerations inherent in interspecies and inter-individual extrapolations.

Toxicokinetics refers to the processes of absorption, distribution, elimination, and metabolism of a toxicant. *Toxicodynamics* refers to the actions and interactions of the toxicant within the organism and describes processes at organ, tissue, cellular, and molecular levels. This figure shows how uncertainty in extrapolation both across and within species can be considered as being due to two key factors: a kinetic component and a dynamic component. Refer to the text for detailed explanations. (Adapted from Renwick, 1999, 1998.)

This overall approach has important implications for how we utilize new toxicologic research. Most efforts to modify the uncertainty factors have focused on more effective use of toxicokinetic information, yet there is also a need to focus on the toxicodynamic aspects of this uncertainty. For example, a Nuclear Regulatory Commission (NRC) report that reviewed how new advances in developmental biology can improve the research relevant for developmental toxicology risk assessment has identified highly conserved cell signaling pathways essential for all development processes across all species (NRC, 2000). Such "dynamic" information is not yet being considered following chemical impacts, but such data on known similarities in comparison of critical pathways across species may be useful in reducing the uncertainty in the TD components of the interspecies portion of the equation. This is one example of how new information may enhance the scientific basis of our approaches for risk assessment.

NOAEL values have also been utilized for risk assessment by evaluating a "margin of exposure" (MOE), where the ratio of the NOAEL determined in animals and expressed as mg/kg/day is compared with the level to which a human may be exposed. For example, human exposures to a specific chemical agent are calculated to be solely via drinking water, and the total daily intake of the compound is 0.04 mg/kg/day. If the NOAEL for neurotoxicity is 100 mg/kg/day, then the MOE would be 2500 for the oral exposure route for neurotoxicity. Such a large value is reassuring to public health officials. Low values of MOE indicate that the human levels of exposure are close to levels for the NOAEL in animals. There is usually no factor included in this calculation for differences in human or animal susceptibility or animal-to-human extrapolation; thus, MOE values of less than 100 have been used by regulatory agencies as flags for requiring further evaluation. A "margin of safety" (MOS) can also be calculated and is frequently utilized in evaluating pharmaceutical agents where an effective therapeutic dose is compared with a dose causing toxicity (see Chap. 2).

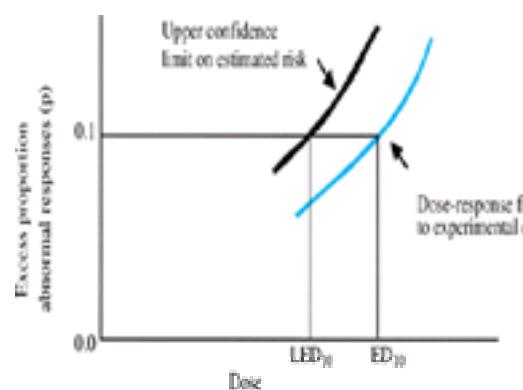
The NOAEL approach has been criticized on several points, including that (1) the NOAEL must, by definition, be one of the experimental doses tested; (2) once this is identified, the rest of the dose–response curve is ignored; (3) experiments that test fewer animals result in larger NOAELs and thus larger reference doses, rewarding testing procedures that produce less certain rather than more certain NOAEL values; and (4) the NOAEL approach does not identify the actual responses at the NOAEL and will vary based on experimental design, leading to setting of regulatory limits at varying levels of risk. Because of these limitations, an alternative to the NOAEL approach, the benchmark dose (BMD) method, was first proposed by Crump (1984) and extended by Kimmel and Gaylor (1988). In this approach, the dose response is modeled and the lower confidence bound for a dose at a specified response level [benchmark response (BMR)] is calculated. The BMR is usually specified at 1, 5, or 10 percent. Figure 4-5 shows how a BMD is calculated using a 10 percent benchmark response and a 95 percent lower confidence bound on dose. The BMDx (with x representing the percent benchmark response) is used as an alternative to the NOAEL value for reference dose calculations. Thus, the RfD would be


Figure 4-5. Illustration of benchmark dose (BMD) approach.

The LED_{10} is the lower confidence limit of the dose (ED_{10}) associated with a 10 percent incidence of adverse effect. (Based on Kavlock, 1995.)

$$RfD = BMDx/UF * MF$$

The proposed values to be used for the uncertainty factors and modifying factors for BMDs can range from the same factors as for the NOAEL to lower values due to increased confidence in the response level and increased recognition of experimental variability due to use of a lower confidence bound on dose (Barnes et al., 1995). EPA has developed software for the application of benchmark dose methods (http://www.epa.gov/ncea/bmds.htm) and is developing a technical guidance document to provide guidelines for application of BMDs (EPA, 2000c). These guidelines will address issues of appropriate response levels to be used for various endpoints and

how to utilize the LED_x versus ED_x in RfD calculations.

The benchmark dose approach has been applied to study several non-cancer endpoints, including developmental (Allen et al., 1994a, 1994b) and reproductive toxicity (Auton, 1994). The most extensive studies with developmental toxicity have shown that BMD_{05} values were similar to a statistically derived NOAEL for a wide range of developmental toxicity endpoints and that results from using generalized dose–response models were similar to statistical models designed specifically to represent unique features of developmental toxicity testing. A generalized log logistic dose response model offered other advantages in dealing with litter size and intralitter correlations (Allen et al., 1994b).

Advantages of the benchmark dose approach can include (1) the ability to take into account the full dose–response curve, as opposed to focusing on a single test dose as is done in the NOAEL approach; (2) the inclusion of a measure of variability (confidence limit); (3) the use of responses within the experimental range versus extrapolation of responses to low doses not tested experimentally; and (4) the use of a consistent benchmark response level for RfD calculations across studies. Obviously, limitations in the animal bioassays in regard to minimal test doses for evaluation, shallow dose responses, and use of study designs with widely spaced test doses will limit the utility of these assays for any type of quantitative assessments, whether NOAEL- or BMD-based approaches.

Some common environmental exposures—such as those for lead and other criteria air pollutants—are so close to LOAELs that the regulatory agencies use an informal margin-of-safety approach heavily weighted with consideration of technical feasibility (see Risk Commission, 1997).

Nonthreshold Approaches

As Fig. 4-3 shows, numerous dose–response curves can be proposed in the low-dose region of the dose–response curve if a threshold assumption is not made. Because the risk assessor generally needs to extrapolate beyond the region of the dose–response curve for which experimentally observed data are available, the choice of models to generate curves in this region has received lots of attention. For nonthreshold responses, methods for dose–response assessments have also utilized models for extrapolation to de minimus ($10^{-4} – 10^{-6}$) risk levels at very low doses, far below the biologically observed response range and far below the effect levels evaluated for threshold responses. Two general types of dose–response models exist: statistical (or probability distribution models) and mechanistic models (Krewski and Van Ryzin, 1981).

The distribution models are based on the assumption that each individual has a tolerance level for a test agent and that this response level is a variable following a specific probability distribution function. These responses can be modeled using a cumulative dose–response function. Chapter 2 discusses the common normal distribution pattern (see Fig. 2-3). A log probit model estimates the probability of response at a specified dose (d); thus, P(d) = F[a + b log d], where F is the cumulative function for a standard normal distribution of the log tolerances with standard deviations s and mean μ, a equals μ/s, and b equals the slope of the probit line (–1/s). The probit curve at low doses usually assumes an S -shape. Chapter 2 discusses determination of the LD_{50} value from such a curve. However, extrapolation of the experimental data from 50 percent response levels to a: "safe," "acceptable," or "de minimus" level of exposure—e.g., one in a million risk above background—illustrates the huge gap between scientific observations and highly protective risk limits (sometimes called *virtually safe doses,* or those corresponding to a 95 percent upper confidence limit on adverse response rates).

The log logistic model was derived from chemical kinetic theory. The probability of response at dose d is defined as P(d) = [1 - exp (a + b log d)]$^{-1}$. Like the probit model, this model defines sigmoidal curves that are symmetrical around the 50 percent response level; however, the log logistic curves approach the 0 and 100 percent response levels with a more shallow curve shape. The logit and probit curves are indistinguishable in fitting the data in the region of the response curve where experimentally derived data are present (Brown, 1984; Hartung, 1987).

Models Derived from Mechanistic Assumptions

This modeling approach designs a mathematical equation to describe dose–response relationships that are consistent with postulated biological mechanisms of response. These models are based on the idea that a response (toxic effect) in a particular biological unit (animal, human, pup, etc.) is the result of the random occurrence of one or more biological events (stochastic events).

Radiation research has spawned a series of such "hit models" for cancer modeling, where a hit is defined as a critical cellular event that must occur before a toxic effect is produced. These models assume that (1) an infinitely large number of targets exists, for example in the DNA; (2) the organism responds with a toxic response only after a minimum number of targets has been modified; (3) a critical target is altered if a sufficient number of hits occurs; and (4) the probability of a hit in the low dose range of the dose–response curve is proportional to the dose of the toxicant (Brown, 1984).

The simplest mechanistic model is the one-hit (one-stage) linear model in which only one hit or critical cellular interaction is required for a cell to be altered. For example, based on somatic mutation theory, a single mutational change would be sufficient for a cell to become cancerous through a transformational event and dose-independent clonal expansion. The probability statement for these models is P(d) = 1 – exp $^{(-ld)}$, where ld equals the number of hits occurring during a time period. A single molecule of a genotoxic carcinogen would have a minute but finite chance of causing a mutational event.

As theories of cancer have grown in complexity, so too have these hit-based mechanistic models. Multihit models have been developed that can describe hypothesized single-target multihit events, as well as multitarget, multihit events in carcinogenesis. The probability statements for these models is P(d) = $\int_0^{\lambda d} x^{k-1} \exp(-x)/\Gamma(k)$ dx, where G(k) denotes the gamma function with k = critical number of hits for the adverse response. The Weibull model has a dose–response function with characteristics similar to those of the multihit models, where the response equation is P(d) = 1 – exp [–ld ^{k}]. Here again, k = critical number of hits for the toxic cellular response.

Armitage and Doll (1957) developed a multistage model for carcinogenesis that was based on these equations and on the hypothesis that a series of ordered stages was required before a cell could undergo mutation, initiation, transformation, and progression to form a tumor. This relationship was generalized by Crump (1980) by maximizing the likelihood function over polynomials, so that the probability statement is:

$$P(d) = 1 - \exp [-(l_0 + l_1 d^1 + l_2 d^2 \ldots l_k d^k)]$$

If the true value of l_1 is replaced with l_1^* (the upper confidence limit of l_1), then a linearized multistage model can be derived where the expression is dominated by (ld*)d at low doses. The slope on this confidence interval, q$_1$*, is used by EPA for quantitative cancer assessment. To obtain an upper 95 percent confidence interval on risk, the q$_1$* value (risk/D dose in mg/kg/ day) is multiplied by the amount of exposure (mg/kg/day). Thus, the upper-bound estimate on risk (R) is calculated as:

$$R = q_1^* [risk(mg/kg/day)^{-1}] \times exposure (mg/kg/day)$$

This relationship has been used to calculate a "virtually safe dose" (VSD), which represents the lower 95 percent confidence limit on a dose that gives an "acceptable level" of risk (e.g., upper confidence limit for 10^{-6} excess risk). The integrated risk information system (IRIS) developed by EPA gives q* values for many environmental carcinogens (EPA, 2000a). Because both the q$_1$* and VSD values are calculated using 95 percent confidence intervals, the values are believed to represent conservative, protective estimates. The use of the maximum likelihood estimates (MLE values) from the linearized multistage models has not been accepted due to problems in the stability of MLE estimates at low dose using the linearized multistage (LMS) model.

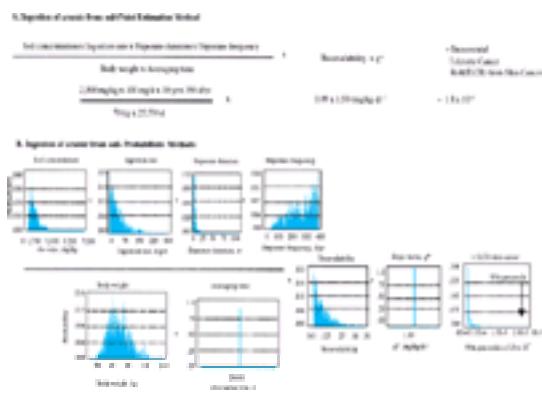
The EPA has utilized the LMS model to calculate "unit risk estimates" in which the upper confidence limit on increased individual lifetime risk of cancer for a 70-kg human breathing 1 μg/m^3 of contaminated air or drinking 2 L/day of water containing 1 ppm (1mg/L) is estimated over a 70-year life span. The example given in Fig. 4-7 shows calculation of incremental lifetime cancer risk (ILCR) of skin cancer using soil exposure and q* values for inorganic arsenic.


Figure 4-7. Example of risk calculations for incremental lifetime cancer risk (ILCR) of skin cancer due to ingestion of arsenic in soil.

A. Point exposure estimation method for calculation of ILCR. Point estimates for arsenic exposure input parameters are used in this example to calculate the ILCR. This exposure estimate is multiplied by the bioavailability of arsenic in soil to calculate the dose. Multiplication of the dose by the slope factor (q*) yields the lifetime risk. *B.* Probabilistic exposure methods for calculating the incremental lifetime cancer risk (ILCR) from arsenic ingestion. In this example, the soil concentration, ingestion rate, exposure duration and frequency, body weight, and bioavailability are modeled as distributions. Note that q* and averaging time (years) are given as single-point estimations. This method yields a distribution of ILCR, with a 95th percentile upper confidence interval of 2.3×10^{-5}. (From Calabrese, 1989; Davis, 1990; EPA, 1989a, 1989b, 1992, 1999; Israeli, 1992; Brorby, 1993; ATSDR, 1998.)

Toxicologic Enhancements of the Models

Three exemplary areas of research that have improved the models used in risk extrapolation are time to tumor information, physiologically based toxicokinetic modeling, and biologically based dose–response modeling (Albert, 1994). Chapter 7 discusses in detail improvements in our estimation of exposure and offers approaches on how to model "target internal effective dose" in risk assessment rather than just using single-value "external exposure doses." In this chapter we discuss the biologically based dose– response (BBDR) modeling.

BBDR modeling aims to make the generalized mechanistic models discussed in the previous section more clearly reflect specific biological processes. Measured rates are incorporated into the mechanistic equations to replace default or computer-generated values. For example, the Moolgavkar-Venson-Knudson (MVK) model is based on a two-stage model for carcinogenesis, where two mutations are required for carcinogenesis and birth and death rates of cells are modeled through clonal expansion and tumor formation. This model has been applied effectively to human epidemiologic data on retinoblastoma. In animal studies, kidney and liver tumors in the 2-acetylaminofluorene (2-AAF) "mega mouse" study, bladder cancer in saccharin-exposed rats, rat lung tumors following radiation exposure, rat liver tumors following N-nitrosomorpholine exposure, respiratory tract tumors following benzo[a]pyrene exposure, and mouse liver tumors following chlordane exposure have been modeled (NRC, 1993a; Cohen and Ellwein, 1990; Moolgavkar and Luebeck, 1990). Additional applications are needed to continue validation of the model (NRC, 1993a). EPA relied on receptor binding theory in its 1994 dioxin risk reassessment (EPA, 1994b) and is currently considering expanded mechanism-based cancer modeling approaches where cytochrome P450 1A2 (CYP1A2) or epidermal growth factor (EGF) receptor concentrations are used as surrogate dose metrics within these two-stage cancer models. Kohn et al. (1993) and Anderson et al. (1993) have used physiologically based toxicokinetics (PBTK) and BBDR information to improve dioxin risk assessment.

Development of biologically based dose–response models for endpoints other than cancer are limited; however, several approaches have been explored in developmental toxicity, utilizing cell cycle kinetics, enzyme activity, litter effects, and cytotoxicity as critical endpoints (Rai and Van Ryzin, 1985; Faustman et al., 1989; Shuey et al., 1994; Leroux et al., 1996, 2000). Of particular interest are approaches that link pregnancy-specific toxicokinetic models with temporally sensitive toxicodynamic models for developmental impacts (Faustman et al., 1999). Unfortunately, there is a lack of specific, quantitative biological information for most toxicants and for most endpoints (NRC, 2000).

In the absence of detailed mechanistic information, EPA has proposed, in their revised cancer guidelines, use of "mode of action" (MOA) information (EPA, 1999). MOA information describes key events and processes leading to molecular and functional effects that would in general explain the overall process of cancer development. In many cases these could be plausible hypothesized MOAs for both cancer and other toxicity endpoints, but the detailed mechanistic nuances might not be fully investigated. EPA has proposed using such MOA information to suggest specific, nondefault approaches for cancer risk assessments and for evaluating toxicity of compounds with common MOAs in cumulative risk assessments (EPA, 1996b, 1998b). For cancer risk assessments, this means using benchmark-like "points of departure" at the ED_{01} or LED_{01} and using a slope from that point that could represent linear or nonlinear options. This would bring quantitative approaches for carcinogens into a similar construct as what is proposed for quantitation of noncancer endpoints. Such approaches are being discussed in EPA's new draft cancer guidelines (EPA, 1999). These build upon guidance developed by the WHO's International Programme on Chemical Safety Harmonization Project (WHO, 2000). Critical to the MOA development is the use of "criteria of causality" considerations, which build on Hill criteria used in epidemiology (Hill, 1965; Faustman et al., 1996; EPA 1999). MOA-based approaches should facilitate incorporation of new scientific information and hence be responsive to the challenges outlined in the 1994 NRC report (NRC, 1994).

One of the key challenges over the next decade for toxicologists doing risk assessments will be interpretation and linking of observations from highly sensitive molecular and genome-based methods with the overall process of toxicity (NRC, 2000; Iyers et al., 1999; Andersen and Barton, 1999; Eisen et al., 1998; Limbird and Taylor, 1998). The basic need for linkage of observations was highlighted in early biomarker work. NRC reports on biomarkers (NRC, 1989a, 1989b, 1992a, 1992b) drew distinctions for biomarkers of effect, exposure, and susceptibility across a continuum of exposure, effect, and disease/toxicity. Biomarkers of early effects, like frank clinical pathology, arise as a function of exposure, response, and time. Early, subtle, and possibly reversible effects can generally be distinguished from irreversible disease states.

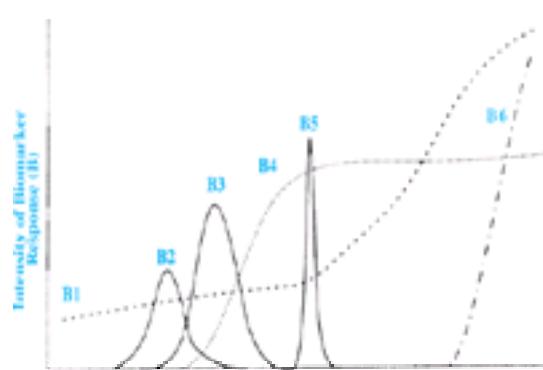
Nowhere is the challenge for interpretation of early and highly sensitive responses (biomarkers) made clearer than in the complicated data from gene expression arrays. Because our relatively routine ability to monitor gene responses—up to tens of thousands of them simultaneously—has grown exponentially in the last 5 years, the need for toxicologists to interpret such observations for risk assessment and for the overall process of toxicity has been magnified with equal or greater intensity. Figure 4-6 provides a simplified but illustrative example of multiple biomarker responses with dose or time. For microarray data, each gene response or cluster of genes can have its own pattern of response (peak and overall duration of response). For this to be meaningful for the overall process of toxicity, such responses (e.g., responses B2, B3, and B4) need to be examined in relationship to toxicity. In this example, developmental toxicity could be modeled as response B1 and lethality as B6. In order to describe these responses as relevant for either endpoint of toxicity, the strength, consistency, and coherence of both the temporal and dose relationships would need to be established (Faustman et al., 1999).


Figure 4-6. Hypothetical biomarker response relationships.

This figure illustrates a variety of dose-related biomarker responses shown as biomarker intensity (B) plotted against dose or time. The text expands upon the

potentially complex relationships between biomarkers of early effect versus toxicity that can occur when very sensitive molecular biomarkers are utilized for toxicity assessment. (Adapted from Waterfield and Timbrell, 1999, and Depledge, 1993.)

Microarray analysis for risk assessment will require much more sophisticated analyses than the cluster analysis techniques currently described in the literature (Eisen et al., 1998). Semiparametric likelihood models and Bayesian inference approaches are promising (Griffith and Brutlage, 2000), as are support vector machine methods (Brown et al., 2000). Because of the vast number of measured responses with gene expression arrays, pattern analysis techniques are being used. However, the extensive databases across chemical classes, pathological conditions, and stages of disease progression that are essential for these analyses are only now being developed through federal funding (NCI Cancer Genome Anatomy Project and NIEHS Environmental Genome Project) and by pharmaceutical agencies and trade organizations. For toxicologists and risk assessors, it will be both exciting and challenging to be faced with interpretation of results from such amazingly sensitive tools (NRC, 2000).

Exposure Assessment

The primary objectives of exposure assessment are to determine source, type, magnitude, and duration of contact with the agent of interest. Obviously, this is a key element of the risk assessment process, as hazard does not occur in the absence of exposure. However, it is also frequently identified as the key area of uncertainty in the overall risk determination. Here, the primary focus is on uses of exposure information in quantitative risk assessment.

Obviously, the primary goal of such calculations is to determine not only the type and amount of total exposure but also to find out specifically how much may be reaching target tissues. A key step in making an exposure assessment is determining what exposure pathways are relevant for the risk scenario under development. The subsequent steps entail quantitation of each pathway identified as a potentially relevant exposure and then summarizing these pathway-specific exposures for calculation of overall exposure. The EPA has published numerous documents which provide guidelines for determining such exposures (EPA, 1992, EPA 1989a). Such calculations can include an estimation of total exposures for a specified population as well as calculation of exposure for highly exposed individuals. The use of a hypothetical maximally exposed individual (MEI) is no longer favored in exposure assessment due to its extremely conservative assumptions at each step of the estimation. However, point estimates of exposure continue to utilize high-end and theoretical upper-bound exposure estimates.

Conceptually such calculations are designed to represent "a plausible estimate" of exposure of individuals in the upper 90th percentile of the exposure distribution. Upper-bound estimations would be "bounding calculations" designed to represent exposures at levels that exceed the exposures experienced by all individuals in the exposure distribution and are calculated by assuming limits for all exposure variables. A calculation for individuals exposed at levels near the middle of the exposure distribution is a central estimate. Figure 4-7 gives example risk calculations using two types of exposure estimation procedures (EPA, 1989a, 1989b, 1992). Part A shows a point estimation method for the calculation of arsenic (As) exposure via a soil ingestion route. In this hypothetical scenario, As exposure is calculated using point estimates, and a lifetime average daily dose (LADD) is calculated as follows:

$$LADD = \frac{\text{concentration of the} \times \text{contact} \times \text{contact} \times \text{exposure}}{\text{toxicant in the} \quad \text{rate} \quad \text{fraction} \quad \text{duration}}{\text{exposure media}}{(\text{body weight})(\text{lifetime})}$$

Many exposures are now estimated using exposure factors probability distributions rather than single point estimates for the factors within the LADD equation (Finley et al., 1994; Cullen and Frey, 1999). Such approaches can provide a reality check and can be useful for generating more realistic exposure profiles. Part B of Fig. 4-7 shows how this is done using an example arsenic risk scenario with soil As concentration, ingestion rate, exposure duration, frequency, body weight, and bioavailability modeled as distributed variables. Using Monte Carlo simulation techniques, an overall incremental lifetime cancer risk (ILCR) distribution can be generated and a 95th percentile for population risk obtained. The *EPA Exposure Factors Handbook*, which is on-line (http://www. epa.gov/nceawww1/exposure.htm), provides useful information about exposure distributions (EPA, 1989b). This handbook also provides exposure information for specific populations of interest; for example, see Table 4-6 for an example of age-specific exposure information for infants and children for drinking water intake. Exposure data for drinking water, food consumption, soil ingestion, inhalation rates, dermal absorption, product use, and human activity patterns are included on this database.

AGE GROUP	INTAKE (mL/day) MEAN	10th-90th PERCENTILES	INTAKE (mL/kg-day) MEAN	10th-90th PERCENTILES
Infants (<1 year)	302	0-649	43.5	0-101.8
Children (1-10 years)	736	286-1294	35.5	12.5-64.4
Teens (11-19 years)	965	353-1701	18.2	6.5-32.3
Adults (20-64 years)	1366	559-2268	19.9	8.1-33.7
Adults (65+ years)	1459	751-2287	21.8	10.9-34.7
All ages	1193	423-2092	22.6	8.2-30.8

Table 4-6 Example Exposure Factor Handbook Information: Drinking Water Intake

Additional considerations for exposure assessments include how time and duration of exposures are evaluated in risk assessments. In general, estimates for cancer risk use averages over a lifetime. In a few cases, short-term exposure limits (STELs) are required (for example, ethylene oxide) and characterization of brief but high levels of exposure is required. In these cases exposures are not averaged over the lifetime. With developmental toxicity, a single exposure can be sufficient to produce an adverse developmental effect; thus, daily doses are used, rather than lifetime weighted averages. This is also important due to the time-dependent specificity of many adverse developmental outcomes and invalidation of Haber's law seen with developmental toxicity (Weller et al., 1999; EPA, 1991a).

The Food Quality Protection Act of 1996 has highlighted the need for several additional exposure and risk considerations (EPA, 1996b). These include the need to evaluate total exposures by determining aggregate exposure measures for all exposures to a single substance. Cross-media exposure analyses such as those conducted for lead and mercury are good examples of the value of looking at such total exposures in evaluating human risks. *Cumulative exposures* and *cumulative risk* refer to the total exposure to a group of compounds with similar modes of toxicity. For example, EPA is identifying and categorizing pesticides that act by a common mode of action, and such discussions of cumulative exposures to classes of organophosphates with similar modes of toxic action have been used as examples of classes of pesticides for which cumulative exposure and cumulative risk estimates are needed (EPA, 1998b; ILSI, 1999).

Variation in Susceptibility

Toxicology has been slow to recognize the marked variation among humans. Generally, assay results and toxicokinetic modeling utilize means and standard deviations to measure variation, or even standard errors of the mean, to make the range as small as possible. Outliers are seldom investigated. However, in occupational and environmental medicine, physicians are often asked, "Why me, Doc?" when they inform the patient that exposures on the job might explain a clinical problem. The patient insists that he or she is "no less careful than the next person." So it is important to know whether and how this patient might be at higher risk than others. Furthermore, EPA and OSHA are expected under the Clean Air Act and the Occupational Safety and Health Act to promulgate standards that protect the most susceptible subgroups or individuals in the population. By focusing investigators on the most susceptible individuals, there might also be a better chance of recognizing and elucidating underlying mechanisms (Omenn et al., 1990).

Host factors that influence susceptibility to environmental exposures include genetic traits, sex and age, preexisting diseases, behavioral traits (most importantly,

smoking), coexisting exposures, medications, vitamins, and protective measures. Genetic studies are of two kinds: (1) investigations of the effects of chemicals and radiation on the genes and chromosomes, which are termed *genetic toxicology* (Chap. 9)—these tests measure evidence and rates of mutations, adduct formation, chromosomal aberrations, sister chromatid exchange, DNA repair and oncogene activation; and (2) ecogenetic studies, identifying inherited variation in susceptibility (predisposition and resistance) to specific exposures, ranging across pharmaceuticals ("pharmacogenetics"), pesticides, inhaled pollutants, foods, food additives, sensory stimuli, allergic and sensitizing agents, and infectious agents. Inherited variation in susceptibility has been demonstrated for all these kinds of external agents. In turn, the ecogenetic variation may affect either the biotransformation systems that activate and detoxify chemicals or the sites of action in target tissues.

Ecogenetics is still in its infancy; development of new methods and specific biomarkers of biotransformation and sites of action of chemicals may permit rapid advances (Nebert, 1999). With the rapid progress on the human genome project, identification of human polymorphisms has greatly expanded. A database of particular interest is the Human DNA Polymorphisms database (http://192.236.17.70:80/genetics), which contains significant information of Human DNA polymorphisms and their analysis. Cytochrome P450 polymorphisms are discussed at http://www. imm.ki.se/CYPalleles.

INFORMATION RESOURCES

The Toxicology Data Network (TOXNET) (http://sis.nlm.nih.gov/ sis1/) from the National Library of Medicine provides access to a cluster of databases on toxicology, hazardous chemicals, and related areas including EPA's Integrated Risk Information System (IRIS) (EPA, 2000a), Hazardous Substances Data Bank, the National Cancer Institute's Chemical Carcinogenesis Research Information System, and EPA's Gene-Tox peer-reviewed mutagenicity test database. These information sources vary in the level of assessment included in the database, ranging from just listings of scientific references without comment to extensive peer-reviewed risk assessment information.

The World Health Organization (http://www.who.int) pro-vides chemical-specific information through the International Programme on Chemical Safety (http://www.who.int/pcs/IPCS/ index.htm) criteria documents and health and safety documents (WHO, 2000). The International Agency for Research on Cancer (IARC) provides information on specific classes of carcinogens as well as individual agents. The National Institutes for Environmental Health Sciences (NIEHS) National Toxicology Program provides technical reports on the compounds tested as a part of this national program and in its report on carcinogens (ninth report released in year 2000) also provides carcinogen-specific information (http://ehis.niehs.nih.gov/roc/toc9.html).

RISK PERCEPTION AND COMPARATIVE ANALYSES OF RISK

Individuals respond very differently to information about hazardous situations and products, as do communities and whole societies (Fischhoff, 1981, 1993, 1996; Sandman, 1993; NRC, 1996; Risk Commission, 1997; Institute of Medicine, 1999). Understanding these behavioral responses is critical in stimulating constructive risk communication and evaluating potential risk management options. In a classic study, students, League of Women Voters members, active club members, and scientific experts were asked to rank 30 activities or agents in order of their annual contribution to deaths (Slovic et al., 1979). Club members ranked pesticides, spray cans, and nuclear power as safer than did other lay persons. Students ranked contraceptives and food preservatives as riskier and mountain climbing as safer than did others. Experts ranked electric power, surgery, swimming, and x-rays as more risky and nuclear power and police work as less risky than did lay persons. There are also group differences in perceptions of risk from chemicals among toxicologists, correlated with their employment in industry, academia, or government (Neal et al., 1994).

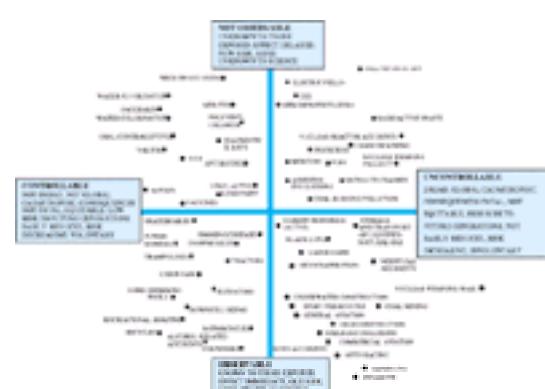
Psychological factors such as dread, perceived uncontrollability, and involuntary exposure interact with factors that represent the extent to which a hazard is familiar, observable, and "essential" for daily living (Lowrance, 1976; Morgan, 1993). Figure 4-8 presents a grid on the parameters controllable/ uncontrollable and observable/not observable for a large number of risky activities; for each of the two paired main factors, highly correlated factors are described in the boxes.


Figure 4-8. Perceptions of risk illustrated using a "risk space" axis diagram.

Risk space has axes that correspond roughly to a hazard's perceived "dreadedness" and to the degree to which it is familiar or observable. Risks in the upper right quadrant of this space are most likely to provoke calls for government regulation. (Morgan, 1993; Slovic, 1988.)

Public demand for government regulations often focuses on involuntary exposures (especially in the food supply, drinking water, and air) and unfamiliar hazards, such as radioactive waste, electromagnetic fields, asbestos insulation, and genetically modified crops and foods. Many people respond very negatively when they perceive that information about hazards or even about new technologies without reported hazards has been withheld by the manufacturers (genetically modified foods) or by government agencies (HIV-contaminated blood transfusions in the 1980s; extent of hazardous chemical or radioactive wastes).

Perceptions of risk led to the addition of an extra safety factor (default value 10) for children in the Food Quality Protection Act of 1996. Engineering-based "as low as reasonably achievable" (ALARA) approaches also reflect the general "precautionary principle," which is strongly favored by those who, justifiably, believe we are far from knowing all risks given the limited toxicity testing (Roe et al., 1997).

A politically controversial matter has been the introduction of organized comparative risk assessment projects. Comparative risk analysis is a planning and decision-influencing tool that ranks various kinds of environmental problems to establish their relative significance and priority for action. Many states have mounted explicit programs. EPA Science Advisory Board reports entitled *Unfinished Business* (EPA, 1987) and *Reducing Risk* (EPA, 1990) were significant priority-setting exercises. This approach is so logical that it may be surprising to learn that comparisons of risks are so controversial. Public health and environmental agency officials routinely practice comparative risk assessment, at least intuitively, in deciding how to allocate their own time, their staff's time, and other resources. They must make judgments about what and how to advise their local communities about potential and definite risks. They must anticipate the question "Compared to what?"

Most people, of course, regularly compare risks of alternative activities—on the job, in recreational pursuits, in interpersonal interactions, and in investments. Since 1993, members of Congress have pressed for the systematic use by federal regulatory agencies of comparisons of similar and dissimilar risks. The aim was to make the benefits and costs of health, safety, and environmental protection more explicit and more comprehensible, with more cost-effective decisions. However, determining how best to conduct comparative risk analyses has proved difficult due to the great variety of health and environmental benefits, the gross uncertainties of dollar estimates of benefits and costs, and the different distributions of benefits and costs across the population. Even more important than these technical challenges was the highly partisan nature of the debate during 1994–1995, as these analytical schemes were linked with strong antiregulatory proposals and characterized by opponents as tactics for avoiding necessary actions.

From the other side of the political spectrum a broad concept called "environmental justice" has emerged, reflecting the ethical guidance that poor, disenfranchised neighborhoods should be protected as much as well-to-do neighborhoods (Rios et al., 1993; Institute of Medicine, 1999). In fact, the poor may need greater protection due to coexisting higher risk factors for poor pregnancy outcomes, impaired growth and development, smoking-related cancers, asthma, lead toxicity, and other health problems. On the other hand, the compelling needs to overcome low rates of prenatal care and childhood immunization, acute lead toxicity from bullets, poor housing, lack of education, and joblessness or low-wage jobs often make hypothetical or long-term relatively low-level estimated risks from chemical pollutant exposures less

salient to these communities. One approach to a comprehensive assessment of priorities is the preparation of specific "community risk profiles" (Wernick, 1995).

SUMMARY

The National Research Council and Risk Commission frameworks for risk assessment and risk management provide a consistent databased approach for evaluating risks and taking action to reduce risks. The objectives of risk assessments vary with the issues, risk management needs, and statutory requirements. However, the frameworks are sufficiently flexible to address these various objectives and to accommodate new knowledge while also providing guidance for priority setting in industry, environmental organizations, and government regulatory and public health agencies. Toxicology, epidemiology, exposure assessment, and clinical observations can be linked with biomarkers, cross-species investigations of mechanisms of effects, and systematic approaches to risk assessment, risk communication, and risk management. Advances in toxicology are certain to improve the quality of risk assessments for a broad array of health endpoints as scientific findings substitute data for assumptions and help to describe and model uncertainty more credibly.

CHAPTER 5

ABSORPTION, DISTRIBUTION, AND EXCRETION OF TOXICANTS

Karl K. Rozman and Curtis D. Klaassen

INTRODUCTION

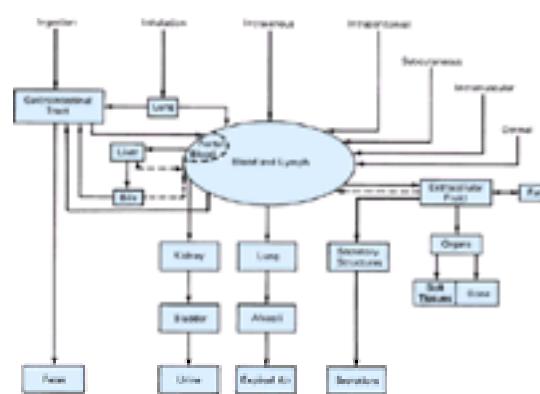
As was noted in Chap. 2 and Chap. 3, the toxicity of a substance depends on the dose; that is, the greater the amount of a chemical taken up by an organism, the greater the toxic response. This concept, which is known as *dose response,* requires elaboration, because ultimately it is not the dose but the concentration of a toxicant at the site or sites of action (target organ or tissue) that determines toxicity. It should be noted that the words *toxicant, drug, xenobiotic* (foreign compound), and *chemical* are used interchangeably throughout this chapter, since all chemical entities, whether endogenous or exogenous in origin, can cause toxicity at some dose. The concentration of a chemical at the site of action is proportional to the dose, but the same dose of two or more chemicals may lead to vastly different concentrations in a particular target organ of toxicity. This differential pattern is due to differences in the disposition of chemicals. Disposition may be conceptualized as consisting of absorption, distribution, biotransformation, and excretion. It should be noted, however, that these processes may occur simultaneously. The various factors affecting disposition are depicted in Fig. 5-1. They are discussed in detail in this chapter and Chap. 6. Any or all of these factors may have a minor or major impact on the concentration and thus the toxicity of a chemical in a target organ. For example, (1) if the fraction absorbed or the rate of absorption is low, a chemical may never attain a sufficiently high concentration at a potential site of action to cause toxicity, (2) the distribution of a toxicant may be such that it is concentrated in a tissue other than the target organ, thus decreasing the toxicity, (3) biotransformation of a chemical may result in the formation of less toxic or more toxic metabolites at a fast or slow rate with obvious consequences for the concentration and thus the toxicity at the target site, and (4) the more rapidly a chemical is eliminated from an organism, the lower will be its concentration and hence its toxicity in a target tissue or tissues. Furthermore, all these processes are interrelated and thus influence each other. For example, the rate of excretion of a chemical may depend to a large extent on its distribution and/or biotransformation. If a chemical is distributed to and stored in fat, its elimination is likely to be slow because very low plasma levels preclude rapid renal clearance or other clearances. Some lipid-soluble chemicals are very resistant to biotransformation. Their rate of excretion depends on biotransformation to water-soluble products and/or slow intestinal excretion of the parent compounds. As this brief introduction illustrates, the disposition of xenobiotics is very important in determining the concentration and thus the toxicity of chemicals in organisms.


Figure 5-1. Routes of absorption, distribution, and excretion of toxicants in the body.

The quantitation and determination of the time course of absorption, distribution, biotransformation, and excretion of chemicals are referred to as *pharmacokinetics* or *toxicokinetics* (see Chap. 7). Mathematical models are used to describe parts or the whole process of the disposition of a chemical. Calculations based on these models allow a numerical characterization of disposition (half-life, elimination rate constants, tissue profiles, etc.), which is essential for the assessment of the toxicity of a compound. Examination of species differences combined with knowledge of species-specific pathways of handling chemicals often provides the tools that allow toxicologists to predict disposition and its role in the toxicity of a compound for human exposure.

The skin, lungs, and alimentary canal are the main barriers that separate higher organisms from an environment containing a large number of chemicals. Toxicants have to cross one or several of these incomplete barriers to exert their deleterious effects at one site or several sites in the body. Exceptions are caustic and corrosive agents (acids, bases, salts, oxidizers), which act topically. A chemical absorbed into the bloodstream through any of these three barriers is distributed, at least to some extent, throughout the body, including the site where it produces damage. This site is often called the *target organ* or *target tissue.* A chemical may have one or several target organs, and, in turn, several chemicals may have the same target organ or organs. For example, benzene affects the hematopoietic system and carbon tetrachloride injures the liver. Lead and mercury both damage the central nervous system, the kidneys, and the hematopoietic system. It is self-evident that to produce a direct toxic effect in an organ, a chemical must reach that organ. However, indirect toxic responses may be precipitated at distant sites if a toxicant alters regulatory functions. For example, cholestyramine, a nonabsorbable resin, may trap certain acidic vitamins in the intestinal lumen and cause systemic toxicity in the form of various vitamin deficiency syndromes. Several factors other than the concentration influence the susceptibility of organs to toxicants. Therefore, the organ or tissue with the highest concentration of a toxicant is not necessarily the site where toxicity is exerted. For example, chlorinated hydrocarbon insecticides such as dichlorodiphenyltrichloroethane (DDT) attain their highest concentrations in fat depots of the body but produce no known toxic effect in that tissue. A toxicant may also exert its adverse effect directly on the bloodstream, as with arsine gas, which causes hemolysis.

Toxicants are removed from the systemic circulation by biotransformation, excretion, and storage at various sites in the body. The relative contribution of these processes to total elimination depends on the physical and chemical properties of the chemical. The kidney plays a major role in the elimination of most toxicants, but other organs may be of critical importance with some toxic agents. Examples include the elimination of a volatile agent such as carbon monoxide by the lungs and that of lead in the bile. Although the liver is the most active organ in the biotransformation of toxicants, other organs or tissues [enzymes in plasma, kidney, lungs, gastrointestinal (GI) tract, etc.] may also contribute to overall biotransformation. Biotransformation is often a prerequisite for renal excretion, because many toxicants are lipid-soluble and are therefore reabsorbed from the renal tubules after glomerular filtration. After a toxicant is biotransformed, its metabolites may be excreted preferentially into bile, as are the metabolites of DDT, or may be excreted into urine, as are the metabolites of organophosphate insecticides.

In this chapter, the qualitative aspects of absorption, distribution, and excretion are outlined, whereas their quantitative aspects are treated in Chap. 7. The fourth aspect of disposition—the biotransformation of chemicals—is dealt with in Chap. 6. As most toxic agents have to pass several membranes before exerting toxicity, we start with a discussion of some general characteristics of this ubiquitous barrier in the body.

CELL MEMBRANES

Toxicants usually pass through a number of cells, such as the stratified epithelium of the skin, the thin cell layers of the lungs or the gastrointestinal tract, the capillary endothelium, and the cells of the target organ or tissue. The plasma membranes surrounding all these cells are remarkably similar. The thickness of the cell membrane is about 7 to 9 nm. Biochemical, physiologic, and morphologic (electron microscopy) studies have provided strong evidence that membranes consist of a

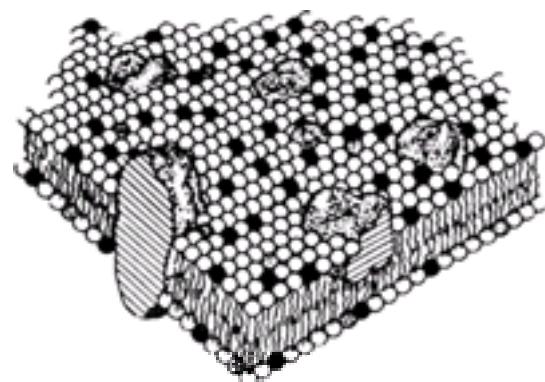
phospholipid bilayer, with polar head groups (phosphatidylcholine, phosphatidylethanolamine) predominating on both the outer and inner surfaces of the membrane and more or less perpendicularly directed fatty acids filling out the inner space. It is also well established that proteins are inserted in the bilayer, and some proteins even cross it, allowing the formation of aqueous pores (Fig. 5-2). Some cell membranes (eukaryotic) have an outer coat or glycocalyx consisting of glycoproteins and glycolipids. The fatty acids of the membrane do not have a rigid crystalline structure but are semifluid at physiologic temperatures. The fluid character of membranes is determined largely by the structure and relative abundance of unsaturated fatty acids. The more unsaturated fatty acids membranes contain, the more fluid-like they are, facilitating more rapid active or passive transport.


Figure 5-2. Schematic model of a biological membrane.

A toxicant may pass through a membrane by one of two general processes: (1) passive transport (diffusion according to Fick's law), in which the cell expends no energy, and (2) specialized transport, in which the cell provides energy to translocate the toxicant across its membrane.

Passive Transport

Simple Diffusion Most toxicants cross membranes by simple diffusion. Small hydrophilic molecules (up to a molecular weight of about 600) presumably permeate membranes through aqueous pores (Benz et al., 1980), whereas hydrophobic molecules diffuse across the lipid domain of membranes. The smaller a hydrophilic molecule is, the more readily it traverses membranes by simple diffusion through aqueous pores. Consequently, ethanol is absorbed rapidly from the stomach and intestine and is distributed equally rapidly throughout the body by simple diffusion from blood into all tissues. The majority of toxicants consist of larger organic molecules with differing degrees of lipid solubility. Their rate of transport across membranes correlates with their lipid solubility, which is frequently expressed as octanol/water partition coefficients of the uncharged molecules, or LogP as depicted in Table 5-1. Thus, the amino acids (negative logP) are water-soluble, whereas the environmental contaminants DDT and TCDD are very lipid soluble (high positive logP).

Substance	LogP
Paraquat	Charged molecule
Sulfobromophthalein	Charged molecule
Cephalosporin C	−4.72
Creatine	−4.46
Glycine	−3.21
Glutathione	−3.05
Ribonucleic acid	−2.80

Digitoxin	3.65
Parathion	3.47
DDT	6.76
TCDD	7.05

Table 5-1 Octanol/Water Partition Coefficients (P) of Different Molecules Expressed as LogP

Many chemicals are weak organic acids or bases. In solution, they are ionized according to Arrhenius's theory. The ionized form usually has low lipid solubility and thus does not permeate readily through the lipid domain of a membrane. Some transport of organic anions and cations (depending on their molecular weight) may occur through the aqueous pores, but this is a slow process (except for compounds of very low molecular weight), as the total surface area of aqueous pores is small compared with the total surface area of the lipid domain of a membrane. In general, the nonionized form of weak organic acids and bases is to some extent lipid-soluble, resulting in diffusion across the lipid domain of a membrane. The rate of transport of the nonionized form is proportional to its lipid solubility. The molar ratio of ionized to nonionized molecules of a weak organic acid or base in solution depends on the ionization constant. The ionization constant provides a measure for the weakness of organic acids and bases. The pH at which a weak organic acid or base is 50 percent ionized is called its pK_a or pK_b. Like pH, both pK_a and pK_b are defined as the negative logarithm of the ionization constant of a weak organic acid or base. With the equation $pK_a = 14 - pK_b$, pK_a can also be calculated for weak organic bases. An organic acid with a low pK_a is a relatively strong acid, and one with a high pK_a is a weak acid. The opposite is true for bases. The numerical value of pK_a does not indicate whether a chemical is an organic acid or a base. Knowledge of the chemical structure is required to distinguish between organic acids and bases.

The degree of ionization of a chemical depends on its pK_a and on the pH of the solution. The relationship between pK_a and pH is described by the Henderson-Hasselbalch equations.

$$\text{For acids: } pK_a - pH = \log \frac{[\text{nonionized}]}{[\text{ionized}]}$$

$$\text{For bases: } pK_a - pH = \log \frac{[\text{ionized}]}{[\text{nonionized}]}$$

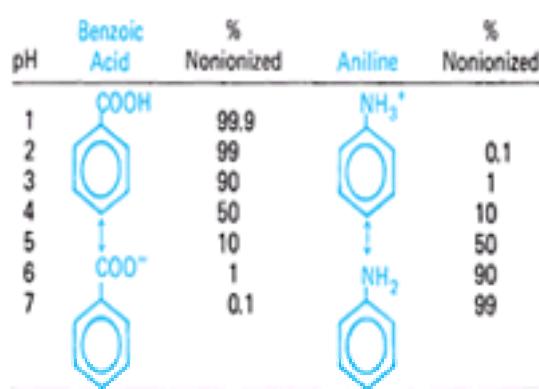
The effect of pH on the degree of ionization of an organic acid (benzoic acid) and an organic base (aniline) is shown in Fig. 5-3. According to the Brönsted-Lowry acid-base theory, an acid is a proton (H^+) donor and a base is a proton acceptor. Thus, the ionized and nonionized forms of an organic acid represent an acid-base pair, with the nonionized moiety being the acid and the ionized moiety being the base. At a low pH, a weak organic acid such as benzoic acid is largely nonionized. At pH 4, exactly 50 percent of benzoic acid is ionized and 50 percent is nonionized, because this is the pK_a of the compound. As the pH increases, more and more protons are neutralized by hydroxyl groups, and benzoic acid continues to dissociate until almost all of it is in the ionized form. For an organic base such as aniline, the obverse is true. At a low pH, when protons are abundant, almost all of aniline is protonated, that is, ionized. This form of aniline is an acid because it can donate protons. As the pH increases, anilinium ions continue to dissociate until almost all the aniline is in the nonionized form, which is the aniline base. As transmembrane passage is largely restricted to the nonionized form, benzoic acid is more readily translocated through a membrane from an acidic environment, whereas more aniline is transferred from an alkaline environment.


Figure 5-3. Effect of pH on the ionization of benzoic acid (pK$_a$ 4) and aniline (pK$_a$ = 5).

Filtration When water flows in bulk across a porous membrane, any solute small enough to pass through the pores flows with it. Passage through these channels is called *filtration,* as it involves bulk flow of water caused by hydrostatic or osmotic force. One of the main differences between various membranes is the size of these channels. In the kidney glomeruli, these pores are relatively large (about 70 nm), allowing molecules smaller than albumin (molecular weight 60,000) to pass through. The channels in most cells are much smaller (<4 nm), permitting substantial passage of molecules with molecular weights of no more than a few hundred (Schanker, 1961, 1962).

Special Transport

There are numerous compounds whose movement across membranes cannot be explained by simple diffusion or filtration. Some compounds are too large to pass through aqueous pores or too insoluble in lipids to diffuse across the lipid domains of membranes. Nevertheless, they are often transported very rapidly across membranes, even against concentration gradients. To explain these phenomena, the existence of specialized transport systems has been postulated. These systems are responsible for the transport across cell membranes of many nutrients, such as sugars and amino and nucleic acids, and also those of some foreign compounds.

Active Transport The following properties characterize an active transport system: (1) chemicals are moved against electrochemical or concentration gradients, (2) the transport system is saturated at high substrate concentrations and thus exhibits a transport maximum (T$_m$), (3) the transport system is selective for certain structural features of chemicals and has the potential for competitive inhibition between compounds that are transported by the same transporter, and (4) the system requires expenditure of energy, so that metabolic inhibitors block the transport process.

Substances actively transported across cell membranes presumably form a complex with a membrane-bound macromolecular carrier on one side of the membrane. The complex subsequently traverses to the other side of the membrane, where the substance is released. Afterward, the carrier returns to the original surface to repeat the transport cycle.

Significant advances in the understanding of active transport systems for xenobiotics have been made in the last few years. The table below indicates that there are a number of families of xenobiotic transporters. The first family of transporters identified were the multidrug-resistant (mdr) proteins or p-glycoproteins. The gene for this protein was identified in tumor cells resistant to chemotherapeutic anticancer drugs. It was determined that this transporter exudes chemotherapeutic drugs out of the tumor cells, and thus contributes to their resistance. Subsequently, it has been determined that mdr also protects the intact animal from chemicals by exuding chemicals out of intestinal cells, brain endothelial cells, liver cells, and kidney cells as well as protecting the fetus from some chemicals. Another family of proteins are the multi-resistant drug proteins. This family also exudes chemicals out of cells; however, phase II metabolites (glucuronides and glutathione conjugates) appear to be their preferred substrates. The name *organic-anion transporting peptide (oatp) family* is a misnomer because this transporter family transports not only acids, but also bases, and neutral compounds. They appear to be especially important in the hepatic uptake of xenobiotics. In contrast, the organic anion transporter (oat) family is especially important in the renal uptake of anions, whereas the organic cation transporter (oct) family is important in both the renal and hepatic uptake of xenobiotics. The nucleotide transporter (nt) family, the divalent-metal ion transporter (dmt), and the peptide transporter (pept) aid in gastrointestinal absorption of nucleotides, metals, and di- and tri-peptides.

NAME	ABBREVIATION	FUNCTION
Multi-drug-resistant protein or p-glycoprotein	mdr	Decrease GI absorption
		Blood-brain barrier
		Biliary excretion
		Placental barrier
Multi-resistant drug protein	mrp	Urinary excretion
		Biliary excretion
Organic-anion transporting polypeptide	oatp	Hepatic uptake
Organic-anion transporter	oat	Kidney uptake
Organic-cation transporter	oct	Kidney uptake
		Liver uptake
		Placental barrier
Nucleotide transporter	nt	GI absorption
Divalent-metal ion transporter	dmt	GI absorption
Peptide transporter	pept	GI absorption

Facilitated Diffusion Facilitated diffusion applies to carrier-mediated transport that exhibits the properties of active transport except that the substrate is not moved against an electrochemical or concentration gradient and the transport process does not require the input of energy; that is, metabolic poisons do not interfere with this transport. The transport of glucose from the GI tract across the basolateral membrane of the intestinal epithelium, from plasma into red blood cells, and from blood into the central nervous system (CNS) occurs by facilitated diffusion.

Additional Transport Processes Other forms of specialized transport have been proposed, but their overall importance is not as well established as that of active transport and facilitated diffusion. Phagocytosis and pinocytosis are proposed mechanisms for cell membranes flowing around and engulfing particles. This type of transfer has been shown to be important for the removal of particulate matter from the alveoli by phagocytes and from blood by the reticuloendothelial system of the liver and spleen.

ABSORPTION

The process by which toxicants cross body membranes and enter the bloodstream is referred to as *absorption.* There are no specific systems or pathways for the sole purpose of absorbing toxicants. Xenobiotics penetrate membranes during absorption by the same processes as do biologically essential substances such as oxygen, foodstuffs, and other nutrients. The main sites of absorption are the GI tract, lungs, and skin. However, absorption may also occur from other sites, such as the subcutis, peritoneum, or muscle if a chemical is administered by special routes. Experimentalists and medical professionals often distinguish between parenteral and enteral administration of drugs and other xenobiotics. It is important to know that enteral administration includes all routes pertaining to the alimentary canal (sublingual, oral, and rectal), whereas parenteral administration involves all other routes (intravenous, intraperitoneal, intramuscular, subcutaneous, etc.).

Absorption of Toxicants by the Gastrointestinal Tract

The GI tract is one of the most important sites where toxicants are absorbed. Many environmental toxicants enter the food chain and are absorbed together with food from the GI tract. This site of absorption is of particular interest to toxicologists because suicide attempts frequently involve an overdose of an orally ingested drug.

Oral intake is also the most common route by which children are accidentally exposed to poisons.

The GI tract may be viewed as a tube traversing the body. Although it is within the body, its contents can be considered exterior to the body. Therefore, unless a noxious agent has caustic or irritating properties, poisons in the GI tract usually do not produce systemic injury to an individual until they are absorbed.

Absorption of toxicants can take place along the entire GI tract, even in the mouth and rectum. Therefore, drugs such as nitroglycerin are administered sublingually and others are administered rectally, whereas the majority of drugs are given orally. If a toxicant is an organic acid or base, it tends to be absorbed by simple diffusion in the part of the GI tract in which it exists in the most lipid-soluble (nonionized) form. Because gastric juice is acidic and the intestinal contents are nearly neutral, the lipid solubility of weak organic acids or bases can differ markedly in these two areas of the GI tract. One can determine by the Henderson-Hasselbalch equations the fraction of a toxicant that is in the nonionized (lipid-soluble) form and estimate the rate of absorption from the stomach or intestine. According to this equation, a weak organic acid is present mainly in the nonionized (lipid-soluble) form in the stomach and predominantly in the ionized form in the intestine. Therefore, one would expect that weak organic acids are absorbed more readily from the stomach than from the intestine. In contrast, organic bases (except very weak organic bases) are not in the lipid-soluble form in the stomach but are in that form in the intestine, suggesting that the absorption of such compounds occurs predominantly in the intestine rather than in the stomach. However, the Henderson-Hasselbalch equations have to be interpreted with some qualifications because other factors—such as the mass action law, surface area, and blood flow rate—have to be taken into consideration in examining the absorption of weak organic acids or bases. For example, only 1 percent of benzoic acid is present in the lipid-soluble form in the intestine. Therefore, one might conclude that the intestine has little capacity to absorb this organic acid. However, absorption is a dynamic process. The blood keeps removing benzoic acid from the lamina propria of the intestine, and according to the mass action law, the equilibrium will always be maintained at 1 percent in the nonionized form, providing continuous availability of benzoic acid for absorption. Moreover, absorption by simple diffusion is also proportional to the surface area. Because the small intestine has a very large surface (the villi and microvilli increase the surface area approximately 600-fold), the overall capacity of the intestine for absorption of benzoic acid is quite large. Similar considerations are valid for the absorption of all weak organic acids from the intestine.

The mammalian GI tract has specialized transport systems (carrier-mediated) for the absorption of nutrients and electrolytes (Table 5-2). The absorption of some of these substances is complex and depends on a number of factors. The absorption of iron, for example, depends on the need for iron and takes place in two steps: Iron first enters the mucosal cells and then moves into the blood. The first step is relatively rapid, whereas the second is slow. Consequently, iron accumulates within the mucosal cells as a protein-iron complex termed *ferritin.* When the concentration of iron in blood drops below normal values, some iron is liberated from the mucosal stores of ferritin and transported into the blood. As a consequence, the absorption of more iron from the intestine is triggered to replenish these stores. Calcium is also absorbed by a two-step process: first absorption from the lumen and then exudation into the interstitial fluid. The first step is faster than the second, and therefore intracellular calcium rises in mucosal cells during absorption. Vitamin D is required for both steps of calcium transport.

	Location of Absorptive Capacity			
	Small Intestine			
SUBSTRATES	UPPER	MIDDLE	LOWER	COLON
Sugar (glucose, galactose, etc.)	+ +	+ + +	+ +	0
Neutral amino acids	+ +	+ + +	+ +	0
Basic amino acids	+ +	+ +	+ +	?
Gamma globulin (newborn animals)	+	+ +	+ + +	?
Pyrimidines (thymine and uracil)	+	+	?	?

Table 5-2 Site Distribution of Specialized Transport Systems in the Intestine of Man and Animals

The GI tract also has at least one active transport system that decreases the absorption of xenobiotics. The multi-drug–resistance transporter (mdr, also termed p-glycoprotein) is localized in enterocytes. When chemicals that are substrates for mdr enter the enterocyte, they are exuded back into the intestinal lumen. Thus, the immunosuppressive drug cyclosporine and the chemotherapeutic anticancer drugs paclitaxel (taxol), colchicine, and vincristine are not readily absorbed from the GI tract for this reason.

Some xenobiotics can be absorbed by the same specialized transport systems. For example, 5-fluorouracil is absorbed by the pyrimidine transport system (Schanker and Jeffrey, 1961), thallium by the system that normally absorbs iron (Leopold et al., 1969), and lead by the calcium transporter (Sobel et al., 1938). Cobalt and manganese compete for the iron transport system (Schade et al., 1970; Thomson et al., 1971a, 1971b). Some dipeptide and oligopeptide transporters have been well characterized and have been shown to play an important role in the active absorption of drugs containing a b-lactam structure (Tsuji et al., 1993; Dantzig et al., 1994). Transepithelial absorption of dipeptides (e.g., glycylsarcosine) and b-lactam antibiotics at low concentrations occurs predominantly by active carrier-mediated mechanisms at both apical and basolateral membranes (Thwaites et al., 1993).

The number of toxicants actively absorbed by the GI tract is low; most enter the body by simple diffusion. Although lipid-soluble substances are absorbed by this process more rapidly and extensively than are water-soluble substances, the latter may also be absorbed to some degree. After oral ingestion, about 10 percent of lead, 4 percent of manganese, 1.5 percent of cadmium, and 1 percent of chromium salts are absorbed. If a compound is very toxic, even small amounts of absorbed material produce serious systemic effects. An organic compound that would not be expected to be absorbed on the basis of the pH-partition hypothesis is the fully ionized quaternary ammonium compound pralidoxime chloride (2-PAM; molecular weight 137), yet it is absorbed almost entirely from the GI tract (Levine and Steinberg, 1966). The mechanism by which some lipid-insoluble compounds are absorbed is not entirely clear. It appears that organic ions of low molecular weight (122 to 188) can be transported across the mucosal barrier by paracellular transport, that is, passive penetration through aqueous pores at the tight junctions (Aungst and Shen, 1986), or by active transport as discussed above.

It is interesting to note that even particulate matter can be absorbed by the GI epithelium. Particles of an azo dye, variable in size but averaging several thousand nanometers in diameter, have been shown to be taken up by the duodenum (Barnett, 1959). Emulsions of polystyrene latex particles 22 µm in diameter have been demonstrated to be carried through the cytoplasm of the intestinal epithelium in intact vesicles and discharged into the interstices of the lamina propria, followed by absorption into the lymphatics of the mucosa (Sanders and Ashworth, 1961). Particles appear to enter intestinal cells by pinocytosis, a process that is much more prominent in newborns than in adults (Williams and Beck, 1969). These examples demonstrate some of the principles and the variety of toxicants that can be

absorbed at least to some extent by the GI tract.

The resistance or lack of resistance of chemicals to alteration by the acidic pH of the stomach, enzymes of the stomach or intestine, or the intestinal flora is of extreme importance. A toxicant may be hydrolyzed by stomach acid or biotransformed by enzymes of the microflora of the intestine to new compounds with a toxicity greatly different from that of the parent compound. For example, snake venom is much less toxic when administered orally rather than intravenously because it is broken down by digestive enzymes of the GI tract. Ingestion of well water with a high nitrate content produces methemoglobinemia much more frequently in infants than in adults. This is due to the higher pH of the GI tract in newborns, with the consequence of greater abundance of certain bacteria, especially *Escherichia coli,* which convert nitrate to nitrite. Nitrite formed by bacterial action produces methemoglobinemia (Rosenfield and Huston, 1950). Nitrite is also used as a food additive in meats and smoked fish. Some fish, vegetables, and fruit juices contain secondary amines. The acidic environment of the stomach facilitates a chemical reaction between nitrite and secondary amines, leading to the formation of carcinogenic nitrosamines (Chap. 8). Also, the intestinal flora can reduce aromatic nitro groups to aromatic amines that may be goitrogenic or carcinogenic (Thompson et al., 1954). Intestinal bacteria, specifically *Aerobacter aerogenes,* have been shown to degrade DDT to DDE (Mendel and Walton, 1966).

Many factors alter the GI absorption of toxicants. For example, editic acid [ethylenediaminetetraacetic acid (EDTA)] increases the absorption of some toxicants by increasing intestinal permeability. Simple diffusion is proportional not only to surface area and permeability but also to residency time in various segments of the alimentary canal. Therefore, the rate of absorption of a toxicant remaining for longer periods in the intestine increases, whereas that with a shorter residency time decreases. The residency time of a chemical in the intestine depends on intestinal motility. Some agents used as laxatives are known to exert effects on the absorption of xenobiotics by altering intestinal motility (Levine, 1970).

Experiments have shown that the oral toxicity of some chemicals is increased by diluting the dose (Ferguson, 1962; Borowitz et al., 1971). This phenomenon may be explained by more rapid stomach emptying induced by increased dosage volume, which in turn leads to more rapid absorption in the duodenum because of the larger surface area there.

The absorption of a toxicant from the GI tract also depends on the physical properties of a compound, such as lipid solubility, and the dissolution rate. Although it is often generalized that an increase in lipid solubility increases the absorption of chemicals, an extremely lipid-soluble chemical does not dissolve in the GI fluids, and absorption is low (Houston et al., 1974). If the toxicant is a solid and is relatively insoluble in GI fluids, it will have limited contact with the GI mucosa; therefore its rate of absorption will be low. Also, the larger the particle size is, the less will be absorbed, as the dissolution rate is inversely proportional to particle size (Gorringe and Sproston 1964; Bates and Gibaldi, 1970). This explains why metallic mercury is relatively nontoxic when ingested orally and why powdered arsenic is significantly more toxic than its coarse granular form (Schwartze, 1923).

The amount of a chemical entering the systemic circulation after oral administration depends on several factors. First, it depends on the amount absorbed into the GI cells. Further, before a chemical enters the systemic circulation, it can be biotransformed by the GI cells or extracted by the liver and excreted into bile with or without prior biotransformation. The lung can also contribute to the biotransformation or elimination of chemicals before their entrance into the systemic circulation, although its role is less well defined than that of the intestine and liver. This phenomenon of the removal of chemicals before entrance into the systemic circulation is referred to as *presystemic elimination,* or *first-pass effect.*

A number of other factors have been shown to alter absorption. For example, one ion can alter the absorption of another: Cadmium decreases the absorption of zinc and copper, and calcium that of cadmium; zinc decreases the absorption of copper, and magnesium that of fluoride (Pfeiffer, 1977). Milk has been found to increase lead absorption (Kelly and Kostial, 1973), and starvation enhances the absorption of dieldrin (Heath and Vandekar, 1964). The age of animals also appears to affect absorption: Newborn rats absorbed 12 percent of a dose of cadmium, whereas adult rats absorbed only 0.5 percent (Sasser and Jarboe, 1977). While lead and many other heavy metal ions are not absorbed readily from the GI tract, EDTA and other chelators increase the lipid solubility and thus the absorption of complexed ions. Thus, it is important not to give a chelator orally when excess metal is still present in the GI tract after oral ingestion.

The principles of GI absorption may be summarized in the following way. Penetration of amphophilic (having both lipophilic and hydrophilic molecular characteristics) substances across the GI wall occurs according to the basic principles of physicochemistry, with the unstirred water layer representing the rate-determining barrier for the more lipophilic molecules and the epithelial cell membrane representing that for the more hydrophilic compounds. Unlike the skin, which is virtually impenetrable to molecules at the extreme ends of the lipophilicity/hydrophilicity scale, the GI tract can also absorb such compounds. Some extremely hydrophilic compounds are absorbed by active processes, whereas extremely lipophilic compounds [2, 3, 7, 8-tetrachlorodibenzo- *p*-dioxin (TCCD), DDT, polychlorinated biphenyls (PCBs), etc.] ride in on the "coattails" of lipids via the micelles and subsequent biological processes related to lipid metabolism.

In general, gastrointestinal absorption of xenobiotics was thought to be similar between species. The work of Dreyfuss and colleagues illustrates the fallacy of this assumption (Dreyfuss et al., 1978). Absorption of nadolol (calculated from AUC after ip and oral dosing) was essentially complete in the dog, substantially less in humans, and quite limited in the rat (Table 5-3). Urinary and fecal excretion of nadolol support the bioavailability data. However, excretory data further indicate that in addition to the nonabsorbed portion of this compound, biliary and possibly nonbiliary sources also contribute to the fecal excretion of this compound. Calabrese (1984) reported evidence for species differences in the absorption of at least 38 compounds, indicating that nadolol is not an exceptional case.

Table 5-3 Absorption and Excretion of Radioactivity in Rats, Dogs, and Man after Nadolol

The rate-limiting barrier in the absorption of most xenobiotics is the unstirred water layer along the intestinal mucosa (Hayton, 1980). The effect of the unstirred water layer as a possible cause of species differences in absorption of xenobiotics has not been investigated. However, Thomson et al. (1983) studied the effect of the unstirred water layer on the absorption of fatty acids and cholesterol. These authors concluded that the thickness of the unstirred water layer may contribute to species differences in the absorption of lipophilic compounds, but other tissue-specific differences must also exist because species differences persisted when the unstirred water layer was diminished as a barrier for hydrophobic compounds by stirring.

Anatomical (allometric) considerations are another likely reason for species differences in intestinal absorption. The relative length of intestinal segments is quite variable (Iatropoulos, 1986), and substantial functional differences exist between such species as ruminants and omnivores (Smith, 1986). Because most xenobiotics are transported across the gastrointestinal mucosa by passive diffusion, and because this transport is surface area– and site-dependent, it can be expected that these factors will be responsible for species differences in some instances. Many xenobiotics are weak organic acids or bases. For such compounds, gastrointestinal absorption is dependent on the pH along the gastrointestinal tract. Table 5-4, shows that each segment of the gut reveals considerable species specificity, with differences of up to 2 pH units. This can translate into two orders of magnitude difference in concentration of the undissociated versus dissociated moiety of a weak organic acid or base.

*Modified from Smith (1965).

Table 5-4 pH of the Gastrointestinal Contents of Various Species4

An additional factor that may result in species-dependent absorption of xenobiotics is the gastrointestinal flora. In general, the microflora in animals is remarkably similar, although qualitative and quantitative differences have been reported (Smith, 1965). Notable deviations to this generalization do exist, such as the rabbit and human (Table 5-5). In contrast to other species, the microflora in these two species is very low in the upper gastrointestinal tract. Because absorption of some xenobiotics requires prior bacterial hydrolysis, some species differences may be due to differences in microflora. As an example, cycasin (Rozman and Iatropoulos, 1987) is poorly absorbed by gnotobiotic animals; however, the aglycone of cycasin is readily absorbed. Therefore, species with bacterial b-glucosidase activity in the upper small intestine readily absorb the aglycone (methylazoxymethanol), but species like human, with very low levels of microflora in the upper gastrointestinal tract, may not absorb this compound to any major extent.

Absorption of Toxicants by the Lungs

It is well known that toxic responses to chemicals can result from their absorption after inhalation. The most frequent cause of death from poisoning—carbon monoxide—and probably the most important occupational disease—silicosis—are both due to the absorption or deposition of airborne poisons in the lungs. This site of absorption has been employed in chemical warfare (chlorine and phosgene gas, lewisite, mustard gas) and in the execution of criminals in the gas chamber (hydrogen cyanide).

Toxicants absorbed by the lungs are usually gases (e.g., carbon monoxide, nitrogen dioxide, and sulfur dioxide), vapors of volatile or volatilizable liquids (e.g., benzene and carbon tetrachloride), and aerosols. Because the absorption of inhaled gases and vapor differs from that of aerosols, aerosols are discussed separately below. However, the absorption of gases and vapors is governed by the same principles, and therefore the word *gas* is used to represent both in this section.

Gases and Vapors The absorption of inhaled gases takes place mainly in the lungs. However, before a gas reaches the lungs, it passes through the nose, with its turbinates, which increase the surface area. Because the mucosa of the nose is covered by a film of fluid, gas molecules can be retained by the nose and not reach the lungs if they are very water soluble or react with cell surface components. Therefore, the nose acts as a "scrubber" for water-soluble gases and highly reactive gases, partially protecting the lungs from potentially injurious insults. A case in point is formaldehyde. The drawback of this protective mechanism for the lungs is that a typical nose breather such as a rat develops tumors of the nasal turbinates when chronically exposed to high levels of formaldehyde by inhalation.

Absorption of gases in the lungs differs from intestinal and percutaneous absorption of compounds in that the dissociation of acids and bases and the lipid solubility of molecules are less important factors in pulmonary absorption because diffusion through cell membranes is not rate-limiting in the pulmonary absorption of gases. There are at least three reasons for this. First, ionized molecules are of very low volatility, and consequently their concentration in normal ambient air is insignificant. Second, the epithelial cells lining the alveoli—that is, type I pneumocytes—are very thin and the capillaries are in close contact with the pneumocytes, so that the distance for a chemical to diffuse is very short. Third, chemicals absorbed by the lungs are removed rapidly by the blood, as it takes only about three-fourths of a second for the blood to go through the extensive capillary network in the lungs.

When a gas is inhaled into the lungs, gas molecules diffuse from the alveolar space into the blood and then dissolve. Except for some gases with a special affinity for certain body components (e.g., the binding of carbon monoxide to hemoglobin), the uptake of a gas by a tissue usually involves a simple physical process of dissolving. The end result is that gas molecules partition between the two media: air and blood during the absorptive phase and blood and other tissues during the distributive phase. As the contact of the inspired gas with blood continues in the alveoli, more molecules dissolve in blood until gas molecules in blood are in equilibrium with gas molecules in the alveolar space. At equilibrium, the ratio of the concentration of chemical in the blood and chemical in the gas phase is constant. This solubility ratio is called the *blood-to-gas partition coefficient.* This constant is unique for each gas. Note that only the ratio is constant, not the concentrations, as, according to Henry's law, the amount of gas dissolved in a liquid is proportional to the partial pressure of the gas in the gas phase at any given concentration before or at saturation. Thus, the higher the inhaled concentration of a gas (i.e., the higher the partial pressure), the higher the gas concentration in blood, but the ratio does not change unless saturation has occurred. When equilibrium is reached, the rate of transfer of gas molecules from the alveolar space to blood equals the rate of removal by blood from the alveolar space. For example, chloroform has a high (15) and ethylene a low (0.14) blood/gas phase solubility ratio. For a substance with a low solubility ratio, such as ethylene, only a small percentage of the total gas in the lungs is removed by blood during each circulation because blood is soon saturated with the gas. Therefore, an increase in the respiratory rate or minute volume does not change the transfer of such a gas to blood. In contrast, an increase in the rate of blood flow markedly increases the rate of uptake of a compound with a low solubility ratio because of more rapid removal from the site of equilibrium, that is, the alveolar membranes. It has been calculated that the time to equilibrate between the blood and the gas phase for a relatively insoluble gas is about 8 to 21 min.

Most of a gas with a high solubility ratio, such as chloroform, is transferred to blood during each respiratory cycle so that little if any remains in the alveoli just before the next inhalation. The more soluble a toxic agent is in blood, the more of it will be dissolved in blood by the time equilibrium is reached. Consequently, the time required to equilibrate with blood is very much longer for a gas with a high solubility ratio than for a gas with a low ratio. This has been calculated to take a minimum of 1 h for compounds with a high solubility ratio, although it may take even longer if the gas also has high tissue affinity (i.e., high fat solubility). With these highly soluble gases, the principal factor limiting the rate of absorption is respiration. Because the blood is already removing virtually all of a gas with a high solubility ratio from the lungs, increasing the blood flow rate does not substantially increase the rate of absorption. However, the rate can be accelerated greatly by increasing the rate of respiration, or the minute volume.

Thus, the rate of absorption of gases in the lungs is variable and depends on a toxicant's solubility ratio (concentration in blood/concentration in gas phase before or at saturation) at equilibrium. For gases with a very low solubility ratio, the rate of transfer depends mainly on blood flow through the lungs (perfusion-limited), whereas for gases with a high solubility ratio, it is primarily a function of the rate and depth of respiration (ventilation-limited). Of course, there is a wide spectrum of

intermediate behavior between the two extremes, with the median being a blood/gas concentration ratio of about 1.2.

The blood carries the dissolved gas molecules to the rest of the body. In each tissue, the gas molecules are transferred from the blood to the tissue until equilibrium is reached at a tissue concentration dictated by the tissue-to-blood partition coefficient. After releasing part of the gas to tissues, blood returns to the lungs to take up more of the gas. The process continues until a gas reaches equilibrium between blood and each tissue according to the tissue-to-blood partition coefficients characteristic of each tissue. At this time, no net absorption of gas takes place as long as the exposure concentration remains constant, because a steady state has been reached. Of course, if biotransformation and excretion occur, alveolar absorption will continue until a corresponding steady state is established.

Aerosols and Particles The degree of ionization and the lipid solubility of chemicals are very important for oral and percutaneous exposures, whereas water solubility, tissue reactivity, and blood to gas phase partition coefficients are important after exposure to gases and vapors. The important characteristics that affect absorption after exposure to aerosols are the aerosol size and water solubility of a chemical present in the aerosol.

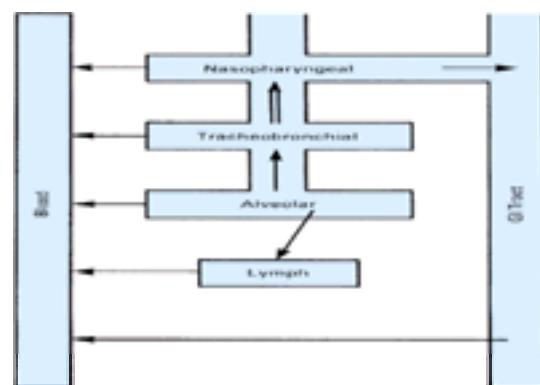
The site of deposition of aerosols depends largely on the size of the particles. This relationship is discussed in detail in   Chap. 15. Particles 5 μm or larger usually are deposited in the nasopharyngeal region (Fig. 5-4). Those deposited on the unciliated anterior portion of the nose tend to remain at the site of deposition until they are removed by nose wiping, blowing, or sneezing. The mucous blanket of the ciliated nasal surface propels insoluble particles by the movement of the cilia. These particles and particles inhaled through the mouth are swallowed within minutes. Soluble particles may dissolve in the mucus and be carried to the pharynx or may be absorbed through the nasal epithelium into blood.


Figure 5-4. Schematic diagram of the absorption and translocation of chemicals by lungs.

Particles of 2 to 5 μm are deposited mainly in the tracheobronchiolar regions of the lungs, from which they are cleared by retrograde movement of the mucus layer in the ciliated portions of the respiratory tract. The rate of cilia-propelled movement of mucus varies in different parts of the respiratory tract, although in general it is a rapid and efficient transport mechanism. Measurements have shown transport rates between 0.1 and 1 mm per minute, resulting in removal half-lives between 30 and 300 min. Coughing and sneezing greatly increase the movement of mucus and particulate matter toward the mouth. Particles eventually may be swallowed and absorbed from the GI tract.

Particles 1 μm and smaller penetrate to the alveolar sacs of the lungs. They may be absorbed into blood or cleared through the lymphatics after being scavenged by alveolar macrophages.

In addition to gases, liquid aerosols and particles can be absorbed in the alveoli. The mechanisms responsible for the removal or absorption of particulate matter from the alveoli (usually less than 1 μm in diameter) are less clear than those responsible for the removal of particles deposited in the tracheobronchial tree. Removal appears to occur by three major mechanisms. First, particles may be removed from the alveoli by a physical process. It is thought that particles deposited on the fluid layer of the alveoli are aspirated onto the mucociliary escalator of the tracheobronchial region. From there, they are transported to the mouth and may be swallowed, as was mentioned previously. The origin of the thin fluid layer in the alveoli is probably a transudation of lymph and secretions of lipids and other components by the alveolar epithelium. The alveolar fluid flows by an unknown mechanism to the terminal bronchioles. This flow seems to depend on lymph flow, capillary action, the respiratory motion of the alveolar walls, the cohesive nature of the respiratory tract's fluid blanket, and the propelling power of the ciliated bronchioles. Second, particles from the alveoli may be removed by phagocytosis. The principal cells responsible for engulfing alveolar debris are the mononuclear phagocytes, the macrophages. These cells are found in large numbers in normal lungs and contain many phagocytized particles of both exogenous and endogenous origin. They apparently migrate to the distal end of the mucociliary escalator and are cleared and eventually swallowed. Third, removal may occur via the lymphatics. The endothelial cells lining lymphatic capillaries are permeable for very large molecules (molecular weight >10 ^{6}) and for particles, although the rate of penetration is low above a molecular weight of 10,000 (Renkin, 1968). Nevertheless, the lymphatic system plays a prominent role in collecting high-molecular-weight proteins leaked from cells or blood capillaries and particulate matter from the interstitium and the alveolar spaces. Particulate matter may remain in lymphatic tissue for long periods, and this explains the name "dust store of the lungs."

For the reasons discussed above, the overall removal of particles from the alveoli is relatively inefficient; on the first day only about 20 percent of particles are cleared, and the portion remaining longer than 24 h is cleared very slowly. The rate of clearance by the lungs can be predicted by a compound's solubility in lung fluids. The lower the solubility, the lower the removal rate. Thus, it appears that removal of particles from the lungs is largely due to dissolution and vascular transport. Some particles may remain in the alveoli indefinitely. This may occur when proliferating instead of desquamating alveolar cells ingest dust particles and, in association with a developing network of reticulin fibers, form an alveolar dust plaque or nodule.

Species differences in the absorption of toxicants by the lungs are due to differences in physiology (rate of respiration, blood flow rate, etc.) and to differential exposure conditions (e.g., life span).

Absorption of Toxicants through the Skin

Human skin comes into contact with many toxic agents. Fortunately, the skin is not very permeable and therefore is a relatively good barrier for separating organisms from their environment. However, some chemicals can be absorbed by the skin in sufficient quantities to produce systemic effects. For example, nerve gases such as sarin are readily absorbed by intact skin. Also, carbon tetrachloride can be absorbed through the skin in sufficient quantities to cause liver injury. Various insecticides have caused death in agricultural workers after absorption through intact skin (Chap. 22).

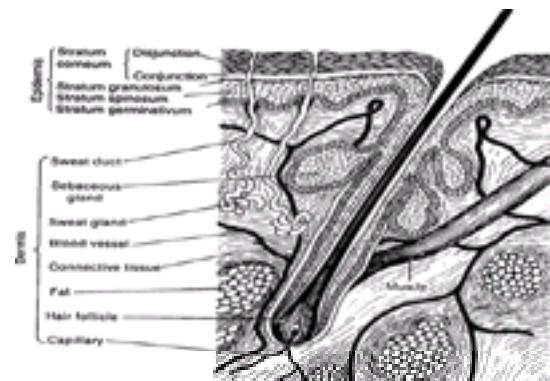
To be absorbed through the skin, a toxicant must pass through the epidermis or the appendages (sweat and sebaceous glands and hair follicles). Sweat glands and hair follicles are scattered in varying densities on the skin. Their total cross-sectional area is probably between 0.1 and 1.0 percent of the total skin surface. Although the entry of small amounts of toxicants through the appendages may be rapid, chemicals are absorbed mainly through the epidermis, which constitutes the major surface area of the skin. Chemicals that are absorbed through the skin have to pass through several cell layers (a total of seven) before entering the small blood and lymph capillaries in the dermis (Fig. 5-5). The rate-determining barrier in the dermal absorption of chemicals is the epidermis. More accurately, it is the stratum corneum (horny layer), the uppermost layer of the epidermis (Dugard, 1983). This is the outer horny layer of the skin, consisting of densely packed keratinized cells that have lost their nuclei and thus are biologically inactive. Passage through the six other cell layers is much more rapid than is passage through the stratum corneum. Therefore, the most important considerations regarding the dermal absorption of xenobiotics relate to the stratum corneum.


Figure 5-5. Diagram of a cross section of human skin.

The first phase of percutaneous absorption is diffusion of xenobiotics through the rate-limiting barrier, the stratum corneum. Studies have shown that the stratum corneum is replenished about every 3 to 4 weeks in adults. This complex process includes a gross dehydration and polymerization of intracellular matrix that results in keratin-filled dried cell layers. In the course of keratinization, the cell walls apparently double in thickness owing to the inclusion or deposition of chemically resistant materials. This change in the physical state of the tissue causes a commensurate change in its diffusion barrier property. The transformation is from an aqueous fluid medium that is characterized by liquid state to a dry, keratinous semisolid state with much lower permeability for toxicants by diffusion (permeability by diffusion = diffusivity).

In contrast to the complexity of the GI tract, the skin is a simpler penetration barrier for chemicals because passage through dead cell layers is the rate-determining step. It is clear that all toxicants move across the stratum corneum by passive diffusion. Kinetic measurements suggest that polar and nonpolar toxicants may diffuse through the stratum corneum by different mechanisms. Polar substances appear to diffuse through the outer surface of protein filaments of the hydrated stratum corneum, whereas nonpolar molecules dissolve in and diffuse through the lipid matrix between the protein filaments (Blank and Scheuplein, 1969). The rate of diffusion of nonpolar toxicants is proportional to their lipid solubility and is inversely related to their molecular weight (Marzulli et al., 1965). However, there are limits to the generalization of this theory. The rate of dermal penetration of highly lipophilic chemicals such as TCDD is very limited (Weber et al., 1991). Their solubility in triglycerides is relatively good, but not in phospholipids and other lipids with polar head groups. Because the stratum corneum contains a very low amount of triglycerides (2.8 percent in pigs, 0 percent in humans) and much cholesterol (26.0 percent in pigs, 26.9 percent in humans), some cholesterol esters (4.1 percent in pigs, 10 percent in humans), and various ceramides (44.2 percent in pigs, 41.1 percent in humans), it is not surprising that the absorption of highly lipophilic toxicants through the skin remains quite limited (Wertz and Downing, 1991). Ceramides are moderately lipophilic, as they are amides and/or esters of saturated and unsaturated fatty acids. Thus, the stratum corneum consists of about 75 to 80 percent moderately lipophilic materials. The simple physicochemical fact of *similis similibus solvontur* ("similar dissolves similar") explains the validity of the lipophilicity theory for molecules of moderate lipophilicity that also possess some hydrophilic regions. However, for both extreme ends of the lipophilicity/hydrophilicity spectrum, the stratum corneum represents a nearly impenetrable barrier unless those compounds damage the upper layer of the skin. A slow rate of penetration is possible for such substances via the appendages, provided that they remain in contact with a large skin surface area for prolonged periods.

Human stratum corneum displays significant differences in structure and chemistry from one region of the body to another, and these differences affect the permeability of the skin to chemicals. Skin from the plantar and palmar regions is much different from skin from other areas of the body in that the stratum corneum of the palms and soles is adapted for weight bearing and friction. The stratum corneum of the rest of the body surface is adapted for flexibility and fine sensory discrimination. The permeability of the skin depends on both the diffusivity and the thickness of the stratum corneum. While the stratum corneum is much thicker on the palms and soles (400 to 600 μm in callous areas) than on the arms, back, legs, and abdomen (8 to 15 μm), it has much higher diffusivity per unit thickness. Consequently, toxicants readily cross scrotum skin, since it is extremely thin and has high diffusivity; cross the abdominal skin less rapidly, as it is thicker and exhibits less diffusivity; and cross the sole with the greatest difficulty because the distance to traverse is great even though diffusivity there is highest.

The second phase of percutaneous absorption consists of diffusion of the toxicant through the lower layers of the epidermis (stratum granulosum, spinosum, and germinativum) and the dermis. These cell layers are far inferior to the stratum corneum as diffusion barriers. In contrast to the stratum corneum, they contain a porous, nonselective, aqueous diffusion medium. Toxicants pass through this area by diffusion and enter the systemic circulation through the numerous venous and lymphatic capillaries in the dermis. The rate of diffusion depends on blood flow, interstitial fluid movement, and perhaps other factors, including interactions with dermal constituents.

The absorption of toxicants through the skin varies, depending on the condition of the skin. Because the stratum corneum plays a critical role in determining cutaneous permeability, removal of this layer causes a dramatic increase in the permeability of the epidermis for a variety of large or small molecules, both lipid-soluble and water-soluble (Malkinson, 1964). Agents such as acids, alkalis, and mustard gases that injure the stratum corneum increase its permeability. The most frequently encountered penetration-enhancing damage to the skin results from burns and various skin diseases. Water plays an extremely important role in skin permeability. Under normal conditions, the stratum corneum is partially hydrated, containing about 7 percent water by weight. This amount of water increases the permeability of the stratum corneum approximately tenfold over the permeability that exists when it is completely dry. On additional contact with water, the stratum corneum can increase its weight of tightly bound water up to three- to fivefold, and this results in an additional two- to threefold increase in permeability. Studies of the dermal absorption of toxicants often utilize the method of Draize and associates (1944), wrapping plastic around animals and placing the chemical between the plastic and the skin (occlusive application). This hydrates the stratum corneum and enhances the absorption of some toxicants.

Solvents such as dimethyl sulfoxide (DMSO) also can facilitate the penetration of toxicants through the skin. DMSO increases the permeability of the barrier layer of the skin—that is, the stratum corneum. Little information is available about the mechanism by which DMSO enhances skin permeability. However, it has been suggested that DMSO (1) removes much of the lipid matrix of the stratum corneum, making holes on artificial shunts in the penetration barrier; (2) produces reversible configurational changes in protein structure brought about by the substitution of integral water molecules; and (3) functions as a swelling agent (Allenby et al., 1969; Dugard and Embery, 1969).

Various species have been employed in studying the dermal absorption of toxicants. Considerable species variations have been observed in cutaneous permeability. For many chemicals the skin of rats and rabbits is more permeable, whereas the skin of cats is usually less permeable, while the cutaneous permeability characteristics of guinea pigs, pigs, and monkeys are often similar to those observed in humans (Scala et al., 1968; Coulston and Serrone, 1969; Wester and Maibach, 1977). Species differences in percutaneous absorption account for the differential toxicity of insecticides in insects and humans. For example, the LD_{50} of injected DDT is approximately equal in insects and mammals, but DDT is much less toxic to mammals than to insects when it is applied to the skin. This appears to be due to the fact that DDT is poorly absorbed through the skin of mammals but passes readily through the chitinous exoskeleton of insects. Furthermore, insects have a much greater body surface area relative to weight than do mammals (Winteringham, 1957; Albert, 1965; Hayes, 1965).

Species differences related to dermal absorption of xenobiotics has been appreciated (Calabrese, 1984), perhaps because dermal absorption of endogenous or exogenous compounds may vary by orders of magnitude (Kao et al., 1985). According to Dugard (1983), two factors are important in dermal absorption of chemicals: the appendages (sweat ducts, pilosebaceous ducts) in the early phase of absorption and the stratum corneum in the late and dominating phase of absorption. Both factors are highly species-dependent. Because the stratum corneum is much thicker in humans than in animals, human skin is usually less permeable for xenobiotics than is animal skin. However, the thinner stratum corneum in animals is often compensated for by a relatively thick hair cover, diminishing direct contact of the skin with a xenobiotic. Sweat and pilosebaceous ducts also reveal great species variability. Eccrine sweat glands are located in the pads of the extremities of all mammals. However, the general body surface of man contains 100 to $600/m^2$ of coiled tubular sweat glands, whereas rodents and rabbits have none. The number of pilosebaceous ducts in humans and pigs is similar (about $40/cm^2$), but rodents may have 100 times more (Calabrese, 1984). Moreover, biotransformations in skin that facilitate absorption also display great species variability (Kao et al., 1985).

Another important potential rate-limiting step in the dermal absorption of chemicals is the cutaneous blood flow. Due to an important thermoregulatory function of the skin in humans as opposed to furred animals, there is a much more extensive vasculature in humans than in most mammals (Calabrese, 1984). This brief discussion illustrates that species differences in the disposition of xenobiotics after dermal exposure may be due to numerous anatomic, physiologic, and biochemical factors.

Absorption of Toxicants after Special Routes of Administration

Toxicants usually enter the bloodstream after absorption through the skin, lungs, or GI tract. However, in studying chemical agents, toxicologists frequently administer them to laboratory animals by special routes. The most common routes are (1) intraperitoneal, (2) subcutaneous, (3) intramuscular, and (4) intravenous. The intravenous route introduces the toxicant directly into the bloodstream, eliminating the process of absorption. Intraperitoneal injection of toxicants into laboratory animals is also a common procedure. It results in rapid absorption of xenobiotics because of the rich blood supply and the relatively large surface area of the peritoneal cavity. In addition, this route of administration circumvents the delay and variability of gastric emptying. Intraperitoneally administered compounds are absorbed primarily through the portal circulation and therefore must pass through the liver before reaching other organs (Lukas et al., 1971). Subcutaneously and intramuscularly administered toxicants are usually absorbed at slower rates but enter directly into the general circulation. The rate of absorption by these two routes can be altered by changing the blood flow to the injection site. For example, epinephrine causes vasoconstriction and will decrease the rate of absorption if it is coinjected intramuscularly with a toxicant. The formulation of a xenobiotic may also affect the rate of absorption; toxicants are absorbed more slowly from suspensions than from solutions.

The toxicity of a chemical may or may not depend on the route of administration. If a toxicant is injected intraperitoneally, most of the chemical enters the liver via the portal circulation before reaching the general circulation. Therefore, an intraperitoneally administered compound may be completely extracted and biotransformed by the liver with subsequent excretion into the bile without gaining access to the systemic circulation. Propranolol (Shand and Rangno, 1972) and lidocaine (Boyes et al., 1970) are two drugs with efficient extraction during the first pass through the liver. Any toxicant displaying the first-pass effect with selective toxicity for an organ other than the liver and GI tract is expected to be much less toxic when administered intraperitoneally than when injected intravenously, intramuscularly, or subcutaneously. For compounds with no appreciable biotransformation in the liver, toxicity ought to be independent of the route of administration if the rates of absorption are equal. This discussion indicates that it is possible to obtain some preliminary information on the biotransformation and excretion of xenobiotics by comparing their toxicity after administration by different routes.

DISTRIBUTION

After entering the blood by absorption or intravenous administration, a toxicant is available for distribution (translocation) throughout the body. Distribution usually occurs rapidly. The rate of distribution to organs or tissues is determined primarily by blood flow and the rate of diffusion out of the capillary bed into the cells of a particular organ or tissue. The final distribution depends largely on the affinity of a xenobiotic for various tissues. In general, the initial phase of distribution is dominated by blood flow, whereas the eventual distribution is determined largely by affinity. The penetration of toxicants into cells occurs by passive diffusion or special transport processes, as was discussed previously. Small water-soluble molecules and ions apparently diffuse through aqueous channels or pores in the cell membrane. Lipid-soluble molecules readily permeate the membrane itself. Very polar molecules and ions of even moderate size (molecular weight of 50 or more) cannot enter cells easily except by special transport mechanisms because they are surrounded by a hydration shell, making their actual size much larger.

Volume of Distribution

Total body water may be divided into three distinct compartments: (1) plasma water, (2) interstitial water, and (3) intracellular water. Extracellular water is made up of plasma water plus interstitial water. The concentration of a toxicant in blood depends largely on its volume of distribution. For example, if 1 g of each of several chemicals were injected directly into the bloodstreams of 70-kg humans, marked differences in their plasma concentrations would be observed depending on the distribution. A high concentration would be observed in the plasma if the chemical were distributed into plasma water only, and a much lower concentration would be reached if it were distributed into a large pool, such as total body water (see below).

The distribution of toxicants is usually complex and cannot be equated with distribution into one of the water compartments of the body. Binding to and/or dissolution in various storage sites of the body, such as fat, liver, and bone, are usually more important factors in determining the distribution of chemicals.

COMPARTMENT	% OF TOTAL	LITERS IN 70-kg HUMAN	PLASMA CONCENTRATION AFTER 1 g OF CHEMICAL
Plasma water	4.5	3	333 mg/liter
Total extracellular water	20	14	71 mg/liter
Total body water	55	38	26 mg/liter
Tissue binding	—	—	0–25 mg/liter

Some toxicants do not readily cross cell membranes and therefore have restricted distribution, whereas other toxicants rapidly pass through cell membranes and are distributed throughout the body. Some toxicants accumulate in certain parts of the body as a result of protein binding, active transport, or high solubility in fat. The site of accumulation of a toxicant may also be its site of major toxic action, but more often it is not. If a toxicant accumulates at a site other than the target organ or tissue, the accumulation may be viewed as a protective process in that plasma levels and consequently the concentration of a toxicant at the site of action are diminished. In this case, it is assumed that the chemical in the storage depot is toxicologically inactive. However, because any chemical in a storage depot is in equilibrium with the free fraction of toxicant in plasma, it is released into the circulation as the unbound fraction of toxicant is eliminated, for example, by biotransformation.

Storage of Toxicants in Tissues

Since only the free fraction of a chemical is in equilibrium throughout the body, binding to or dissolving in certain body constituents, greatly alters the distribution of a xenobiotic. Toxicants are often concentrated in a specific tissue. Some xenobiotics attain their highest concentrations at the site of toxic action, such as carbon monoxide, which has a very high affinity for hemoglobin, and paraquat, which accumulates in the lungs. Other agents concentrate at sites other than the target organ. For example, lead is stored in bone, but manifestations of lead poisoning appear in soft tissues. The compartment where a toxicant is concentrated can be thought of as a storage depot. Toxicants in these depots are always in equilibrium with the free fraction in plasma. As a chemical is biotransformed or excreted from the body, more is released from the storage site. As a result, the biological half-life of stored compounds can be very long. The following discussion deals with the major storage sites for xenobiotics in the body.

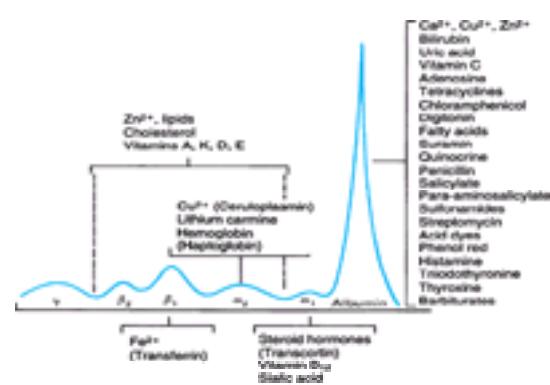
Plasma Proteins as Storage Depot Several plasma proteins bind xenobiotics as well as some physiologic constituents of the body. As depicted in Fig. 5-6, albumin can bind a large number of different compounds. Transferrin, a beta globulin, is important for the transport of iron in the body. The other main metal-binding protein in plasma is ceruloplasmin, which carries most of the copper. The alpha- and beta-lipoproteins are very important in the transport of lipid-soluble compounds such as vitamins, cholesterol, and steroid hormones as well as xenobiotics. The gamma globulins are antibodies that interact specifically with antigens. Compounds possessing basic characteristics often bind to a $_1$ acid glycoprotein (Wilkinson, 1983).


Figure 5-6. Ligand interactions with plasma proteins.

Many therapeutic agents have been examined with respect to plasma protein binding. The extent of plasma protein binding varies considerably among xenobiotics. Some, such as antipyrine, are not bound; others, such as secobarbital, are bound to about 50 percent; and some, like warfarin, are 99 percent bound. Plasma proteins can bind acidic compounds such as phenylbutazone, basic compounds such as imipramine, and neutral compounds such as digitoxin.

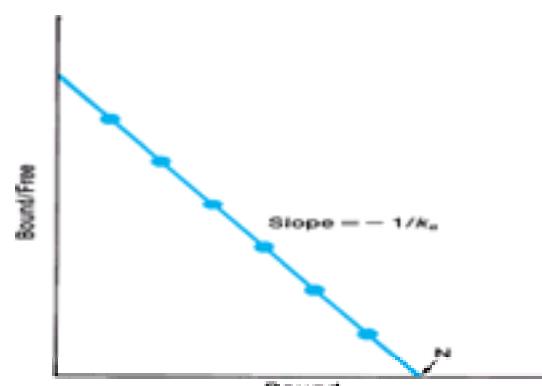
The binding of toxicants to plasma proteins is usually determined by equilibrium dialysis or ultrafiltration. The fraction that passes through the dialysis membrane or appears in the ultrafiltrate is the unbound, or free, fraction. The total concentration is the sum of the bound and free fractions. The bound fraction thus can be determined from the difference between the total and free fractions. The binding of toxicants to plasma proteins can be analyzed through the use of Scatchard plots (Scatchard, 1949). In this analysis, the ratio of bound to free ligand (toxicant) is plotted on the ordinate and the concentration of bound ligand is plotted on the abscissa, depicted in Fig. 5-7. From this analysis, the number of ligand binding sites *(N)* per molecule of protein and the affinity constant of the protein-ligand complex can be determined. The Scatchard plot frequently exhibits nonlinearity, indicating the presence of two or more classes of binding sites with different affinities and capacity characteristics.


Figure 5-7. Schematic representation of the Scatchard plot for the analysis of the binding of toxicants to proteins.

Most xenobiotics that are bound to plasma proteins bind to albumin. Albumin is the most abundant protein in plasma and serves as a depot and transport protein for many endogenous and exogenous compounds. Long-chain fatty acids and bilirubin are endogenous ligands with affinity for albumin. There appear to be six binding regions on the protein (Kragh-Hansen, 1981). Protein-ligand interactions occur primarily as a result of hydrophobic forces, hydrogen bonding, and Van der Waals forces. Because of their high molecular weight, plasma proteins and the toxicants bound to them cannot cross capillary walls. Consequently, the fraction of toxicant bound to plasma proteins is not immediately available for distribution into the extravascular space or filtration by the kidneys. However, the interaction of a chemical with plasma proteins is a reversible process. As unbound chemical diffuses out of capillaries, bound chemical dissociates from the protein until the free fraction reaches equilibrium between the vascular space and the extravascular space. In turn, diffusion in the extravascular space to sites more distant from the capillaries continues, and the resulting concentration gradient provides the thermodynamic force for continued dissociation of the bound fraction in plasma. Active transport processes are not limited by the binding of chemicals to plasma proteins.

The binding of chemicals to plasma proteins is of special importance to toxicologists because severe toxic reactions can occur if a toxicant is displaced from plasma proteins by another agent, increasing the free fraction of the toxicant in plasma. This will result in an increased equilibrium concentration of the toxicant in the target organ, with the potential for toxicity. For example, if a strongly bound sulfonamide is given concurrently with an antidiabetic drug, the sulfonamide may displace the antidiabetic drug and induce a hypoglycemic coma. Xenobiotics can also compete with and displace endogenous compounds that are bound to plasma proteins. The importance of this phenomenon was demonstrated in a clinical trial comparing the efficacy of tetracycline with that of a penicillin-sulfonamide mixture in the management of bacterial infections in premature infants (Silverman et al., 1956). The penicillin-sulfonamide mixture led to much higher mortality than did the tetracycline, because the sulfonamide displaced a considerable amount of bilirubin from albumin. The bilirubin then diffused into the brain through the not fully developed blood-brain barrier of the newborn, causing a severe form of brain damage termed *kernicterus.*

Most research on the binding of xenobiotics to plasma proteins has been conducted with drugs. However, other chemicals, such as the insecticide dieldrin, also bind avidly to plasma proteins (99 percent). Therefore, it is to be expected that chemical-chemical interactions that alter plasma protein binding occur with many different xenobiotics.

Plasma protein bonding can also give rise to species differences in the disposition of xenobiotics. For example, plasma protein binding of clofibric acid reveals considerable differences between mice, rats, and humans, which roughly correlates with the half-lives of this compound in these species (Table 5-6). Because clofibric acid is primarily eliminated in all three species by glomerular filtration without tubular reabsorption (pK_a = 3), differences in the free fraction of this compound in plasma of various species provide part of the explanation for the observed species differences. The other major factor is renal clearance (blood flow–dependent). Additional factors that influence plasma protein binding may also be responsible for species differences, as discussed by Wilkinson (1983). Most important among them are species differences in the concentration of albumin, in binding affinity, and/or in competitive binding of endogenous substances.

SPECIES	PLASMA PROTEIN BINDING (%)	HALF-LIFE (h)
Man	97	21
Rat	75	6
Mouse	45	2

*Modified from Cayen (1980).

Table 5-6 Plasma Protein Binding and Half-life of Clofibric Acid in the Mouse, Rat, and Man6

Liver and Kidney as Storage Depots The liver and kidney have a high capacity for binding a multitude of chemicals. These two organs probably concentrate more toxicants than do all the other organs combined. Although the mechanisms by which the liver and kidney remove toxicants from the blood have not been established, active transport or binding to tissue components seems to be involved in most cases.

A protein in the cytoplasm of the liver (ligandin) has been identified as having a high affinity for many organic acids. It has been suggested that this protein may be important in the transfer of organic anions from plasma into liver (Levi et al., 1969). This protein also binds azo dye carcinogens and corticosteroids (Litwack et al., 1971). Another protein—metallothionein—has been found to bind cadmium and zinc with high affinities in the kidney and liver. Hepatic uptake of lead illustrates how rapidly liver binds foreign compounds: just 30 min after a single dose, the concentration of lead in liver is 50 times higher than the concentration in plasma (Klaassen and Shoeman, 1974).

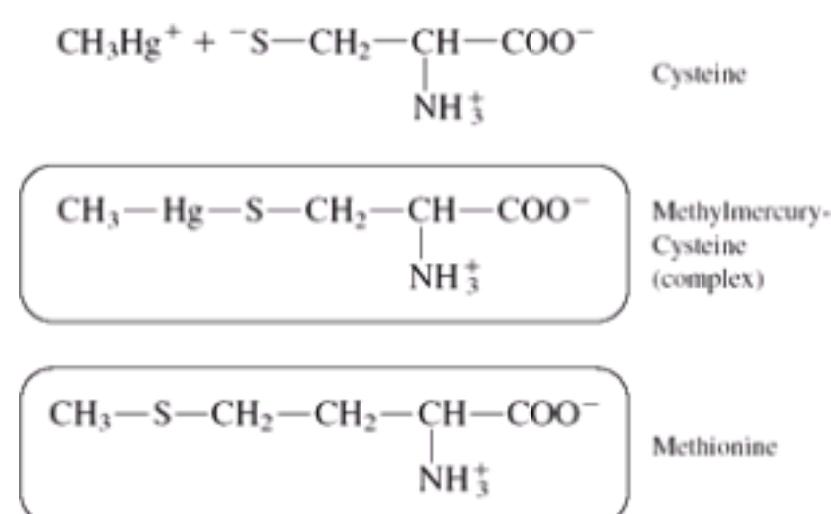
Fat as Storage Depot Many organic compounds in the environment are highly lipophilic. This characteristic permits rapid penetration of cell membranes and uptake by tissues. Therefore, it is not surprising that highly lipophilic toxicants are distributed and concentrated in body fat. Such accumulation in adipose tissue has been demonstrated for a number of chemicals, including chlordane, DDT, and polychlorinated and polybrominated biphenyls.

Toxicants appear to accumulate in fat by dissolution in neutral fats, which constitute about 50 percent and 20 percent of the body weight of obese individuals and lean athletic individuals, respectively. Thus, large amounts of toxicants with a high lipid/water partition coefficient may be stored in body fat. Storage lowers the concentration of the toxicant in the target organ; therefore, the toxicity of such a compound can be expected to be less severe in an obese person than in a lean individual. However, of more practical concern is the possibility of a sudden increase in the concentration of a chemical in the blood and thus in the target organ of toxicity when rapid mobilization of fat occurs. Several studies have shown that signs of intoxication can be produced by short-term starvation of experimental animals that were previously exposed to persistent organochlorine insecticides.

One frequently overlooked cause of species differences in the distribution of xenobiotics that are stored in fat is the different rate of growth of mammals (Scheufler and Rozman, 1986). As Freeman and colleagues (1988) demonstrated using a physiologically based pharmacokinetic model, tissue and whole body growth contribute more to the distribution and elimination profile of hexachlorobenzene than does excretion.

Bone as Storage Depot Compounds such as fluoride, lead, and strontium may be incorporated and stored in bone matrix. For example, 90 percent of the lead in the body is eventually found in the skeleton.

Skeletal uptake of xenobiotics is essentially a surface chemistry phenomenon, with exchange taking place between the bone surface and the fluid in contact with it. The fluid is the extracellular fluid, and the surface is that of the hydroxyapatite crystals of bone mineral. Many of those crystals are very small, so that the surface is large in proportion to the mass. The extracellular fluid brings the toxicant into contact with the hydration shell of the hydroxyapatite, allowing diffusion through it and penetration of the crystal surface. As a result of similarities in size and charge, F^- may readily displace OH^-, whereas lead or strontium may substitute for calcium in the hydroxyapatite lattice matrix through an exchange-absorption reaction.

Deposition and storage of toxicants in bone may or may not be detrimental. Lead is not toxic to bone, but the chronic effects of fluoride deposition (skeletal fluorosis) and radioactive strontium (osteosarcoma and other neoplasms) are well documented.


Foreign compounds deposited in bone are not sequestered irreversibly by that tissue. Toxicants can be released from the bone by ionic exchange at the crystal surface and dissolution of bone crystals through osteoclastic activity. An increase in osteolytic activity such as that seen after parathyroid hormone administration leads to enhanced mobilization of hydroxyapatite lattice, which can be reflected in an increased plasma concentration of toxicants.

Blood-Brain Barrier

The blood-brain barrier is not an absolute barrier to the passage of toxic agents into the CNS. Instead, it represents a site that is less permeable than are most other areas of the body. Nevertheless, many poisons do not enter the brain in appreciable quantities because of this barrier.

There are four major anatomic and physiologic reasons why some toxicants do not readily enter the CNS. First, the capillary endothelial cells of the CNS are tightly joined, leaving few or no pores between the cells. Second, the brain capillary endothelial cells contain an ATP-dependent transporter, the multi-drug–resistant (mdr) protein that exudes some chemicals back into the blood. Third the capillaries in the CNS are to a large extent surrounded by glial cell processes (astrocytes). Fourth, the protein concentration in the interstitial fluid of the CNS is much lower than that in other body fluids. For small to medium-sized water-soluble molecules, the tighter junctions of the capillary endothelium and the lipid membranes of the glial cell processes represent the major barrier. Lipid-soluble compounds have to traverse not only the membranes of the endothelial cells but also those of glial cell processes. More important, perhaps, the low protein content of the interstitial fluid in the brain greatly limits the movement of water-insoluble compounds by paracellular transport, which is possible in a largely aqueous medium only when such compounds are bound to proteins. These features provide some protection against the distribution of toxicants to the CNS and thus against toxicity.

The effectiveness of the blood-brain barrier varies from one area of the brain to another. For example, the cortex, the lateral nuclei of the hypothalamus, the area postrema, the pineal body, and the posterior lobe of the hypophysis are more permeable than are other areas of the brain. It is not clear whether this is due to the increased blood supply to those areas, a more permeable barrier, or both. In general, the entrance of toxicants into the brain follows the same principle that applies to transfer across other cells in the body. Only the free fraction of a toxicant (i.e., not bound to plasma proteins) equilibrates rapidly with the brain. Lipid solubility plays an important role in determining the rate of entry of a compound into the CNS, as does the degree of ionization, as discussed earlier. In general, increased lipid solubility enhances the rate of penetration of toxicants into the CNS, whereas ionization greatly diminishes it. Pralidoxime (2-PAM), a quaternary nitrogen derivative, does not readily penetrate the brain and is ineffective in reversing the inhibition of brain cholinesterase caused by organophosphate insecticides. It is not clear why some very lipophilic chemicals, such as TCDD, are not readily distributed into the brain, which in fact displays the lowest concentration among all tissues and body fluids (Weber et al., 1993). It is likely, though, that strong binding to plasma proteins or lipoproteins, as well as the composition of the brain (mainly phospholipids), limits the entry of very lipophilic compounds into the brain. Some xenobiotics, although very few, appear to enter the brain by carrier-mediated processes. For example, methylmercury combines with cysteine, forming a structure similar to methionine (see above), and the complex is then accepted by the large neutral amino acid carrier of the capillary endothelial cells (Clarkson, 1987).

$$CH_3Hg^+ + {}^-S-CH_2-\underset{\underset{NH_3^+}{|}}{CH}-COO^- \qquad \text{Cysteine}$$

$$\boxed{CH_3-Hg-S-CH_2-\underset{\underset{NH_3^+}{|}}{CH}-COO^-} \qquad \begin{matrix}\text{Methylmercury-}\\\text{Cysteine}\\\text{(complex)}\end{matrix}$$

$$\boxed{CH_3-S-CH_2-CH_2-\underset{\underset{NH_3^+}{|}}{CH}-COO^-} \qquad \text{Methionine}$$

Active transport processes decrease the concentration of xenobiotics in the brain. The multidrug resistant protein (mdr) has been demonstrated in endothelial cells in the brain (Schinkel et al., 1994) and is responsible for transporting some chemicals from endothelial cells back into the blood. Ivermectin, an insecticide, has been known to be much more toxic in mdr-null mice (LD50 » 0.4–0.6 mg/kg) than in control mice (50–60 mg/kg). This increased sensitivity to ivermectin in the mdr-null mice is due to 80-fold higher brain ivermectin concentrations.

The blood-brain barrier is not fully developed at birth, and this is one reason why some chemicals are more toxic in newborns than to adults. Morphine, for example, is three to ten times more toxic to newborn than to adult rats because of the higher permeability of the brain of a newborn to morphine (Kupferberg and Way, 1963). Lead produces encephalomyelopathy in newborn rats but not in adults, also apparently because of differences in the stages of development of the blood brain barrier (Pentschew and Garro, 1966).

Passage of Toxicants across the Placenta

For years the term *placental barrier* was associated with the concept that the main function of the placenta is to protect the fetus against the passage of noxious substances from the mother. However, the placenta has many functions: it provides nutrition for the conceptus, exchanges maternal and fetal blood gases, disposes of fetal excretory material, and maintains pregnancy through complex hormonal regulation. Most of the vital nutrients necessary for the development of the fetus are transported by active transport systems. For example, vitamins, amino acids, essential sugars, and ions such as calcium and iron are transported from mother to fetus against a concentration gradient (Young, 1969; Ginsburg, 1971). In contrast, most toxic agents pass the placenta by simple diffusion. The only exceptions are a few antimetabolites that are structurally similar to endogenous purines and pyrimidines, which are the physiologic substrates for active transport from the maternal to the fetal circulation.

Many foreign substances can cross the placenta. In addition to chemicals, viruses (e.g., rubella virus), cellular pathogens (e.g., syphilis spirochetes), globulin antibodies, and erythrocytes (Goldstein et al., 1974) can traverse the placenta. Anatomically, the placental barrier consists of a number of cell layers interposed

between the fetal and maternal circulations. The number of layers varies with the species and the state of gestation. Placentas in which the maximum number of cell layers are present (all six layers) are called *epitheliochoria.* (Table 5-7). Those in which the maternal epithelium is absent are referred to as *syndesmochorial.* When only the endothelial layer of the maternal tissue remains, the tissue is termed *endotheliochorial;* when even the endothelium is gone, so that the chorionic villi bathe in the maternal blood, the tissue is called *hemochorial.* In some species, some of the fetal layers are absent and are called *hemoendotheliai* (Dames, 1968). Within the same species, the placenta may also change its histologic classification during gestation (Amaroso, 1952). For example, at the beginning of gestation, the placenta of a rabbit has six major layers (epitheliochorial), and at the end it has only one (hemoendothelial). One might suspect that a relatively thin placenta such as that of a rat would be more permeable to toxic agents than is the placenta of humans, whereas a thicker placenta such as that of a goat would be less permeable. The exact relationship of the number of layers of the placenta to its permeability has not been investigated. Currently, it is not considered to be of primary importance in determining the distribution of chemicals to the fetus.

Table 5-7 Tissues Separating Fetal and Maternal Blood

The same factors are important determinants of the placental transfer of xenobiotics by passive diffusion (particularly lipid/water solubility), as was discussed above for the passage of molecules across body membranes.

Recently it has been shown that the placenta contains active transport systems that protect the fetus from some xenobiotics. For example, multi-drug–resistant null (mdr null) fetuses are more susceptible to cleft palate produced by a photoisomer of avermectin due to higher concentrations in the mdr null fetuses (Lankas et al., 1998).

The placenta has biotransformation capabilities that may prevent some toxic substances from reaching the fetus (Juchau, 1972). Among the substances that cross the placenta by passive diffusion, more lipid-soluble substances more rapidly attain a maternal-fetal equilibrium. Under steady-state conditions, the concentrations of a toxic compound in the plasma of the mother and fetus are usually the same. The concentration in the various tissues of the fetus depends on the ability of fetal tissue to concentrate a toxicant. For example, the concentration of diphenylhydantoin in the plasma of the fetal goat was about half of that found in the mother. This was due to differences in plasma protein concentration and the binding affinity of diphenylhydantoin to plasma proteins (Shoeman et al., 1972). Also, some organs, such as the liver of the newborn (Klaassen, 1972) and the fetus, do not concentrate some xenobiotics, and therefore lower levels are found in the liver of the fetus. In contrast, higher concentrations of some chemicals, such as lead and dimethylmercury, are encountered in the brain of the fetus because of the fetus's not fully developed blood-brain barrier. Differential body composition between mother and fetus may be another reason for an apparent placental barrier. For example, fetuses have very little fat. Accordingly, and in contrast to the mothers, they do not accumulate highly lipophilic chemicals such as TCDD (Li et al., 1995).

Redistribution of Toxicants

As mentioned earlier, blood flow to and the affinity of an organ or tissue are the most critical factors that affect the distribution of xenobiotics. Chemicals can have an affinity to a binding site (e.g., intracellular protein or bone matrix) or to a cellular constituent (e.g., fat). The initial phase of distribution is determined primarily by blood flow to the various parts of the body. Therefore, a well-perfused organ such as the liver may attain high initial concentrations of a xenobiotic. However, the affinity of less well perfused organs or tissues may be higher for a particular xenobiotic, causing redistribution with time. For example, 2 h after administration, 50 percent of a dose of lead is found in the liver (Klaassen and Shoeman,1974). However, 1 month after dosing, 90 percent of the dose remaining in the body is associated with the crystal lattice of bone. Similarly, 5 min after an intravenous dose of a lipophilic chemical such as TCDD, about 15 percent of the dose is localized in the lungs, but only about 1 percent in adipose tissue. However, 24 h later, only 0.3 percent of the remaining dose is found in the lungs but about 20 percent in adipose tissue (Weber et al., 1993).

EXCRETION

Toxicants are eliminated from the body by several routes. The kidney is perhaps the most important organ for the excretion of xenobiotics, as more chemicals are eliminated from the body by this route than by any other (Chap. 14). Many xenobiotics, though, have to be biotransformed to more water-soluble products before they can be excreted into urine (Chap. 6). The second important route of elimination of many xenobiotics is via feces, and the third, primarily via the lungs. Biliary excretion of xenobiotics and/or their metabolites is most often the major source of fecal excretion, but a number of other sources can be significant for some compounds. All body secretions appear to have the ability to excrete chemicals; toxicants have been found in sweat, saliva, tears, and milk (Stowe and Plaa, 1968).

Urinary Excretion

The kidney is a very efficient organ for the elimination of toxicants from the body. Toxic compounds are excreted with urine by the same mechanisms the kidney uses to remove the end products of intermediary metabolism from the body: glomerular filtration, tubular excretion by passive diffusion, and active tubular secretion.

The kidney receives about 25 percent of the cardiac output, about 20 percent of which is filtered at the glomeruli. The glomerular capillaries have large pores (70 nm). Therefore, compounds up to a molecular weight of about 60,000 (proteins smaller than albumin) are filtered at the glomeruli. The degree of plasma protein binding affects the rate of filtration, because protein-xenobiotic complexes are too large to pass through the pores of the glomeruli.

A toxicant filtered at the glomeruli may remain in the tubular lumen and be excreted with urine. Depending on the physicochemical properties of a compound, it may be reabsorbed across the tubular cells of the nephron back into the bloodstream. The principles governing the reabsorption of toxicants across the kidney tubules are the same as those discussed earlier in this chapter for passive diffusion across cell membranes. Thus, toxicants with a high lipid/water partition coefficient are reabsorbed efficiently, whereas polar compounds and ions are excreted with urine. As can be deduced from the Henderson-Hasselbalch equations, bases are excreted (i.e., not reabsorbed) to a greater extent at lower and acids at higher urinary pH values. A practical application of this knowledge is illustrated by the treatment of phenobarbital poisoning with sodium bicarbonate. The percentage of ionization can be increased markedly within physiologically attainable pH ranges for a weak organic acid such as phenobarbital (pK_a 7.2). Consequently, alkalinization of urine by the administration of sodium bicarbonate results in a significant increase in the excretion of phenobarbital (Weiner and Mudge, 1964). Similarly, acceleration of salicylate loss via the kidney can be achieved through the administration of sodium bicarbonate.

Toxic agents can also be excreted from plasma into urine by passive diffusion through the tubule. This process is probably of minor significance because filtration is much faster than excretion by passive diffusion through the tubules, providing a favorable concentration gradient for reabsorption rather than excretion. Exceptions to this generalization may be some organic acids (pK_a » 3 to 5) and bases (pK_a » 7 to 9) that would be largely ionized and thus trapped at the pH of urine (pH » 6). For renal excretion of such compounds, the flow of urine is likely to be important for the maintenance of a concentration gradient, favoring excretion. Thus, diurectics can hasten the elimination of weak organic acids and bases.

Xenobiotics can also be excreted into urine by active secretion. During the last few years a number of transporters have been identified in the kidney. Figure 5-8 illustrates the various families of transporters in the kidney. The organic-anion transporter (oat) family is localized on the basolateral membranes of the proximal tubule. This family is responsible for the renal uptake of organic acids such as *p*-aminohippurate. The organic-cation transporting (oct) family is responsible for the

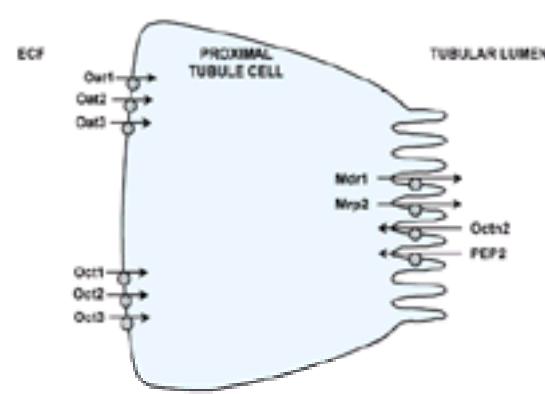
renal uptake of some cations. Once xenobiotics are in the tubular cell, they are exuded into the lumen by multi-drug—resistant protein (mdr) and by multi-resistant drug protein (mrp). In contrast, the organic cation transporter (octn2) and peptide transporter (PEP2) reabsorb chemicals from the tubular lumen.


Figure 5-8. Schematic model showing the transport systems in the proximal tubule of the kidney.

The families of transporters are organic anion transporters (oat), organic-cation transporters (oct), multidrug resistant protein (mdr), multiresistant drug protein (mrp), and peptide transporters (PEP). ECF = extracellular fluid.

Some less polar xenobiotics may diffuse into the lumen. In contrast to filtration, protein-bound toxicants are available to active transport. As in all active transport systems, renal secretion of xenobiotics also reveals competition. This fact was put to use during World War II, when penicillin was in short supply. Penicillin is actively secreted by the organic acid system of the kidney. To lengthen its half-life and duration of action, another acid was sought to compete with penicillin for renal secretion; probenecid was successfully introduced for this purpose. Uric acid is also secreted actively by renal tubules. It is of clinical relevance that toxicants transported by the organic acid transport system can increase the plasma uric acid concentration and precipitate an attack of gout.

Because many functions of the kidney are incompletely developed at birth, some xenobiotics are eliminated more slowly in newborns than in adults and therefore may be more toxic to newborns. For example, the clearance of penicillin by premature infants is only about 20 percent of that observed in older children (Barnett et al., 1949). It has been demonstrated that the development of this organic acid transport system in newborns can be stimulated by the administration of substances normally excreted by this system (Hirsch and Hook, 1970). Some compounds, such as cephaloridine, are known to be nephrotoxic in adult animals but not in newborns. Because active uptake of cephaloridine by the kidneys is not well developed in newborns, this agent is not concentrated in the tubules and consequently is not nephrotoxic. If the development of active transport in newborns is stimulated, the kidneys take up cephaloridine more readily and nephrotoxicity is observed (Wold et al., 1977). Also, nephrotoxicity can be blocked by probenecid, which competitively inhibits the uptake of cephaloridine into the kidneys (Tune et al., 1977).

The renal proximal tubule reabsorbs small plasma proteins that are filtered at the glomerulus. Thus, if a toxicant binds to those small proteins, it can be carried into the proximal tubule cells and exert toxicity. For example, cadmium bound to metallothionein, a small metal-binding protein, is readily taken up by the kidney, leading to kidney injury (Dorian et al., 1992). Similarly, chemicals such as limonene (present in orange juice) and trimethyl pentane (present in gasoline) bind to a $_{2u}$-globulin and are taken up by the proximal tubule to produce hyaline droplet nephropathy and eventually renal tumors in male rats (Lehman-McKeeman and Caudill, 1992). Fortunately, a_{2L}-globulin is expressed only by male rats.

Species differences in regard to the urinary excretion of weak organic acids and bases are observed frequently, as the pH of urine varies widely among species. Differences in renal clearance also can occur for compounds filtered at the glomeruli because of differences in plasma protein binding. Interestingly, species variations also can arise as a result of differences in active renal secretion, as has been shown for captopril (Migdalof et al., 1984).

Additional factors affecting the excretion of xenobiotics are exemplified by the disposition of griseofulvin in rats and rabbits (Table 5-8). Rabbits excrete most of a dose of griseofulvin as 6-demethylgriseofulvin in urine. Urinary excretion of this compound is to be expected, because its molecular weight is only 328. Molecules with molecular weight (MW) < 350 tend to be preferentially excreted in urine, whereas those between 350 and 700 are predominately excreted in bile. Because the molecular weight of griseofulvin conjugates is about 500, it is not surprising that rats which biotransform griseofulvin extensively (phase II) excrete much of a dose in bile. This is an example of biotransformation exerting a critical influence on the excretion of a xenobiotic.

Table 5-8 Urinary and Biliary Excretion of Griseofulvin and/or Metabolites in Rats and Rabbits

Fecal Excretion

Fecal excretion is the other major pathway for the elimination of xenobiotics from the body. Fecal excretion of chemicals is a complex process that is not as well understood as urinary excretion. Several important sources and many more minor sources contribute to the excretion of toxicants via the feces.

Nonabsorbed Ingesta In addition to indigestible material, varying proportions of nutrients and xenobiotics that are present in food or are ingested voluntarily (drugs) pass through the alimentary canal unabsorbed, contributing to fecal excretion. The physicochemical properties of xenobiotics and the biological characteristics that facilitate absorption were discussed earlier in this chapter. In general, most human-made chemicals are at least to some extent lipophilic and thus are available for absorption. Exceptions include some macromolecules and some essentially completely ionized compounds of higher molecular weight. For example, the absorption of polymers or quaternary ammonium bases is quite limited in the intestine. Consequently, most of a dose of orally administered sucrose polyester, cholestyramine, or paraquat can be found in feces. It is rare for 100 percent of a compound to be absorbed. Therefore, the nonabsorbed portion of xenobiotics contributes to the fecal excretion of most chemicals to some extent.

Biliary Excretion The biliary route of elimination is perhaps the most important contributing source to the fecal excretion of xenobiotics and is even more important for the excretion of their metabolites. The liver is in a very advantageous position for removing toxic agents from blood after absorption from the GI tract, because blood from the GI tract passes through the liver before reaching the general circulation. Thus, the liver can extract compounds from blood and prevent their distribution to other parts of the body. Furthermore, the liver is the main site of biotransformation of toxicants and the metabolites thus formed may be excreted directly into bile. Xenobiotics and/or their metabolites entering the intestine with bile may be excreted with feces: when the physicochemical properties favor reabsorption, an enterohepatic circulation may ensue.

Foreign compounds excreted into bile are often divided into three classes on the basis of ratio of their concentration in bile versus that in plasma. Class A substances

have a ratio of nearly 1 and include sodium, potassium, glucose, mercury, thallium, cesium, and cobalt. Class B substances have a ratio of bile to plasma greater than 1 (usually between 10 and 1000). Class B substances include bile acids, bilirubin, sulfobromophthalein, lead, arsenic, manganese, and many other xenobiotics. Class C substances have a ratio below 1 (e.g., inulin, albumin, zinc, iron, gold, and chromium). Compounds rapidly excreted into bile are most likely to be found among class B substances. However, a compound does not have to be highly concentrated in bile for biliary excretion to be of quantitative importance. For example, mercury is not concentrated in bile, yet bile is the main route of excretion for this slowly eliminated substance.

The mechanism of transport of foreign substances from plasma into liver and from liver into bile is not known with certainty. Especially little is known about the mechanism of the transfer of class A and class C compounds. However, it is thought that most class B compounds are actively transported across both sides of the hepatocyte.

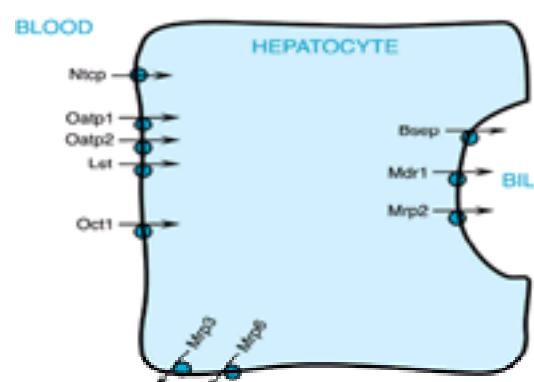
Figure 5-9 illustrates the myriad of transporters localized on hepatic parenchymal cells. Sodium-dependent taurocholate peptide (ntcp) is present on the sinusoidal side of the parenchymal cell and transports bile acids such as taurocholate into the liver, whereas the bile salt excretory protein (bsep) transports bile acids out of the liver cell into the bile canaliculi. The sinusoidal membrane of the hepatocyte has a number of transporters including organic-anion polypeptide (oatp) 1 and 2, liver specific transporter (lst), and organic-cation (oct) transporters that transport xenobiotics into the liver. Once inside the hepatocyte, the xenobiotic can be transported into the blood or bile, or often is biotransformed by phase I and II drug metabolizing enzymes to more water-soluble products and then transported into the bile or back into the blood. Multi-drug–resistant protein one (mdr1) and multi-resistant drug protein two (mrp2) are responsible for transporting xenobiotics into bile, whereas mrp3 and mrp6 transport xenobiotics back into the blood.


Figure 5-9. Schematic model showing the transport systems in the liver.

ntcp = sodium dependent taurocholate peptide, oatp = organic-anion transporting polypeptide, lst = liver specific transporter, oct = organic-cation transporter, bsep = bile salt excretory protein, mdr = multidrug resistant protein, mrp = multiresistant drug protein.

The biliary excretion of two organic acids—sulfobromophthalein (BSP) and indocyanine green (ICG)—has been particularly well examined. The rate of removal of these two dyes has long been used in liver function tests. The test is performed by injecting the dye intravenously and determining its plasma disappearance profile. A lack of proper plasma clearance of BSP or ICG indicates reduced biliary excretion, suggesting liver injury. Bilirubin is also actively transported from plasma into bile. Therefore, jaundice is often observed after a liver injury.

As with renal tubular secretion, toxic agents bound to plasma proteins are fully available for active biliary excretion. The relative importance of biliary excretion depends on the substance and species concerned. It is not known which factors determine whether a chemical will be excreted into bile or into urine. However, low-molecular-weight compounds are poorly excreted into bile while compounds or their conjugates with molecular weights exceeding about 325 can be excreted in appreciable quantities. Glutathione and glucuronide conjugates have a high predilection for excretion into bile. The percentages of a large number of compounds excreted into bile have been tabulated (Klaassen et al., 1981). Marked species variation exists in the biliary excretion of foreign compounds with consequences for the biological half-life of a compound and its toxicity. This species variation in biliary excretion is compound-specific. It is therefore difficult to categorize species into "good" or "poor" biliary excretors. However, in general, rats and mice tend to be better biliary excretors than are other species (Klaassen and Watkins, 1984).

Once a compound is excreted into bile and enters the intestine, it can be reabsorbed or eliminated with feces. Many organic compounds are conjugated before excretion into bile. Such polar metabolites are not sufficiently lipid-soluble to be reabsorbed. However, intestinal microflora may hydrolyze glucuronide and sulfate conjugates, making them sufficiently lipophilic for reabsorption. Reabsorption of a xenobiotic completes an enterohepatic cycle. Repeated enterohepatic cycling may lead to very long half-lives of xenobiotics in the body. Therefore, it is often desirable to interrupt this cycle to hasten the elimination of a toxicant from the body. This principle has been utilized in the treatment of dimethylmercury poisoning; ingestion of a polythiol resin binds the mercurial and thus prevents its reabsorption (Magos and Clarkson, 1976).

An increase in hepatic excretory function also has been observed after pretreatment with some drugs (Klaassen and Watkins, 1984). For example, it has been demonstrated that phenobarbital increases plasma disappearance by enhancing the biliary excretion of BSP and a number of other compounds. The increase in bile flow caused by phenobarbital appears to be an important factor in increasing the biliary excretion of BSP. However, other factors, such as the induction of some phase II enzymes, also can increase the conjugating capacity of the liver and thus enhance the plasma disappearance and biliary excretion of some compounds. Not all microsomal enzyme inducers increase bile flow and excretion; 3-methylcholanthrene and benzo[a]pyrene are relatively ineffective in this regard.

An increase in biliary excretion can decrease the toxicity of xenobiotics. Phenobarbital treatment of laboratory animals has been shown to enhance the biliary excretion and elimination of methylmercury from the body (Klaassen, 1975; Magos and Clarkson, 1976). Two steroids known to induce microsomal enzymes—spironolactone and pregnenolone-16a-carbonitrile—have also been demonstrated to increase bile production and to enhance biliary excretion of BSP (Zsigmond and Solymoss, 1972). These two steroids have also been shown to decrease the toxicity of several chemicals (Selye, 1970, 1971), including cardiac glycosides (Selye et al, 1969), by increasing their biliary excretion. This in turn decreases the concentration of cardiac glycosides in the heart, their target organ of toxicity (Castle and Lage, 1972, 1973; Klaassen, 1974a).

The hepatic excretory system is not fully developed in newborns, and this is another reason why some compounds are more toxic to newborns than to adults (Klaassen, 1972, 1973a). For example, ouabain is about 40 times more toxic in newborn than in adult rats. This is due to an almost complete inability of the newborn rat liver to remove ouabain from plasma. A decreased excretory function of newborn liver also has been demonstrated for other xenobiotics (Klaassen, 1973b). The development of hepatic excretory function can be promoted in newborns by administering a microsomal enzyme inducer (Klaassen, 1974b).

The toxicity of some compounds can be directly related to their biliary excretion. For example, indomethacin can cause intestinal lesions. The sensitivity of various species to this toxic response is directly related to the amount of indomethacin excreted into bile. The formation of intestinal lesions can be abolished by bile duct ligation (Duggan et al., 1975).

Often the elimination of a compound occurs by different routes in different species, as shown in the case of indomethacin in the dog and the rhesus monkey (Table 5-9). Dogs excrete most of a dose in feces, whereas monkeys excrete the majority of a dose in urine. Both species excrete similarly large quantities of a dose in bile. Because dogs excrete most of a dose in bile as conjugates (MW > 500), it is to be expected that these hydrophilic indomethacin derivatives will not be reabsorbed unless they are hydrolyzed by intestinal bacteria to the reabsorbable parent compound, or to phase I metabolites (which do have good bioavailability). Based on available experimental data, it is not possible to decide with certainty whether or not this is occurring in the dog. It appears that indomethacin undergoes enterohepatic circulation with repeated conjugation in the liver and deconjugation in the small intestine, with a gradual "loss" of conjugates into the large intestine. However, because almost all of fecal excretion consists of indomethacin, it is apparent that the large intestinal flora hydrolyzes the indomethacin conjugates. Limited reabsorption of indomethacin is not surprising (pK_a » 4.5, colon pH » 8), because more than 99.7 percent of indomethacin is ionized in the large intestine, which has a small surface area (compared to the small intestine). This does not allow for a sufficiently rapid shift in the mass balance to result in substantial reabsorption.

COMPOUND	Urine		Bile		Feces	
	DOG	MONKEY	DOG	MONKEY	DOG	MONKEY
Indomethacin	0.6ᵃ	10.5	3.8	33.6	61.7	4
Phase I metabolites	4.1	24.2	NIᵇ	NI	2.7	6
Phase II metabolites	3.3	17.5	52.1	8.1	3.1	NI
Total dose excreted	7.9	52.7	55.9	51.7	76.3	10

ᵃ Values represent % of dose excreted.
ᵇ NI, not identified or very small amounts.

Table 5-9 Urinary, Biliary, and Fecal Excretion of Indomethacin and/or Its Metabolites in Dogs and Monkeys after Intravenous Dosage

The monkey also reveals extensive enterohepatic recycling of indomethacin (57.7 percent of dose excreted in bile within 2 h). However, most of the biliary excretion consists of parent compound, which is readily reabsorbed in the small intestine, as indicated by the small amount lost into feces (about 10 percent of dose). In contrast to the dog, monkeys excrete most of a dose as phase I metabolites (24.2 percent of dose) and indomethacin (10.5 percent of dose). Because indomethacin has a molecular weight of 358 and phase I metabolites have molecular weights of 220 to 345, these compounds are readily excreted in urine.

Intestinal Excretion It has been shown for a fairly large number of diverse chemicals (e.g., digitoxin, dinitrobenzamide, hexachlorobenzene, ochratoxin A) that their excretion into feces can be explained neither by the unabsorbed portion of an oral dosage nor by excretion into bile (Rozman, 1986). Experiments in bile duct—ligated animals and animals provided with bile fistulas have revealed that the source of many chemicals in feces is a direct transfer from blood into the intestinal contents. This transfer is thought to occur by passive diffusion for most xenobiotics. In some instances, rapid exfoliation of intestinal cells also may contribute to the fecal excretion of some compounds. Intestinal excretion is a relatively slow process. Therefore, it is a major pathway of elimination only for compounds that have low rates of biotransformation and/or low renal or biliary clearance. The rate of intestinal excretion of some lipid-soluble compounds can be substantially enhanced by increasing the lipophilicity of the GI contents—for example, by adding mineral oil to the diet (Rozman, 1986). Active secretion of organic acids and bases also has been demonstrated in the large intestine (Lauterbach, 1977). The importance of active intestinal secretion for fecal elimination has been established only for a few chemicals.

Intestinal Wall and Flora No systematic attempts have been undertaken to assess the role of biotransformation in the intestinal wall in the fecal excretion of xenobiotics. Nevertheless, in recent years evidence has accumulated that mucosal biotransformation and reexcretion into the intestinal lumen occur with many compounds. The significance of these findings for fecal excretion is difficult to judge because further interaction with the intestinal flora may alter these compounds, making them more or less suitable for reabsorption or excretion (Rozman, 1986). More is known about the contribution of the intestinal flora to fecal excretion. It has been estimated that 30 to 42 percent of fecal dry matter originates from bacteria. Chemicals originating from the nonabsorbed portion of an oral dose, the bile, or the intestinal wall are taken up by these microorganism according to the principles of membrane permeability. Therefore, a considerable proportion of fecally excreted xenobiotic is associated with the excreted bacteria. However, chemicals may be profoundly altered by bacteria before excretion with feces, particularly in the large intestine, where intestinal flora are most abundant, and intestinal contents remain for 24 h or longer. It seems that biotransformation by intestinal flora favors reabsorption rather than excretion. Nevertheless, there is evidence that in many instances xenobiotics found in feces derive from bacterial biotransformation. The importance of microbial biotransformation for fecal excretion can be studied by performing experiments in normal versus gnotobiotic animal (animals with no microflora).

Exhalation

Substances that exist predominantly in the gas phase at body temperature are eliminated mainly by the lungs. Because volatile liquids are in equilibrium with their gas phase in the alveoli, they also may be excreted via the lungs. The amount of a liquid eliminated via the lungs is proportional to its vapor pressure. A practical application of this principle is seen in the breath analyzer test for determining the amount of ethanol in the body. Highly volatile liquids such as diethyl ether are excreted almost exclusively by the lungs.

No specialized transport systems have been described for the excretion of toxic substances by the lungs. These substances seem to be eliminated by simple diffusion. Elimination of gases is roughly inversely proportional to the rate of their absorption. Therefore, gases with low solubility in blood, such as ethylene, are rapidly excreted, whereas chloroform, which has a much higher solubility in blood, is eliminated very slowly by the lungs. Trace concentrations of highly lipid-soluble anesthetic gases such as halothane and methoxyflurane may be present in expired air for as long as 2 to 3 weeks after a few hours of anesthesia. Undoubtedly, this prolonged retention is due to deposition in and slow mobilization from adipose tissue of these very lipid-soluble agents. The rate of elimination of a gas with low solubility in blood is perfusion-limited, whereas that of a gas with high solubility in blood is ventilation-limited.

Other Routes of Elimination

Cerebrospinal Fluid A specialized route of removal of toxic agents from a specific organ is represented by the cerebrospinal fluid (CSF). All compounds can leave the CNS with the bulk flow of CSF through the arachnoid villi. In addition, lipid-soluble toxicants also can exit at the site of the blood-brain barrier. It is noteworthy that toxicants also can be removed from the CSF by active transport, similar to the transport systems of the kidneys for the excretion of organic ions.

Milk The secretion of toxic compounds into milk is extremely important because (1) a toxic material may be passed with milk from the mother to the nursing offspring and (2) compounds can be passed from cows to people via dairy products. Toxic agents are excreted into milk by simple diffusion. Because milk is more acidic (pH»6.5) than plasma, basic compounds may be concentrated in milk, whereas acidic compounds may attain lower concentrations in milk than in plasma (Findlay, 1983; Wilson, 1983). More important, about 3 to 4 percent of milk consists of lipids, and the lipid content of colostrum after parturition is even higher. Lipid-soluble xenoiotics diffuse along with fats from plasma into the mammary gland and are excreted with milk during lactation. Compounds such as DDT and polychlorinated and polybrominated biphenyls, dibenzo- p-dioxins, and furans (Van den Berg et al., 1987; Li et al., 1995) are known to occur in milk, and milk can be a major route of their excretion. Species differences in the excretion of xenobiotics with milk are to be expected, as the proportion of milk fat derived from the circulation versus that synthesized de novo in the mammary gland differs widely among species. Metals chemically similar to calcium, such as lead, and chelating agents that form complexes with calcium also can be excreted into milk to a considerable extent.

Sweat and Saliva The excretion of toxic agents in sweat and saliva is quantitatively of minor importance. Again, excretion depends on the diffusion of the nonionized, lipid-soluble form of an agent. Toxic compounds excreted into sweat may produce dermatitis. Substances excreted in saliva enter the mouth, where they are usually swallowed and thus are available for GI absorption.

CONCLUSION

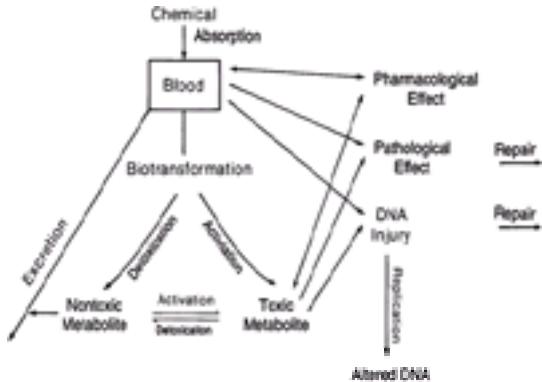
Humans are in continuous contact with toxic agents. Toxicants are in the food we eat, the water we drink, and the air we breathe. Depending on their physical and chemical properties, toxic agents may be absorbed by the GI tract, the lungs, and/or the skin. Fortunately, the body has the ability to biotransform and excrete these compounds into urine, feces, and air. However, when the rate of absorption exceeds the rate of elimination, toxic compounds may accumulate and reach a critical concentration at a certain target site, and toxicity may ensue (Fig. 5-10). Whether a chemical elicits toxicity depends not only on its inherent potency and site specificity but also on how an organism can handle—that is, dispose of—a particular toxicant. Therefore, knowledge of the disposition of chemicals is of great importance in judging the toxicity of xenobiotics. For example, for a potent CNS suppressant that displays a strong hepatic first-pass effect, oral exposure is of less concern than is exposure by inhalation. Also, two equipotent gases, with the absorption of one being perfusion rate-limited and that of the other being ventilation rate-limited, will exhibit completely different toxicity profiles at a distant site because of differences in the concentrations attained in the target organ.


Figure 5-10. Schematic representation of the disposition and toxic effects of chemicals.

Many chemicals have very low inherent toxicity but have to be activated by biotransformation into toxic metabolites; the toxic response then depends on the rate of production of toxic metabolites. Alternatively, a very potent toxicant may be detoxified rapidly by biotransformation. Toxic effects are related to the concentration of the "toxic chemical" at the site of action (in the target organ), whether a chemical is administered or generated by biotransformation in the target tissue or at a distant site. Thus, the toxic response exerted by chemicals is critically influenced by the rates of absorption, distribution, biotransformation, and excretion.

CHAPTER 6

BIOTRANSFORMATION OF XENOBIOTICS

Andrew Parkinson

All organisms are exposed constantly and unavoidably to foreign chemicals, or *xenobiotics,* which include both manufactured and natural chemicals such as drugs, industrial chemicals, pesticides, pollutants, pyrolysis products in cooked food, alkaloids, secondary plant metabolites, and toxins produced by molds, plants, and animals. The physical property that enables many xenobiotics to be absorbed through the skin, lungs, or gastrointestinal tract—namely, their lipophilicity—is an obstacle to their elimination, because lipophilic compounds can be readily reabsorbed. Consequently, the elimination of xenobiotics often depends on their conversion to water-soluble chemicals by a process known as *biotransformation,* which is catalyzed by enzymes in the liver and other tissues. An important consequence of biotransformation is that the physical properties of a xenobiotic are generally changed from those favoring absorption (lipophilicity) to those favoring excretion in urine or feces (hydrophilicity). An exception to this general rule is the elimination of volatile compounds by exhalation, in which case biotransformation to nonvolatile, water-soluble chemicals can retard their rate of elimination. Similarly, biotransformation of xenobiotics in the brain and testis (two organs with a barrier to chemical transport) might also be an obstacle to xenobiotic elimination if the metabolites cannot cross the blood-brain or blood-testis barrier.

Without biotransformation, lipophilic xenobiotics would be excreted from the body so slowly that they would eventually overwhelm and kill an organism. This principle is illustrated by comparing the theoretical and observed rates of elimination of barbital and hexobarbital. The theoretical half-life of barbital, which is water-soluble, closely matches the observed elimination half-life of this drug ($t_{1/2}$ 55 to 75 h), which is eliminated largely unchanged. In contrast, the observed elimination half-life of hexobarbital ($t_{1/2}$ 5 to 6 h) is considerably shorter than the theoretical rate of elimination of this highly lipophilic drug ($t_{1/2}$ 2 to 5 months), the difference being that hexobarbital is biotransformed to water-soluble metabolites that are readily excreted.

A change in pharmacokinetic behavior is not the only consequence of xenobiotic biotransformation nor, in some cases, is it the most important outcome. Xenobiotics exert a variety of effects on biological systems. These may be beneficial, in the case of drugs, or deleterious, in the case of poisons. These effects are dependent on the physicochemical properties of the xenobiotic. In many instances, chemical modification of a xenobiotic by biotransformation alters its biological effects. The importance of this principle to pharmacology is that some drugs must undergo biotransformation to exert their pharmacodynamic effect (i.e., it is the metabolite of the drug, and not the drug itself, that exerts the pharmacologic effect). The importance of this principle to toxicology is that many xenobiotics must undergo biotransformation to exert their characteristic toxic or tumorigenic effect (i.e., many chemicals would be considerably less toxic or tumorigenic if they were not converted to reactive metabolites by xenobiotic-biotransforming enzymes). In most cases, however, biotransformation terminates the pharmacologic effects of a drug and lessens the toxicity of xenobiotics. Enzymes catalyzing biotransformation reactions often determine the intensity and duration of action of drugs and play a key role in chemical toxicity and chemical tumorigenesis (Anders, 1985; Jakoby, 1980; Jakoby et al., 1982; Kato et al., 1989).

To a limited extent, the degree to which organisms are exposed to xenobiotics determines their biotransformation capacity. For example, insects that feed on a variety of plants have a greater capacity to biotransform xenobiotics than insects that feed on a limited number of plants; these, in turn, have a greater capacity to biotransform xenobiotics than insects that feed on a single species of plant. Compared with mammals, fish have a low capacity to metabolize xenobiotics, ostensibly because they can eliminate xenobiotics unchanged across their gills. Species differences in the capacity of mammals to biotransform xenobiotics do not simply reflect differences in exposure. However, some chemicals stimulate the synthesis of enzymes involved in xenobiotic biotransformation. This process, known as enzyme induction, is an adaptive and reversible response to xenobiotic exposure. Enzyme induction enables some xenobiotics to accelerate their own biotransformation and elimination (Conney, 1967). The mechanism and consequences of enzyme induction are discussed further on, under " Induction of Cytochrome P450."

GENERAL PRINCIPLES

Basic Properties of Xenobiotic Biotransforming Enzymes

Xenobiotic biotransformation is the principal mechanism for maintaining homeostasis during exposure of organisms to small foreign molecules, such as drugs. In general, xenobiotic biotransformation is accomplished by a limited number of enzymes with broad substrate specificities. The synthesis of some of these enzymes is triggered by the xenobiotic (by the process of enzyme induction), but in most cases the enzymes are expressed constitutively (i.e., they are synthesized in the absence of a discernible external stimulus). The specificity of xenobiotic biotransforming enzymes is so broad that they metabolize a large variety of endogenous chemicals, such as ethanol, acetone, steroid hormones, vitamins A and D, bilirubin, bile acids, fatty acids, and eicosanoids.

Indeed, xenobiotic biotransforming enzymes, or enzymes that are closely related, play an important role in the synthesis of many of these same molecules. For example, several steps in the synthesis of steroid hormones are catalyzed by cytochrome P450 enzymes in steroidogenic tissues. In general, these steroidogenic enzymes play little or no role in the biotransformation of xenobiotics. In the liver, however, other cytochrome P450 enzymes convert steroid hormones to water-soluble metabolites that are excreted in urine or bile, in an analogous manner to the biotransformation and elimination of xenobiotics.

The structure (i.e., amino acid sequence) of a given biotransforming enzyme may differ among individuals, which can give rise to differences in rates of xenobiotic biotransformation. In general, a variant form of a xenobiotic biotransforming enzyme (known as an *allelic variant* or an *allelozyme*) has diminished enzymatic activity compared with that of the wild-type enzyme, although this is not always the case (see " Alcohol Dehydrogenase," below). However, the impact of amino acid substitution(s) on the catalytic activity of a xenobiotic biotransforming enzyme is usually substrate-dependent, such that an allelic variant may interact normally with some substrates (and inhibitors) but abnormally with others. The study of the causes, prevalence, and impact of heritable differences in xenobiotic biotransforming

enzymes is known as *pharmacogenetics.*

Biotransformation versus Metabolism

The terms *biotransformation* and *metabolism* are often used synonymously, particularly when applied to drugs. For example, xenobiotic biotransforming enzymes are often called drug-metabolizing enzymes. The term *xenobiotic biotransforming enzymes* is more encompassing, although it conceals the fact that steroids and several other endogenous chemicals are substrates for these enzymes. The term *metabolism* is often used to describe the total fate of a xenobiotic, which includes absorption, distribution, biotransformation, and elimination. However, *metabolism* is commonly used to mean biotransformation, which is understandable from the standpoint that the products of xenobiotic biotransformation are known as *metabolites.* Furthermore, individuals with a genetic enzyme deficiency resulting in impaired xenobiotic biotransformation are described as *poor metabolizers* rather than poor biotransformers. (Individuals with the normal phenotype are called *extensive metabolizers.*)

Stereochemical Aspects of Xenobiotic Biotransformation

Many xenobiotics, especially drugs, contain one or more chiral centers and can therefore exist in two mirror-image forms called stereoisomers or enantiomers. The biotransformation of some chiral xenobiotics occurs stereoselectively—meaning that one enantiomer (stereoisomer) is biotransformed faster than its antipode. For example, the antiepileptic drug Mesantoin, which is a racemic mixture of *R*- and *S*-mephenytoin, is biotransformed stereoselectively in humans, such that the *S*-enantiomer is rapidly hydroxylated (by a cytochrome enzyme called CYP2C19) and eliminated faster than the *R*-enantiomer. The ability of some chiral xenobiotics to inhibit xenobiotic biotransforming enzymes can also occur stereoselectively. For example, quinidine is a potent inhibitor of a human cytochrome P450 enzyme called CYP2D6, on which quinine, its antipode, has relatively little inhibitory effect.

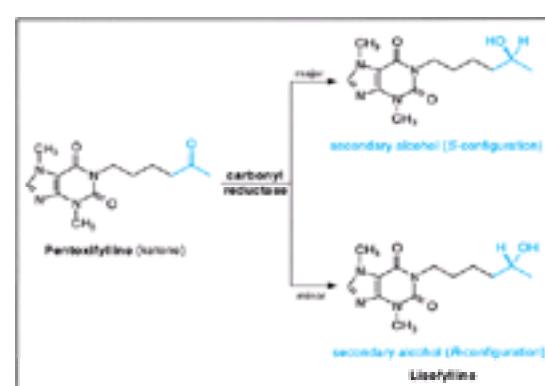
In some cases, achiral molecules (or achiral centers) are converted to a mixture of enantiomeric metabolites, and this conversion may proceed stereoselectively such that one enantiomer is formed preferentially over its antipode. For example, several cytochrome P450 enzymes catalyze the 6-hydroxylation of steroid hormones. Some P450 enzymes (such as CYP2A1) preferentially catalyze the 6a-hydroxylation reaction, whereas other P450 enzymes (such as CYP3A) preferentially catalyze the 6b-hydroxylation reaction (which is a major route of hepatic steroid biotransformation). Ketones can be reduced by carbonyl reductases to a mixture of enantiomeric secondary alcohols, and this often occurs with a high degree of stereoselectivity. For example, pentoxifylline is reduced by carbonyl reductases in blood and liver to a mixture of secondary alcohols, with the major metabolite having an *S*-configuration, as shown in Fig. 6-1. Interestingly, the minor metabolite, a secondary alcohol with the *R*-configuration, has pharmacologic properties distinct from those of its *S*-antipode and its ketone precursor, pentoxifylline. This minor metabolite is known as lisofylline, which is under clinical investigation for the treatment of various diseases.


Figure 6-1. Stereochemical aspects of xenobiotic biotransformation: Formation of two enantiomeric metabolites (secondary alcohols) from a single, achiral molecule (a ketone).

Oxidation of a chiral secondary alcohol to an achiral ketone, and subsequent reduction of the ketone to a secondary alcohol of opposite configuration (*e.g., R*-alcohol ® ketone ® *S*-alcohol) is an example of a process known as *inversion of configuration.*

The reduction of ketones to secondary alcohols is a reversible reaction, and such interconversions can lead to an *inversion of configuration,* in which case a secondary alcohol with, say, an *R*-configuration is oxidized to a ketone (which is achiral); it, in turn, is reduced to a secondary alcohol with an *S*-configuration (i.e., *R*-alcohol ® ketone ® *S*-alcohol). This interconversion between achiral ketones and enantiomeric secondary alcohols likely explains why the administration of pure *R*-albuterol to human volunteers results in the formation of *S*-albuterol, just as the administration of pure *S*-albuterol leads to the formation of *R*-albuterol (Boulton and Fawcett, 1997).

Phase I and Phase II Biotransformation

The reactions catalyzed by xenobiotic biotransforming enzymes are generally divided into two groups, called phase I and phase II, as shown in Table 6-1 (Williams, 1971). Phase I reactions involve hydrolysis, reduction, and oxidation. These reactions expose or introduce a functional group (–OH, –NH $_2$, –SH or –COOH), and usually result in only a small increase in hydrophilicity. Phase II biotransformation reactions include glucuronidation, sulfonation (more commonly called sulfation), acetylation, methylation, conjugation with glutathione (mercapturic acid synthesis), and conjugation with amino acids (such as glycine, taurine, and glutamic acid). The cofactors for these reactions (discussed later) react with functional groups that are either present on the xenobiotic or are introduced/exposed during phase I biotransformation. Most phase II biotransformation reactions result in a large increase in xenobiotic hydrophilicity, hence they greatly promote the excretion of foreign chemicals.

Table 6-1 General Pathways of Xenobiotic Biotransformation and Their Major Subcellular Location

Phase II biotransformation of xenobiotics may or may not be preceded by phase I biotransformation. For example, morphine, heroin, and codeine are all converted to morphine-3-glucuronide. In the case of morphine, this metabolite forms by direct conjugation with glucuronic acid. In the other two cases, however, conjugation with glucuronic acid is preceded by phase I biotransformation: hydrolysis (deacetylation) in the case of heroin and *O*-demethylation (involving oxidation by cytochrome P450) in the case of codeine. Similarly, acetaminophen can be glucuronidated and sulfated directly, whereas phenacetin must undergo phase I metabolism (involving *O*-deethylation to acetaminophen) prior to undergoing phase II biotransformation. These examples illustrate how phase I biotransformation is often required for subsequent phase II biotransformation. In general, phase II biotransformation does not precede phase I biotransformation, although there are exceptions to this rule.

For example, some sulfated steroids (including some steroid disulfates) are hydroxylated by cytochrome P450.

Nomenclature of Xenobiotic Biotransforming Enzymes

The enzymes involved in xenobiotic biotransformation tend to have broad and overlapping substrate specificities, which precludes the possibility of naming the individual enzymes after the reactions they catalyze (which is how most other enzymes are named). Many of the enzymes involved in xenobiotic biotransformation have been cloned and sequenced; in several cases, arbitrary nomenclature systems have been developed based on the primary amino acid sequence of the individual enzymes.

Distribution of Xenobiotic Biotransforming Enzymes

Xenobiotic biotransforming enzymes are widely distributed throughout the body and are present in several subcellular compartments. In vertebrates, the liver is the richest source of enzymes catalyzing biotransformation reactions. These enzymes are also located in the skin, lung, nasal mucosa, eye, and gastrointestinal tract—which can be rationalized on the basis that these are major routes of exposure to xenobiotics—as well as numerous other tissues, including the kidney, adrenal, pancreas, spleen, heart, brain, testis, ovary, placenta, plasma, erythrocytes, platelets, lymphocytes, and aorta (Gram, 1980; Farrell, 1987; Krishna and Klotz, 1994). Intestinal microflora play an important role in the biotransformation of certain xenobiotics. Within the liver (and most other organs), the enzymes catalyzing xenobiotic biotransformation reactions are located primarily in the endoplasmic reticulum (microsomes) or the soluble fraction of the cytoplasm (cytosol), with lesser amounts in mitochondria, nuclei, and lysosomes (see Table 6-1). Their presence in the endoplasmic reticulum can be rationalized on the basis that those xenobiotics requiring biotransformation for urinary or biliary excretion will likely be lipophilic and, hence, soluble in the lipid bilayer of the endoplasmic reticulum.

By extracting and biotransforming xenobiotics absorbed from the gastrointestinal tract, the liver limits the systemic bioavailability of orally ingested xenobiotics, a process known as *first-pass elimination*. In some cases, xenobiotic biotransformation in the intestine contributes significantly to the first-pass elimination of foreign chemicals. For example, the oxidation of cyclosporine by cytochrome P450 and the conjugation of morphine with glucuronic acid in the small intestine limit the systemic bioavailability of these drugs. Under certain circumstances, oxidation of ethanol to acetaldehyde in the gastric mucosa reduces the systemic bioavailability of alcohol. Some extrahepatic sites contain high levels of xenobiotic biotransforming enzymes, but their small size minimizes their overall contribution to the biotransformation of xenobiotics. For example, certain xenobiotic biotransforming enzymes (such as cytochrome P450 enzymes, flavin monooxygenases, glutathione *S*-transferases, and carboxylesterases) are present in nasal epithelium at levels that rival those found in the liver. The nasal epithelium plays an important role in the biotransformation of inhaled xenobiotics, including odorants, but is quantitatively unimportant in the biotransformation of orally ingested xenobiotics (Brittebo, 1993).

The fact that tissues differ enormously in their capacity to biotransform xenobiotics has important toxicologic implications in terms of tissue-specific chemical injury. Several xenobiotics, such as acetaminophen and carbon tetrachloride, are hepatotoxic due to their activation to reactive metabolites in the liver (Anders, 1985). Cells within an organ also differ in their capacity to biotransform xenobiotics, and this heterogeneity also has toxicologic implications. For example, the cytochrome P450 enzymes that activate acetaminophen and carbon tetrachloride to their reactive metabolites are localized in the centrilobular region of the liver (zone 3), which is why these xenobiotics cause centrilobular necrosis. Species differences in xenobiotic biotransforming enzymes have both toxicologic and pharmacologic consequences, as do factors that influence the activity of xenobiotic biotransforming enzymes (Kato, 1979). For example, the duration of action of hexobarbital (i.e., narcosis) in mice (~10 min), rabbits (~50 min), rats (~100 min), and dogs (~300 min) is inversely related to the rate of hexobarbital biotransformation (i.e., 3-hydroxylation) by liver microsomal cytochrome P450, which follows the rank order mouse > rabbit > rat > dog. The duration of action of hexobarbital in rats can be shortened from ~100 to ~30 min by prior treatment with phenobarbital, which induces cytochrome P450 and thereby increases the rate of hexobarbital 3-hydroxylation. By inducing cytochrome P450, treatment of rats with phenobarbital also increases the hepatotoxic effects of acetaminophen and carbon tetrachloride. Species differences in xenobiotic biotransforming enzymes and factors that affect the pharmacologic or toxicologic effects of xenobiotics are discussed throughout this chapter as each of the major xenobiotic biotransforming enzyme systems is described.

XENOBIOTIC BIOTRANSFORMATION BY PHASE I ENZYMES

Phase I reactions involve hydrolysis, reduction, and oxidation of xenobiotics, as shown in Table 6-1. These reactions expose or introduce a functional group (–OH, –NH$_2$, –SH, or –COOH) and usually result in only a small increase in the hydrophilicity of xenobiotics. The functional groups exposed or introduced during phase I biotransformation are often sites of phase II biotransformation.

Hydrolysis

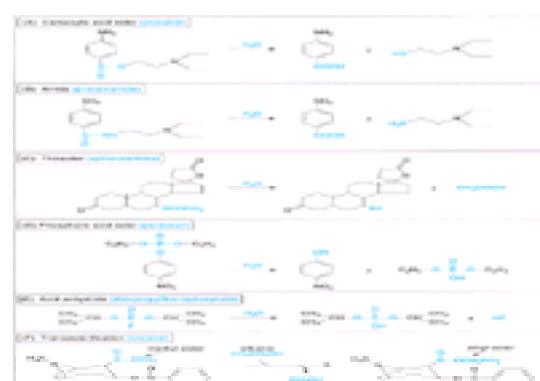
Carboxylesterases, Pseudocholinesterase, and Paraoxonase Mammals contain a variety of hydrolytic enzymes—namely, carboxylesterases, cholinesterases and organophosphatases—that hydrolyze xenobiotics containing such functional groups as a carboxylic acid ester (procaine), amide (procainamide), thioester (spironolactone), phosphoric acid ester (paraoxon), and acid anhydride [diisopropylfluorophosphate (DFP)], as shown in Fig. 6-2 (Satoh and Hosokawa, 1998). The hydrolysis of carboxylic acid esters, amides, and thioesters is largely catalyzed by carboxylesterases (EC 3.1.1.1), which are located in various tissues and serum, and by two esterases in blood: true acetylcholinesterase (EC 3.1.17), which is located on erythrocyte membranes and is a dimeric enzyme (in contrast to the tetrameric form of the same enzyme found in nervous tissue), and pseudocholinesterase (EC 3.1.1.8), which is also known as butyrylcholinesterase and is located in serum. Phosphoric acid esters are hydrolyzed by paraoxonase, a serum enzyme that is known both as an aryldialkylphosphatase (EC 3.1.8.1) or organophosphatase (for its ability to hydrolyze organophosphates such as paraoxon) and as an arylesterase (for its ability to hydrolyze aromatic carboxylic acid esters such as phenylacetate). Phosphoric acid anhydrides, such as DFP, are hydrolyzed by a related organophosphatase, namely diisopropylfluorophosphatase (EC 3.1.8.2). In the presence of an alcohol, carboxylesterases can catalyze the transesterification of xenobiotics, which accounts for the conversion of cocaine (a methyl ester) to ethylcocaine (the corresponding ethyl ester) (Fig. 6-2). Esterases are not the only enzymes capable of cleaving esters. Aldehyde dehydrogenase has esterase activity. Examples are given later in this chapter (under " Cytochrome P450") in which the cleavage of xenobiotics containing a carboxylic acid ester is catalyzed by cytochrome P450.


Figure 6-2. Examples of reactions catalyzed by carboxylesterases, cholinesterases and organophosphatases.

Carboxylesterases in serum and tissues and serum cholinesterase collectively determine the duration and site of action of certain drugs. For example, procaine, a carboxylic acid ester, is rapidly hydrolyzed, which is why this drug is used mainly as a local anesthetic. In contrast, procainamide, the amide analog of procaine, is hydrolyzed much more slowly; hence this drug reaches the systematic circulation, where it is useful in the treatment of cardiac arrhythmia. In general, enzymatic hydrolysis of amides occurs more slowly than that of esters, although electronic factors can influence the rate of hydrolysis. The presence of electron-withdrawing substituents weakens an amide bond, making it more susceptible to enzymatic hydrolysis.

In 1953, Aldridge classified esterases based on the nature of their interaction with organophosphates. Esterases that hydrolyze organophosphates are classified as A-esterases; those that are inhibited by organophosphates are classified as B-esterases, whereas those that do not interact with organophosphates are classified as C-esterases. Carboxylesterases and cholinesterase belong to the B-esterase group, which is also known as the family of serine esterase. Organophosphatases such

as paraoxonase belong to the A-esterase group.

Although they are not inhibited by organophosphates, A-esterases are inhibited by mercurial compounds that react with free sulfhydryl (–SH) groups, such as *para*-chloromercuribenzoate (PCMB), whereas the opposite is true of B-esterases (i.e., they are inhibited by organophosphates but not by PCMB). Augustinsson (1966) postulated that the major difference between A- and B-esterases is that the former contain a cysteine residue at their active site, whereas the latter contain a serine residue. This hypothesis has been substantiated in the case of B-esterases but not in the case of A-esterases.

Carboxylesterases and cholinesterases are B-esterases with a serine residue at the active site. The mechanism of catalysis by B-esterases is analogous to the mechanism of catalysis by serine-proteases. In the case of carboxylesterases, for example, it involves charge relay among a catalytic triad comprised of an acidic amino acid residue [glutamate (Glu$_{335}$)], a basic residue [histidine (His$_{448}$)], and a nucleophilic residue [serine (Ser$_{203}$)] (Yan et al., 1994; Satoh and Hosokawa, 1998). Organophosphates bind to the nucleophilic OH-group on the active site serine residue to form a phosphorus-oxygen bond, which is not readily cleaved by water. Therefore, organophosphates bind stoichiometrically to B-esterases and inhibit their enzymatic activity. The mechanism of catalysis of carboxylesterases is discussed in more detail under "Epoxide Hydrolase," below.

Based on the observation that A-esterases are inhibited by PCMB but not by organophosphates, Augustinsson (1966) postulated that organophosphates bind to a nucleophilic SH-group on an active site cysteine residue and form a phosphorus-sulfur bond, which is readily cleaved by water. A strong argument against this postulate is the fact that, when the only potential active site cysteine residue in human paraoxonase (Cys$_{283}$) is substituted with serine or alanine, there is no loss of catalytic activity (Sorenson et al., 1995). Paraoxonase requires Ca^{2+}, both for stability and catalytic activity, which raises the possibility that the hydrolysis of organophosphates by paraoxonase involves metal-catalyzed hydrolysis, analogous to that proposed for calcium-dependent phospholipase A$_2$ or zinc-dependent phosphotriesterase activity (Sorenson et al., 1995).

Esterases play an important role in limiting the toxicity of organophosphates. The mechanism of toxicity of organophosphorus pesticides (and carbamate insecticides) involves inhibition of brain acetylcholinesterase, which is a serine-containing esterase that terminates the action of the neurotransmitter, acetylcholine. The symptoms of organophosphate toxicity resemble those caused by excessive stimulation of cholinergic nerves. The covalent interaction between organophosphates and brain acetylcholinesterase is analogous to their binding to the active site serine residue in all B-esterases. As previously mentioned, organophosphates are hydrolyzed by some esterases (the A-esterases, such as paraoxonase) and bind stoichiometrically and, for the most part, irreversibly to carboxylesterases and cholinesterases. Both types of interactions (i.e., hydrolysis and covalent binding) play an important role in the detoxication of these compounds. Numerous studies have shown an inverse relationship between esterase activity and susceptibility to the toxic effect of organophosphates. Factors that decrease esterase activity potentiate the toxic effects of organophosphates, whereas factors that increase carboxylesterase activity have a protective effect. For example, the susceptibility of animals to the toxicity of parathion, malathion, and diisopropylfluorophosphate is inversely related to the level of serum esterase activity. Differences in the susceptibility of several mammalian species to organophosphate toxicity can be abolished by pretreatment with selective esterase inhibitors such as cresylbenzodioxaphosphorin oxide, the active metabolite of tri-*orthc*-tolylphosphate (which is also known as tri-*orthc*-cresylphosphate or TOCP). Esterases are not the only enzymes involved in the detoxication of organophosphorus pesticides. Certain organophosphorus compounds are detoxified by cytochrome P450, flavin monooxygenases, and glutathione *S*-transferases.

Pseudocholinesterase is a tetrameric glycoprotein (Mr 342 kDa) containing four identical subunits, each having one catalytic site. The enzyme hydrolyzes succinylcholine, mivacurium, procaine, chlorpropaine, tetracaine, cocaine, heroin and other drugs. The duration of action of the muscle relaxant succinylcholine is determined by serum pseudocholinesterase. In some individuals (~2 percent of Caucasians), succinylcholine causes prolonged muscular relaxation and apnea, which led to the discovery of an atypical form of pseudocholinesterase (Asp$_{70}$ ® Gly$_{70}$) (La Du, 1992; Lockridge, 1992). Although this atypical enzyme has markedly diminished activity toward succinylcholine (which is the genetic basis for the exaggerated response to this muscle relaxant in affected individuals), it nevertheless has appreciable activity toward other substrates, such as acetylcholine and benzoylcholine. The normal and atypical pseudocholinesterases are equally sensitive to the inhibitory effect of certain organophosphates, but the atypical enzyme is relatively resistant to the inhibitory effect of dibucaine, a local anesthetic, which forms the basis of a diagnostic test for atypical pseudocholinesterase. The discovery of atypical pseudocholinesterase is of historical interest because it ushered in the new field of pharmacogenetics. Since the initial discovery of atypical pseudocholinesterase in late 1950s, several allelic variants of the enzyme have been identified.

Carboxylesterases are ~60-kDa glycoproteins that are present in a wide variety of tissues, including serum. Most of the carboxylesterase activity in liver is associated with the endoplasmic reticulum, although considerable carboxylesterase activity is present in lysosomes and cytosol. Carboxylesterases generate pharmacologically active metabolites from several ester or amide prodrugs. For example, lovastatin is converted by liver carboxylesterases to the pharmacologically active metabolite, lovastatin b-hydroxyacid, which inhibits HMG-CoA reductase and lowers plasma cholesterol levels. There is some evidence to suggest that therapeutic effect of lovastatin is diminished in individuals with low levels of liver carboxylesterase activity (Tang and Kalow, 1995). Carboxylesterases have also been implicated in the activation of a number of anticancer agents, such as 7-ethyl-10-[4-(1-piperidino)-1-piperidino] carbonyoxycamptothecin (CPT-11), which shows promising activity against a broad range of tumor types, including colorectal and cervical cancer. The anticancer effects of CPT-11 are dependent on its conversion to ethyl camptothecin, which is catalyzed by one or more carboxylesterases. As a result of their ability to hydrolyze prodrugs, carboxylesterases may have clinical applications in the treatment of certain cancers. They might be used, for example, to activate prodrugs in vivo and thereby generate potent anticancer agents in highly selected target sites (e.g., at the surface of tumor cells, or inside the tumor cells themselves). Carboxylesterases might be targeted to tumor sites with hybrid monoclonal antibodies (i.e., bifunctional antibodies that recognize the carboxylesterase and the tumor cell), or the cDNA encoding a carboxylesterase might be targeted to the tumor cells via a viral vector. In the case of CTP-11, this therapeutic strategy would release the anticancer drug, ethyl camptothecin, in the vicinity of the tumor cells, which would reduce the systemic levels and side effects of this otherwise highly toxic drug (Senter et al., 1996).

In addition to xenobiotics, carboxylesterases hydrolyze numerous endogenous compounds, such as palmitoyl-CoA, monoacylglycerol, diacylglycerol, retinyl ester, platelet-activating factor and other esterified lipids. Carboxylesterases can also catalyze the synthesis of fatty acid ethyl esters, which represents a nonoxidative pathway of ethanol metabolism in adipose and certain other tissues. In the case of platelet-activating factor, carboxylesterases catalyze both the deacetylation of PAF and its subsequent esterification with fatty acids to form phosphatidylcholine (Hosokawa and Satoh, 1998).

Certain carboxylesterases also have a physiologic function in anchoring other proteins to the endoplasmic reticulum. For example, the lysosomal enzyme b-glucuronidase is also present in the endoplasmic reticulum, where it is anchored in the lumen by egasyn, a microsomal carboxylesterase. Egasyn binds to b-glucuronidase via its active site serine residue, which effectively abolishes the carboxylesterase activity of egasyn, although there is no corresponding loss of b-glucuronidase activity. The retention of b-glucuronidase in the lumen of the ER is thought to be physiologically significant. Glucuronidation by microsomal UDPglucuronosyltransferases is a major pathway in the clearance of many endogenous aglycones (such as bilirubin) and xenobiotics (such as drugs). However, hydrolysis of glucuronides by b-glucuronidase complexed with egasyn in the lumen of the endoplasmic reticulum appears to be an important mechanism for recycling endogenous compounds, such as steroid hormones (Dwivedi et al., 1987). The acute-phase response protein, C-response protein, is similarly anchored in the endoplasmic reticulum by egasyn.

A nomenclature system for classifying carboxylesterases has been proposed by Satoh and Hosokawa (1998). The broad substrate specificity of these enzymes precludes the possibility of naming them for the reactions they catalyze, for which reason Satoh and Hosokawa proposed a classification and nomenclature system that is based on a comparison of the amino acid sequences of carboxylesterases (regardless of the species of origin) with the sequence of a human carboxylesterase. Four gene families have been identified (designated CES 1-4) with three subdivisions in the first gene family (namely CES 1A, CES 1B and CES 1C). The first subfamily is further subdivided into three groups (designated CES 1A1, 1A2, and 1A3). Liver microsomes from all mammalian species, including humans, contain at least one carboxylesterase, but the exact number of carboxylesterases expressed in any one tissue or species is not known. Because carboxylesterases are glycoproteins, variations in carbohydrate content can give rise to multiple forms of the same enzyme. Consequently, the large number of carboxylesterases that have been identified by isoelectric focusing and nondenaturing gel electrophoresis probably overestimates the number of genes encoding these enzymes.

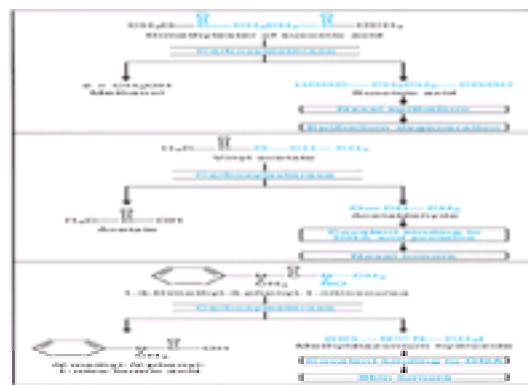
Metabolism of xenobiotics by carboxylesterases is not always a detoxication process. Figure 6-3 shows some examples in which carboxylesterases convert xenobiotics to toxic and tumorigenic metabolites.


Figure 6-3. Activation of xenobiotics to toxic and tumorigenic metabolites by carboxylesterases.

Peptidases With the advent of recombinant DNA techology, numerous human peptides have been mass-produced for use as drugs, and several recombinant peptide hormones, growth factors, cytokines, soluble receptors, and humanized monoclonal antibodies currently are used therapeutically. To avoid acid-precipitation and proteolytic degradation in the gastrointestinal tract, peptides are administered parenterally. Nevertheless, peptides are hydrolyzed in the blood and tissues by a variety of peptidases, including aminopeptidases and carboxypeptidases, which hydrolyze amino acids at the *N*- and *C*-terminus, respectively, and endopeptidases, which cleave peptides at specific internal sites (trypsin, for example, cleaves peptides on the *C*-terminal side of arginine or lysine residues) (Humphrey and Ringrose, 1986). Peptidases cleave the amide linkage between adjacent amino acids, hence, they function as amidases. As in the case of carboxylesterases, the active site of peptidases contains either a serine or cysteine residue, which initiates a nucleophilic attack on the carbonyl moiety of the amide bond. As previously noted, the mechanism of catalysis by serine proteases, such as chymotrypsin, is similar to that by serine esterases (B-esterases).

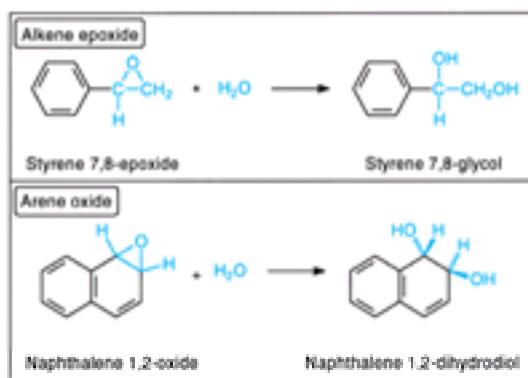
Epoxide Hydrolase Epoxide hydrolase catalyzes the *trans*-addition of water to alkene epoxides and arene oxides (oxiranes), which can form during the cytochrome P450-dependent oxidation of aliphatic alkenes and aromatic hydrocarbons, respectively. As shown in Fig. 6-4, the products of this hydrolysis are vicinal diols with a *trans*-configuration (i.e., *trans*-1,2-dihydrodiols); a notable exception being the conversion of leukotriene A$_4$ (LTA4) to leukotriene B$_4$ (LTB4), in which case the two hydroxyl groups that result from epoxide hydrolysis appear on nonadjacent carbon atoms. Although the levels vary from one tissue to the next, epoxide hydrolase is present in virtually all tissues, including the liver, testis, ovary, lung, kidney, skin, intestine, colon, spleen, thymus, brain, and heart.


Figure 6-4. Examples of the hydrolyation of an alkene epoxide **(top)** *and an arene oxide* (bottom) *by epoxide hydrolase.*

There are five distinct forms of epoxide hydrolase in mammals: microsomal epoxide hydrolase (mEH), soluble epoxide hydrolase (sEH), cholesterol epoxide hydrolase, LTA4 hydrolase, and hepoxilin hydrolase (Beetham et al., 1995). As their names imply, the latter three enzymes appear to hydrolyze endogenous epoxides exclusively and have virtually no capacity to detoxify xenobiotic oxides. LTA4 hydrolase is distinct from the other epoxide hydrolases because it is a bifunctional zinc metalloenzyme that has both epoxide hydrolase and peptidase activity and because the two hydroxyl groups introduced during the conversion of LTA4 to LTB4 are eight carbon atoms apart.

In contrast to the high degree of substrate specificity displayed by the cholesterol, LTA4 and hepoxilin epoxide hydrolases, the microsomal and soluble epoxide hydrolases (mEH and sEH) hydrolyze a wide variety of alkene epoxides and arene oxides. Many epoxides and oxides are intermediary metabolites formed during the cytochrome P450-dependent oxidation of unsaturated aliphatic and aromatic xenobiotics. These electrophilic metabolites might otherwise bind to proteins and nucleic acids and cause cellular toxicity and genetic mutations. Generally, these two forms of epoxide hydrolases and cytochrome P450 enzymes have a similar cellular localization. For example, the distribution of epoxide hydrolase parallels that of cytochrome P450 in liver, lung, and testis. In other words, both enzymes are located in the centrilobular region of the liver (zone 3), in Clara and type II cells in the lung, and in Leydig cells in the testis. The colocalization of epoxide hydrolase and cytochrome P450 presumably ensures the rapid detoxication of alkene epoxides and arene oxides generated during the oxidation metabolism of xenobiotics.

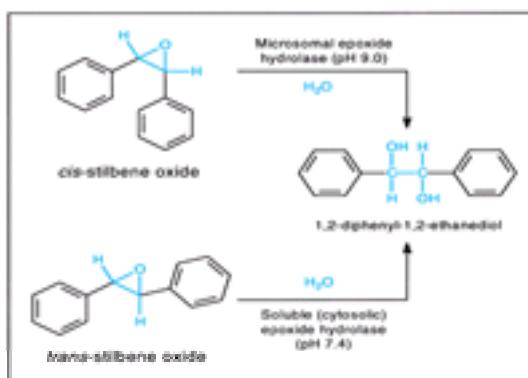
The microsomal and soluble forms of epoxide hydrolase show no evident sequence identity and, not surprisingly, are immunochemically distinct proteins (Beetham et al., 1995). Although both enzymes hydrolyze a broad spectrum of compounds, they exhibit different substrate specificities. For example, mEH rapidly hydrolyzes epoxides on cyclic systems, whereas sEH has little activity toward these compounds. In rat and mouse, these two enzymes can even be distinguished by their stereoselective hydration of stilbene-oxide; mEH preferentially hydrolyzes the *cis*-isomer at pH 9.0, whereas sEH preferentially hydrolyzes the *trans*-isomer at pH 7.4, as shown in Fig. 6-5.


Figure 6-5. Stereoselective hydrolyation of stilbene oxide by microsomal and soluble epoxide hydrolase.

Electrophilic epoxides and arene oxides are constantly produced during the cytochrome P450-dependent oxidation of unsaturated aliphatic and aromatic xenobiotics and are highly reactive to cellular macromolecules such as DNA and protein. Epoxide hydrolases, particularly mEH and sEH, can rapidly convert these potentially toxic metabolites to the corresponding dihydrodiols, which are less reactive and easier to excrete. Thus, epoxide hydrolases are widely considered as a group of detoxication enzymes. In some cases, however, further oxidation of a dihydrodiol can lead to the formation of diol epoxide derivatives that are no longer substrates for epoxide hydrolase because the oxirane ring is protected by bulky substituents that sterically hinder interaction with the enzyme. This point proved to be extremely important in elucidating the mechanism by which polycyclic aromatic hydrocarbons cause tumors in laboratory animals (Conney, 1982). Tumorigenic polycyclic

aromatic hydrocarbons, such as benzo[a]pyrene, are converted by cytochrome P450 to a variety of arene oxides that bind covalently to DNA, making them highly mutagenic to bacteria. One of the major arene oxides formed from benzo[a]pyrene, namely the 4,5-oxide, is highly mutagenic to bacteria but weakly mutagenic to mammalian cells. This discrepancy reflects the rapid inactivation of benzo[a]pyrene 4,5-oxide by epoxide hydrolase in mammalian cells. However, one of the arene oxides formed from benzo[a]pyrene, namely benzo[a]pyrene 7,8-dihydrodiol-9,10oxide, is not a substrate for epoxide hydrolase and is highly mutagenic to mammalian cells and considerably more potent than benzo[a]pyrene as a lung tumorigen in mice.

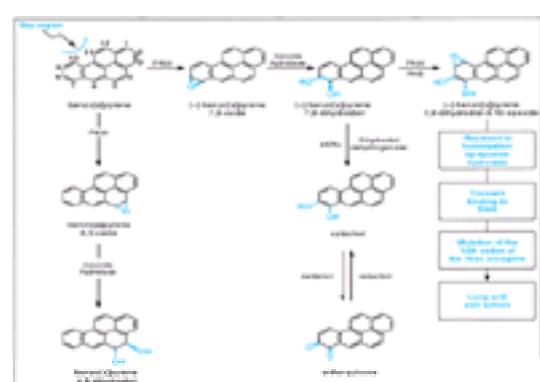
Benzo[a]pyrene 7,8-dihydrodiol-9,10-oxide is known as a bay-region diolepoxide, and analogous bay-region diolepoxides are now recognized as tumorigenic metabolites of numerous polycyclic aromatic hydrocarbons. A feature common to all bay-region epoxides is their resistance to hydrolyation by epoxide hydrolase, which results from steric hindrance from the nearby dihydrodiol group. As shown in Fig. 6-6, benzo[a]pyrene 7,8-dihydrodiol-9,10-oxide is formed in three steps: Benzo[a]pyrene is converted to the 7,8-oxide, which is converted to the 7,8-dihydrodiol, which is converted to the corresponding 9,10-epoxide. The first and third steps are epoxidation reactions catalyzed by cytochrome P450 or prostaglandin H synthase, but the second step is catalyzed by epoxide hydrolase. Consequently, even though epoxide hydrolase plays a major role in detoxifying several benzo[a]pyrene oxides, such as the 4,5-oxide, it nevertheless plays a role in converting benzo[a]pyrene to its ultimate tumorigenic metabolite, benzo[a]pyrene 7,8-dihydrodiol-9,10-oxide.


Figure 6-6. Role of epoxide hydrolase in the inactivation of benzo[a]pyrene 4,5-oxide and in the conversion of benzo[a]pyrene to its tumorigenic bay-region diolepoxide.

Also shown is the role of dihydrodiol dehydrogenase, a member of the aldoketo reductase (AKR) superfamily, in the formation of reactive catechol and *orthc*-quinone metabolites of benzo[a]pyrene.

Not all epoxides are highly reactive and toxic to the cells that produce them. The major metabolite of carbamazepine is an epoxide, which is so stable that carbamazepine-10,11-epoxide is a major circulating metabolite in patients treated with this antiepileptic drug. (Carbamazepine is converted to a second epoxide, which is less stable and more cytotoxic, as shown under "Cytochrome P450," below.) Vitamin K epoxide is also a nontoxic epoxide, which is formed and consumed during the vitamin K–dependent g-carboxylation of prothrombin and other clotting factors in the liver. Vitamin K epoxide is not hydrated by epoxide hydrolase but is reduced by vitamin K epoxide reductase. This enzyme is inhibited by warfarin and related coumarin anticoagulants, which interrupt the synthesis of several clotting factors.

Epoxide hydrolase is one of several inducible enzymes in liver microsomes. Induction of epoxide hydrolase is invariably associated with the induction of cytochrome P450, and several cytochrome P450 inducers, such as phenobarbital and *trans*-stilbene oxide, increase the levels of microsomal epoxide hydrolase by up to threefold. In mice, the levels of epoxide hydrolase in liver microsomes can be increased by almost an order of magnitude by antioxidants such as butylated hydroxytoluene (BHT), butylated hydroxyanisole (BHA), and ethoxyquin. Epoxide hydrolase is one of several preneoplastic antigens that are overexpressed in chemically induced foci and nodules that eventually develop into liver tumors. Several alcohols, ketones, and imidazoles stimulate microsomal epoxide hydrolase activity in vitro. Epoxide hydrolase cannot be inhibited by antibodies raised against the purified enzyme, but it can be inhibited by certain epoxides, such as 1,1,1-trichloropropene oxide and cyclohexene oxide, and certain drugs, such as valpromide (the amide analog of valproic acid) and progabide, a g-aminobutyric acid (GABA) agonist. These latter two drugs potentiate the neurotoxicity of carbamazepine by inhibiting epoxide hydrolase, leading to increased plasma levels of carbamazepine 10,11-epoxide and presumably the more toxic 2,3-epoxide (Kroetz et al., 1993). Several genetic polymorphisms have been identified in the coding region and the 5' region (i.e., the regulatory region) of the gene encoding human mEH (Daly, 1999). Two variants involve substitutions at amino acid 113 (Tyr ® His) or amino acid 139 (His ® Arg), which are encoded by exons 3 and 4, respectively. Although these allelic variant forms of mEH have near normal enzymatic activity (at least 65 percent of normal), they appear to be less stable than the wild-type enzyme. The possibility that these amino acid substitutions might predispose individuals to the adverse effects of antiepileptic drugs has been examined, but no such association was found (Daly, 1999).

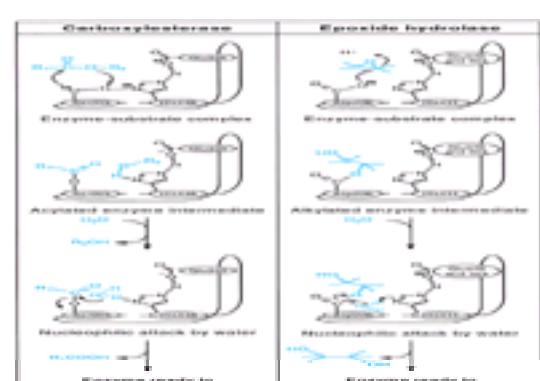
The mechanism of catalysis by epoxide hydrolase is similar to that of carboxylesterase, in that the catalytic site comprises three amino acid residues that form a catalytic triad. In mEH, Asp_{226} functions as the nucleophile, His_{431} the base, and both Glu_{376} and Glu_{404} as the acid, as shown in Fig. 6-7. (In sEH, the corresponding residues are Asp_{333}, His_{503}, and Asp_{495}.) The attack of the nucleophile Asp_{226} on the carbon of the oxirane ring initiates enzymatic activity, leading to the formation of an a-hydroxyesterenzyme intermediate, with the negative charge developing on the oxygen atom stabilized by a putative oxyanion hole. The His_{431} residue (which is activated by Glu_{376} and Glu_{404}) activates a water molecule by abstracting a proton (H^+). The activated (nucleophilic) water then attacks the Cgatom of Asp_{226}, resulting in the hydrolysis of the ester bond in the acyl-enzyme intermediate, which restores the active enzyme and results in formation of a vicinal diol with a *trans*-configuration (Armstrong, 1999). The second step, namely cleavage of the ester bond in the acyl-enzyme intermediate, resembles the cleavage of the ester or amide bond in substrates for serine esterases and proteases.


Figure 6-7. Catalytic cycle of microsomal carboxylesterase (left) **and microsomal epoxide hydrolase** (right)**, two a/b-hydrolase fold enzymes.**

Although epoxide hydrolase and carboxylesterase both have a catalytic triad comprising a nucleophilic, basic, and acidic amino acid residue, there are striking differences in their catalytic machinery, which accounts for the fact that carboxylesterases primarily hydrolyze esters and amides whereas epoxide hydrolases primarily hydrolyze epoxides and oxides. In the triad, both enzymes have histidine as the base and either glutamate or aspartate as the acid, but they differ in the type of amino acids for the nucleophile. Even during catalysis, there is a major difference. In carboxylesterases, the same carbonyl carbon atom of the substrate is attacked initially by the nucleophile Ser_{203} to form a-hydroxyester-enzyme ester that is subsequently attacked by the activated water to release the alcohol product. In contrast, two different atoms in epoxide hydrolase are targets of nucleophilic attacks. First the less hindered carbon atom of the oxirane ring is attacked by the nucleophile Asp_{226} to form a covalently bound ester, and next this ester is hydrolyzed by an activated water that attacks the Cg atom of the Asp_{226} residue, as illustrated in Fig. 6-7. Therefore, in carboxylesterase, the oxygen introduced into the product is derived from the activated water molecule. In contrast, in epoxide hydrolase, the oxygen

introduced into the product is derived from the nucleophile Asp $_{226}$ (Fig. 6-7).

Carboxylesterases and epoxide hydrolases exhibit no primary sequence identity, but they share surprising similarities in the topology of the structure and sequential arrangement of the catalytic triad. Both are members of the a/b-hydrolase fold enzymes, a superfamily of proteins that includes lipases, esterases and haloalkane dehydrogenases (Beetham et al., 1995; Armstrong, 1999). Functionally, proteins in this superfamily all catalyze hydrolytic reactions; structurally, they all contain a similar core segment that comprises eight b-sheets connected by a-helices. They all have a catalytic triad, and the arrangement of the amino acid residues in the triad (i.e., the order of the nucleophile, the acid and the base in the primary sequence) is the mirror image of the arrangement in other hydrolytic enzymes such as trypsin. All three active-site residues are located on loops that are the best conserved structural features in the fold, which likely provides catalysis with certain flexibility to hydrolyze numerous structurally distinct substrates.

Reduction

Certain metals (e.g., pentavalent arsenic) and xenobiotics containing an aldehyde, ketone, disulfide, sulfoxide, quinone, *N*-oxide, alkene, azo, or nitro group are often reduced in vivo, although it is sometimes difficult to ascertain whether the reaction proceeds enzymatically or nonenzymatically by interaction with reducing agents [such as the reduced forms of glutathione, FAD, FMN and NAD(P)]. Some of these functional groups can be either reduced or oxidized. For example, aldehydes (RCHO) can be reduced to an alcohol (RCH_2OH) or oxidized to a carboxylic acid (RCOOH), whereas sulfoxides (R_1SOR_2) can be reduced to a sulfide (R_1SR_2) or oxidized to a sulfone ($R_1SO_2R_2$). In the case of halogenated hydrocarbons, such as halothane, dehalogenation can proceed by an oxidative or reductive pathway, both of which are catalyzed by the same enzyme (namely cytochrome P450). In some cases, such as azo-reduction, nitro-reduction, and the reduction of some alkenes (e.g., cinnamic acid, $C_6H_5CH = CHCOOH$), the reaction is largely catalyzed by intestinal microflora. Many of the reduction reactions described below (including azo-, nitro-, sulfoxide, and *N*-oxide reduction) can be catalyzed by aldehyde oxidase, but this does not appear to be the major enzyme responsible for any of the various reductive pathways of xenobiotic biotransformation.

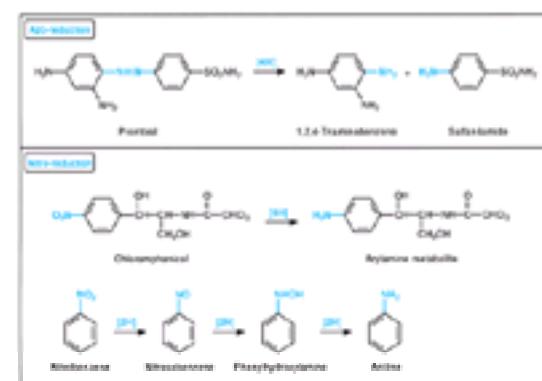
Azo- and Nitro-Reduction Prontosil and chloramphenicol are examples of drugs that undergo azo- and nitro-reduction, respectively, as shown in Fig. 6-8 (Herwick, 1980). Reduction of prontosil is of historical interest. Treatment of streptococcal and pneumococcal infections with prontosil marked the beginning of specific antibacterial chemotherapy. Subsequently, it was discovered that the active drug was not prontosil but its metabolite, sulfanilamide (*para*-aminobenzene sulfonamide), a product of azo-reduction. During azo-reduction, the nitrogen–nitrogen double bond is sequentially reduced and cleaved to produce two primary amines, a reaction requiring four reducing equivalents. Nitro-reduction requires six reducing equivalents, which are consumed in three sequential reactions, as shown in Fig. 6-8 for the conversion of nitrobenzene to aniline.


Figure 6-8. Examples of drugs that undergo azo reduction (prontosil) and nitro reduction (chloramphenicol and nitrobenzene).

Azo- and nitro-reduction are catalyzed by intestinal microflora and by two liver enzymes: cytochrome P450 and NAD(P)H-quinone oxidoreductase (a cytosolic flavoprotein, also known as DT-diaphorase). Under certain circumstances, a third liver enzyme, aldehyde oxidase, may also catalyze azo- and nitro-reduction reactions. The reactions require NAD(P)H and are inhibited by oxygen. The anaerobic environment of the lower gastrointestinal tract is well suited for azo- and nitro-reduction, which is why intestinal microflora contribute significantly to these reactions. Most of the reactions catalyzed by cytochrome P450 involve oxidation of xenobiotics. Azo- and nitro-reduction are examples in which, under conditions of low oxygen tension, cytochrome P450 can catalyze the reduction of xenobiotics.

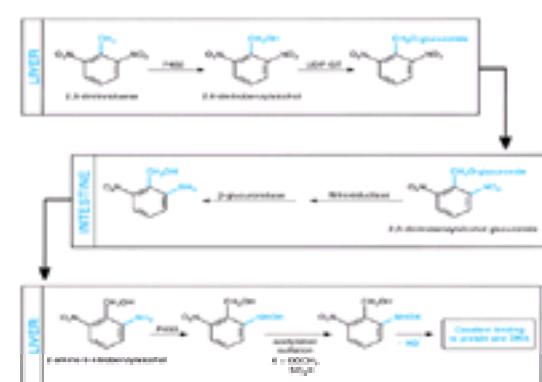
Nitro-reduction by intestinal microflora is thought to play an important role in the toxicity of several nitroaromatic compounds, including 2,6-dinitrotoluene, which is hepatotumorigenic to male rats. The role of nitro-reduction in the metabolic activation of 2,6-dinitrotoluene is shown in Fig. 6-9 (Long and Rickert, 1982; Mirsalis and Butterworth, 1982). The biotransformation of 2,6dinitrotoluene begins in the liver, where it is oxidized by cytochrome P450 and conjugated with glucuronic acid. This glucuronide is excreted in bile and undergoes biotransformation by intestinal microflora. One or more of the nitro groups are reduced to amines by nitroreductase, and the glucuronide is hydrolyzed by b-glucuronidase. The deconjugated metabolites are absorbed and transported to the liver, where the newly formed amine group is *N*-hydroxylated by cytochrome P450 and conjugated with acetate or sulfate. These conjugates form good leaving groups, which render the nitrogen highly susceptible to nucleophilic attack from proteins and DNA; this ostensibly leads to mutations and the formation of liver tumors. The complexity of the metabolic scheme shown in Fig. 6-9 underscores an important principle, namely that the activation of some chemical tumorigens to DNA-reactive metabolites involves several different biotransforming enzymes and may take place in more than one tissue. Consequently, the ability of 2,6-dinitrotoluene to bind to DNA and cause mutations is not revealed in most of the short-term assays for assessing the genotoxic potential of chemical agents. These in vitro assays for genotoxicity do not make allowance for biotransformation by intestinal microflora or, in some cases, the phase II (conjugating) enzymes.


Figure 6-9. Role of nitro reduction by intestinal microflora in the activation of the rat liver tumorigen, 2,6-dinitrotoluene.

Nitro-reduction by intestinal microflora also plays an important role in the biotransformation of musk xylene (1,3,5-trinitro-2- *t*butyl-4,6-dimethylbenzene). Reduction of one or both of the nitro groups is required for musk xylene to induce (as well as markedly inhibit) liver microsomal cytochrome P450 (namely CYP2B) in rodents (Lehman-McKeeman et al., 1999).

Carbonyl Reduction The reduction of certain aldehydes to primary alcohols and of ketones to secondary alcohols is catalyzed by alcohol dehydrogenase and by a family of carbonyl reductases (Weiner and Flynn, 1989). Carbonyl reductases are monomeric, NADPH-dependent enzymes present in blood and the cytosolic fraction of the liver, kidney, brain, and other tissues. The major circulating metabolite of the antipsychotic drug haloperidol is a secondary alcohol formed by carbonyl reductases in the blood and liver, as shown in Fig. 6-10 (Inaba and Kovacs, 1989). Other xenobiotics that are reduced by carbonyl reductases include pentoxifylline (see Fig. 6-1), acetohexamide, daunorubicin, ethacrynic acid, warfarin, menadione, and 4-nitroacetophenone. The reduction of ketones to secondary alcohols by carbonyl reductases may proceed with a high degree of stereoselectivity, as in the case of pentoxifylline (Fig. 6-1) (Lillibridge et al., 1996). Prostaglandins are

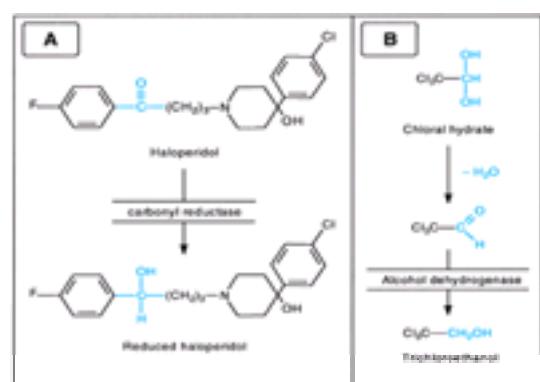
possibly physiologic substrates for carbonyl reductases, and they most certainly are substrates for a class of related enzymes known as prostaglandin dehydrogenases (discussed later in this section).


Figure 6-10. Reduction of xenobiotics by carbonyl reductase (A) *and alcohol dehydrogenase* (B).

In liver, carbonyl reductase activity is present mainly in the cytosolic fraction, but a different carbonyl reductase is present in the microsomal fraction. These enzymes differ in the degree to which they stereoselectively reduce ketones to secondary alcohols. For example, keto-reduction of pentoxifylline produces two enantiomeric secondary alcohols: one with the *R*-configuration (which is known as lisofylline) and one with the *S*-configuration, as shown in Fig. 6-1. Reduction of pentoxifylline by cytosolic carbonyl reductase results in the stereospecific formation (> 95 percent) of the optical antipode of lisofylline, whereas the same reaction catalyzed by microsomal carbonyl reductase produces both lisofylline and its optical antipode in a ratio of about 1 to 5 (Lillibridge et al., 1996).

In rat liver cytosol, the reduction of quinones is primarily catalyzed by DT-diaphorase (see " Quinone Reduction," below), whereas in human liver cytosol, quinone reduction is catalyzed by both DT-diaphorase and carbonyl reductases. Human liver cytosol appears to contain more than one carbonyl reductase. The activity of low- and high-affinity carbonyl reductase activity in human liver cytosol varies about tenfold among individuals (Wong et al., 1993). The number of carbonyl reductases involved in xenobiotic biotransformation is difficult to assess.

Structurally, carbonyl reductases belong to the short-chain dehydrogenase/reductase (SDR) superfamily (which includes certain hydroxysteroid dehydrogenases and prostaglandin dehydrogenases), although certain aldehyde reductases belong to the aldo-keto reductase (AKR) superfamily (which include other hydroxysteroid dehydrogenases and aldose reductases) (Penning, 1997). This latter superfamily of enzymes includes several forms of dihydrodiol dehydrogenase, which are monomeric (~34 kDa), cytosolic NADP(H)-requiring oxidoreductases that oxidize the *trans*-dihydrodiols of various polycyclic aromatic hydrocarbons to the corresponding *ortho*-quinones, which is depicted in Fig. 6-6 (Burczynski and Penning, 2000).

In certain cases, the reduction of aldehydes to alcohols can be catalyzed by alcohol dehydrogenase, as shown in Fig. 6-10 for the conversion of the sedative-hypnotic chloral hydrate to trichloroethanol. Alcohol dehydrogenase typically converts alcohols to aldehydes. In the case of chloral hydrate, the reverse reaction is favored by the presence of the trichloromethyl group, which is a strong electron-withdrawing group.

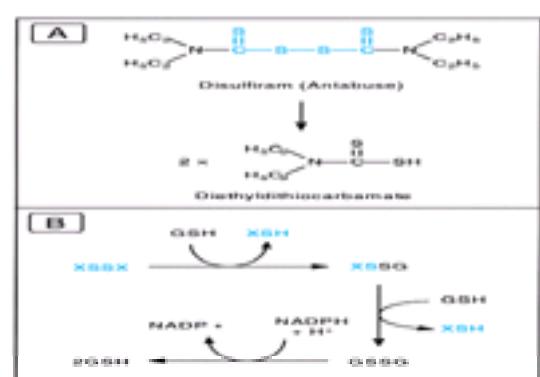
Disulfide Reduction Some disulfides are reduced and cleaved to their sulfhydryl components, as shown in Fig. 6-11 for the alcohol deterrent disulfiram (Antabuse). As shown in Fig. 6-11, disulfide reduction by glutathione is a three-step process, the last step of which is catalyzed by glutathione reductase. The first steps can be catalyzed by glutathione *S*-transferase, or they can occur nonenzymatically.


Figure 6-11. Biotransformation of disulfiram by disulfide reduction (A) *and the general mechanism of glutathione-dependent disulfide reduction of xenobiotics* (B).

ABBREVIATIONS: GSH, glutathione; XSSX, xenobiotic disulfide; GSSG, reduced glutathione. The last reaction in *(B)* is catalyzed by glutathione reductase.

Sulfoxide and *N*-Oxide Reduction Thioredoxin-dependent enzymes in liver and kidney cytosol have been reported to reduce sulfoxides, which themselves may be formed by cytochrome P450 or flavin monooxygenases (Anders et al., 1981). It has been suggested that recycling through these counteracting enzyme systems may prolong the half-life of certain xenobiotics. Sulindac is a sulfoxide that undergoes reduction to a sulfide, which is excreted in bile and reabsorbed from the intestine (Ratnayake et al., 1981). This enterohepatic cycling prolongs its duration of action, such that this nonsteroidal anti-inflammatory drug (NSAID) need only be taken twice daily. Diethyldithiocarbamate methyl ester, a metabolite of disulfiram, is oxidized to a sulfine, which is reduced to the parent methyl ester by glutathione. In the latter reaction, two molecules of glutathione (GSH) are oxidized with reduction of the sulfine oxygen to water (Madan et al., 1994), as shown below:

$$R_1R_2C = S^+ \!—\! O^- + 2\ GSH \circledR R_1R_2C = S + GSSG + H_2O$$

Just as sulfoxide reduction can reverse the effect of sulfoxidation, so the reduction of *N*-oxides can reverse the *N*-oxygenation of amines, which is catalyzed by flavin monooxygenases and cytochrome P450. Under reduced oxygen tension, reduction of the *N*-oxides of imipramine, tiaramide, indicine, and *N,N*-dimethylaniline can be catalyzed by mitochondrial and/or microsomal enzymes in the presence of NADH or NADPH (Sugiura and Kato, 1977). The NADPH-dependent reduction of *N*-oxides in liver microsomes appears to be catalyzed by cytochrome P450 (Sugiura et al., 1976), although in some cases NADPH-cytochrome P450 reductase may play an important role.

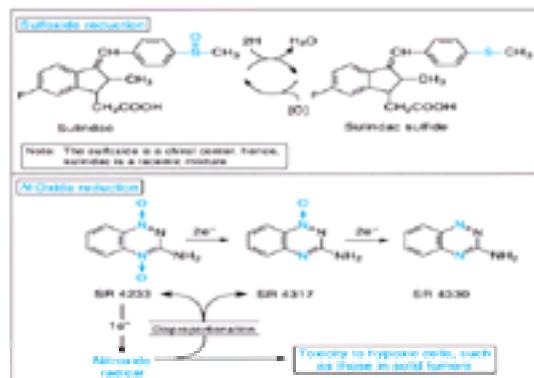
As a class, *N*-oxides are not inherently toxic compounds. However, certain aromatic and aliphatic *N*-oxides have been exploited as bioreductive drugs (also known as DNA-affinic drugs) for the treatment of certain cancers and infectious diseases (Wardman et al., 1995). In these cases, *N*-oxides have been used as prodrugs that are converted to cytotoxic or DNA-binding drugs under hypoxic conditions. The fact that *N*-oxides of certain drugs are converted to toxic metabolites under hypoxic conditions is the basis for their selective toxicity to certain solid tumors (namely those that are hypoxic and hence resistant to radiotherapy) and anaerobic bacteria. For example, tirapazamine (SR 4233) is a benzotriazine di-*N*-oxide that is preferentially toxic to hypoxic cells, such as those present in solid tumors, apparently due to its rapid activation by one-electron reduction of the *N*-oxide to an oxidizing nitroxide radical, as shown in Fig. 6-12 (Walton et al., 1992). This reaction is catalyzed by cytochrome P450 and NADPH-cytochrome P450 reductase (Saunders et al., 2000). Two-electron reduction of the di-*N*-oxide, SR 4233, produces a mono-*N*-oxide, SR 4317, which undergoes a second *N*-oxide reduction to SR 4330. Like SR 4233, the antibacterial agent quindoxin is a di-*N*-oxide whose cytotoxicity is dependent on reductive activation, which is favored by anaerobic conditions.


Figure 6-12. Examples of sulfoxide and **N-oxide reduction.**

Note that tirapazamine (3-amino-1,2,4-benzotriazine-1,4-dioxide or SR4233) is a representative of a class of agents that are activated by reduction, which may be clinically useful in the treatment of certain tumors.

Bioreductive alkylating agents, which include such drugs as mitomycins, anthracyclines, and aziridinylbenzoquinones, represent another class of anticancer agents that require activation by reduction. However, for this class of agents, bioactivation also involves a two-electron reduction reaction, which is largely catalyzed by DT-diaphorase, described in the next section.

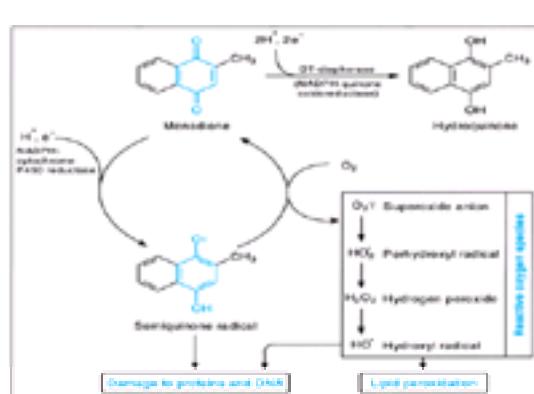
Quinone Reduction Quinones can be reduced to hydroquinones by NAD(P)H-quinone oxidoreductase, a cytosolic flavoprotein also known as DT-diaphorase (Ernster, 1987; Riley and Workman, 1992). An example of this reaction is shown in Fig. 6-13. Formation of the relatively stable hydroquinone involves a two-electron reduction of the quinone with stoichiometric oxidation of NAD[P]H *without* oxygen consumption. The two-electron reduction of quinones also can be catalyzed by carbonyl reductase, especially in humans. Although there are exceptions (see below, this section), this pathway of quinone reduction is essentially nontoxic; that is, it is not associated with oxidative stress, unlike the one-electron reduction of quinones by NADPH-cytochrome P450 reductase (Fig. 6-13). In addition to quinones, substrates for DT-diaphorase include a variety of potentially toxic compounds, including quinone epoxides, quinoneimines, azo dyes, and *C*-nitroso derivatives of arylamines.


Figure 6-13. Two-electron reduction of menadione to a hydroquinone, and production of reactive oxygen species during its one-electron reduction to a semiquinone radical.

The second pathway of quinone reduction is catalyzed by NADPH-cytochrome P450 reductase (a microsomal flavoprotein) and results in the formation of a semiquinone free radical by a one-electron reduction of the quinone. Semiquinones are readily autooxidizable, which leads to nonstoichiometric oxidation of NADPH and oxygen consumption. The oxidative stress associated with autooxidation of a semiquinone free radical, which produces superoxide anion, hydrogen peroxide, and other active oxygen species, can be extremely cytotoxic, as illustrated in Fig. 6-13 for menadione. Oxidative stress appears to be an important component to the mechanism of toxicity of several xenobiotics that either contain a quinone or can be biotransformed to a quinone (Anders, 1985). The production of superoxide anion radicals and oxidative stress are responsible, at least in part, for the cardiotoxic effects of doxorubicin (adriamycin) and daunorubicin (daunomycin), the pulmonary toxicity of paraquat and nitrofurantoin, and the neurotoxic effects of 6-hydroxydopamine. Oxidative stress also plays an important role in the destruction of pancreatic beta cells by alloxan and dialuric acid. Tissues low in superoxide dismutase activity, such as the heart, are especially susceptible to the oxidative stress associated with the redox cycling of quinones. This accounts, at least in part, for the cardiotoxic effects of adriamycin and related anticancer agents.

DT-diaphorase levels are often elevated in tumor cells, which has implications for cancer chemotherapy with agents that are biotransformed by DT-diaphorase (Riley and Workman, 1992). Some cancer chemotherapeutic agents are inactivated by DT-diaphorase, such as SR 4233 (Fig. 6-12), whereas others are activated to cytotoxic metabolites, such as mitomycins, anthracyclines, and aziridinylbenzoquinones. These so-called bioreductive alkylating agents are reduced by DT-diaphorase to generate reactive intermediates that undergo nucleophilic additions with DNA, resulting in single-strand DNA breaks. The reason such drugs are preferentially toxic to tumor cells is that tumor cells, especially those in solid tumors, are hypoxic, and hypoxia induces the synthesis of DT-diaphorase [by a mechanism that involves the activator protein 1 (AP-1) and nuclear factor-kB (NF-kB) response elements in the 5'-promoter region of the DT-diaphorase gene]. Therefore, tumor cells often express high levels of DT-diaphorase, which predisposes them to the toxic effects of mitomycin C and related indolequinones. Interestingly, mitomycin C also up-regulates the expression of DT-diaphorase, which may enable this anticancer drug to stimulate its own metabolic activation in tumor cells (Yao et al., 1997). Induction of DT-diaphorase by mitomycin C, like that by hypoxia, involves transcriptional activation of the AP-1 and NF-kB response elements in the 5'-promoter region of the DT-diaphorase gene. However, whereas activation of the DTdiaphorase AP-1 response element by mitomycin C involves both Jun and Fos, its activation by hypoxia involves only *jun* family dimers (Yao et al., 1997). Other factors that regulate the expression of DT-diaphorase are described below (this section).

It is now apparent that the structure of the hydroquinones produced by DT-diaphorase determines whether the two-electron reduction of quinones results in xenobiotic detoxication or activation. Hydroquinones formed by two-electron reduction of unsubstituted or methyl-substituted 1,4-naphthoquinones (such as menadione) or the corresponding quinone epoxides are relatively stable to autooxidation, whereas the methoxyl, glutathionyl, and hydroxyl derivatives of these compounds undergo autooxidation with production of semiquinones and reactive oxygen species. The ability of glutathionyl derivatives to undergo redox cycling indicates that conjugation with glutathione does not prevent quinones from serving as substrates for DT-diaphorase. The glutathione conjugates of quinones can also be reduced to hydroquinones by carbonyl reductases, which actually have a binding site for glutathione. In human carbonyl reductase, this binding site is Cys $_{227}$, which is involved in binding both substrate and glutathione (Tinguely and Wermuth, 1999). Although oxidative stress is an important mechanism by which quinones cause cellular damage (through the intermediacy of semiquinone radicals and the generation of reactive oxygen species), it should be noted that quinones are Michael acceptors, and cellular damage can occur through direct alkylation of critical cellular proteins and/or DNA (reviewed in Bolton et al., 2000).

DT-diaphorase is a dimer of two equal subunits (Mr 27 kDa) each containing FAD. Mouse, rat, and human appear to possess two, three, and four forms of DT-diaphorase, respectively (Riley and Workman, 1992). The human enzymes are encoded by four distinct gene loci (*DIA 1* through *DIA 4*). The fourth gene locus encodes the form of DT-diaphorase known as NADPH-quinone oxidoreductase-1 (NQO $_1$), which accounts for the majority of DT-diaphorase activity in most human tissues. This enzyme is inducible (see below, this section), and is the ortholog of rat NQO $_1$. A second, noninducible form of DT-diaphorase, NQO $_2$, is polymorphically expressed in humans (Jaiswal et al., 1990).

DT-diaphorase is inducible up to tenfold by two classes of agents, which have been categorized as *bifunctional* and *monofunctional* inducers (Prochaska and Talalay, 1992). The bifunctional agents include compounds like b-naphthoflavone, benzo[a]pyrene, 3-methylcholanthrene and 2,3,7,8-tetrachlorodibenzo- *p*-dioxin (TCDD or dioxin), which induce both phase I enzymes (such as the cytochrome P450 enzyme known as CYP1A1) and phase II enzymes (such as glutathione *S*-transferase and

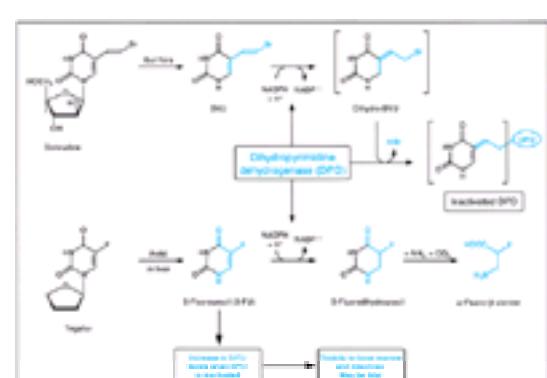
uridine diphosphate [UDP]-glucuronosyltransferase). These agents signal through two distinct mechanisms, one involving the XRE (xenobiotic-response element) and one involving the ARE (antioxidant response element), which is also known as the EpRE (electrophilic response element). (Response elements are short sequences of DNA, often located upstream in the 5'-region of a gene, that bind the transcription factors controlling gene expression.) Some enzymes, such as CYP1A1, are largely regulated by the XRE, whereas others, such as glutathione *S*-transferase, are largely regulated by ARE. Some enzymes, such as DT-diaphorase, are regulated by both.

In order to activate the XRE and induce the synthesis of CYP1A1, the so-called bifunctional agents must first bind to a receptor protein called the *Ah* receptor, which is discussed later on under "Induction of Cytochrome P450." Unlike the bifunctional agents, the monofunctional agents do not bind to the *Ah* receptor and, therefore, do not induce CYP1A1. However, like the bifunctional agents, the monofunctional agents can induce the synthesis of those phase II enzymes that are regulated by the ARE (which includes DT-diaphorase).

The monofunctional agents can be subdivided into two chemical classes: those that cause oxidative stress through redox cycling (e.g., the quinone, menadione, and the phenolic antioxidants *tert*-butylhydroquinone and 3,5-di-*tert*-butylcatechol) and those that cause oxidative stress by depleting glutathione (e.g., fumarates, maleates, acrylates, isothiocyanates, and other Michael acceptors that react with glutathione).

As previously mentioned, agents that signal through the XRE do so by binding to the *Ah* receptor. Agents that signal through the ARE do so by an incompletely characterized mechanism. AREs generally contain two AP1/AP1-like elements arranged as inverse or direct repeats with a 3- to 8-base-pair interval and followed by a "GC" box. Several nuclear factors—including Jun, Fos, Fra, and Nrf2 families—bind the ARE and activate transcription of DT-diaphorase and certain phase II enzymes (Favreau and Pickett, 1991; Rushmore et al., 1991; Hayes and Pullford, 1995; Radjendirane and Jaiswal, 1999). The flavonoid b-naphthoflavone, the polycyclic aromatic hydrocarbon benzo[a]pyrene, and the polyhalogenated aromatic hydrocarbon TCDD all induce DTdiaphorase by both mechanisms; the parent compound binds to the *Ah* receptor and is responsible for inducing CYP1A1, as well as DT-diaphorase, via the XRE, whereas electrophilic and/or redox active metabolites of b-naphthoflavone, benzo[a]pyrene, and TCDD are responsible for inducing glutathione *S*-transferase, as well as DT-diaphorase, via the ARE (Radjendirane and Jaiswal, 1999). The situation with benzo[a]pyrene is quite intriguing. This polycyclic aromatic hydrocarbon binds directly to the *Ah* receptor, which binds to the XRE and induces the synthesis of CYP1A1, which in turn converts benzo[a]pyrene to electrophilic metabolites (such as arene oxides and diolepoxides) and redox active metabolites (such as catechols), as shown in Fig. 6-6. These electrophilic and redox active metabolites then induce enzymes that are regulated by the ARE. However, the catechol metabolites of benzo[a]pyrene are further converted by dihydrodiol dehydrogenase to *ortho*-quinones (Fig. 6-6), and are thereby converted back into planar, hydrophobic compounds that are highly effective ligands for the *Ah* receptor (Burczynski and Penning, 2000). This may be toxicologically important, because the *Ah* receptor may translocate *ortho*-quinone metabolites of benzo[a]pyrene into the nucleus, where they might damage DNA (Bolton et al., 2000).

Among the monofunctional agents that apparently induce DT-diaphorase via ARE is sulforaphane, an ingredient of broccoli that may be responsible for the anticarcinogenic effects of this cruciferous vegetable (Zhang et al., 1992). As mentioned above (this section), hypoxia and the anticancer agent mitomycin C are also inducers of DT-diaphorase, which has implications for cancer chemotherapy.

Dihydropyrimidine Dehydrogenase In 1993, fifteen Japanese patients died as a result of an interaction between two oral medications, Sorivudine, a new antiviral drug for herpes zoster, and Tegafur, a prodrug that is converted in the liver to the anticancer agent 5-fluorouracil. The deaths occurred within 40 days of the Japanese government's approval of Sorivudine for clinical use. The mechanism of the lethal interaction between Sorivudine and Tegafur is illustrated in Fig. 6-14 and involves inhibition dihydropyrimidine dehydrogenase, an NADPH-requiring homodimeric protein (Mr ~210 kDa) containing FMN/FAD, and an iron-sulfur cluster in each subunit. The enzyme is located mainly in liver cytosol, where it catalyzes the reduction of 5-fluorouracil and related pyrimidines. Sorivudine is converted in part by gut flora to (*E*)-5-(2-bromovinyl) uracil (BVU), which lacks antiviral activity but is converted by dihydropyrimidine dehydrogenase to a metabolite that binds covalently to the enzyme. The irreversible inactivation (also known as suicidal inactivation) of dihydropyrimidine dehydrogenase by Sorivudine causes a marked inhibition of 5-fluorouracil metabolism, which increases blood levels of 5-fluorouracil to toxic and, in some cases, lethal levels (Ogura et al., 1998; Kanamitsu et al., 2000).


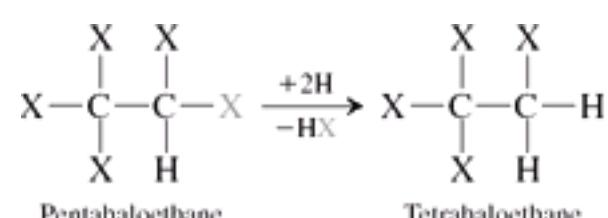


Figure 6-14. Reduction of 5-fluorouracil by dihydropyrimidine dehydrogenase and its inhibition (suicide inactivation) by Sorivudine.
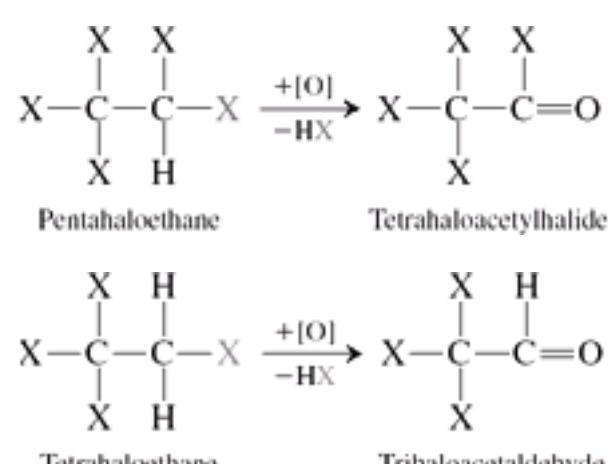
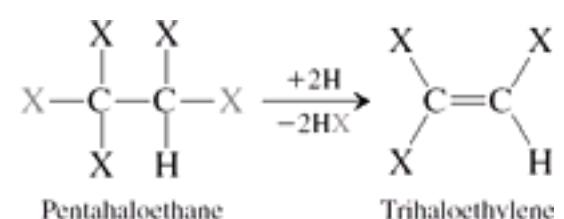


Note: Inhibition of dihydropyrimidine dehydrogenase is the mechanism of fatal interactions between Sorivudine and the 5-fluorouracil prodrug Tegafur.

Severe 5-fluorouracil toxicity has also been documented in rare individuals who are genetically deficient in dihydropyrimidine dehydrogenase. The incidence and underlying mechanism of this genetic polymorphism remain to be determined, although its implication is clear: the dosage of 5-fluoroacil should be decreased in individuals devoid of dihydropyrimidine dehydrogenase or substantially lacking in it. Dosage adjustment may also be necessary for heterozygotes (i.e., individuals with a single copy of the active gene) compared with individuals who are homozygous for the wild-type (active) gene (Diasio et al., 1998).


Dehalogenation There are three major mechanisms for removing halogens (F, Cl, Br, and I) from aliphatic xenobiotics (Anders, 1985). The first, known as *reductive dehalogenation,* involves replacement of a halogen with hydrogen, as shown below:

In the second mechanism, known as *oxidative dehalogenation,* a halogen and hydrogen on the same carbon atom are replaced with oxygen. Depending on the structure of the haloalkane, oxidative dehalogenation leads to the formation of an acylhalide or aldehyde, as shown below:

A third mechanism of dehalogenation involves the elimination of two halogens on adjacent carbon atoms to form a carbon– carbon double bond, as shown below:

A variation on this third mechanism is *dehydrohalogenation,* in which a halogen and hydrogen on adjacent carbon atoms are eliminated to form a carbon–carbon double bond.

Reductive and oxidative dehalogenation are both catalyzed by cytochrome P450. (The ability of cytochrome P450 to catalyze both reductive and oxidative reactions is explained later, under "Cytochrome P450.") Dehalogenation reactions leading to double bond formation are catalyzed by cytochrome P450 and glutathione *S*-transferase. These reactions play an important role in the biotransformation and metabolic activation of several halogenated alkanes, as the following examples illustrate.

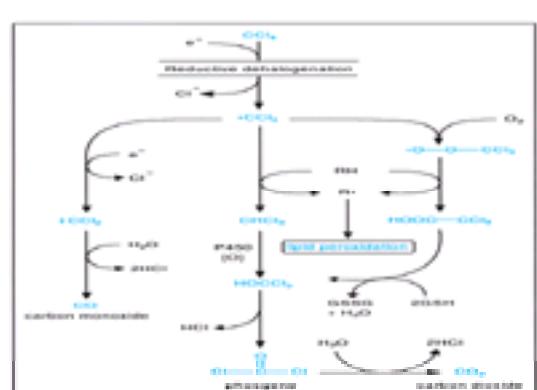
The hepatotoxicity of carbon tetrachloride (CCl_4) and several related halogenated alkanes is dependent on their biotransformation by reductive dehalogenation. The first step in reductive dehalogenation is a one-electron reduction catalyzed by cytochrome P450, which produces a potentially toxic, carbon-centered radical and inorganic halide. In the case of CCl_4, reductive dechlorination produces a trichloromethyl radical ($\bullet CCl_3$), which initiates lipid peroxidation and produces a variety of other metabolites, as shown in Fig. 6-15. Halothane can also be converted by reductive dehalogenation to a carbon-centered radical, as shown in Fig. 6-16. The mechanism is identical to that described for carbon tetrachloride, although in the case of halothane the radical is generated through loss of bromine, which is a better leaving group than chlorine. Figure 6-16 also shows that halothane can undergo oxidative dehalogenation, which involves oxygen insertion at the C–H bond to generate an unstable halohydrin ($CF_3COHClBr$) that decomposes to a reactive acylhalide (CF_3COCl), which can bind to cellular proteins (particularly to amine groups) or further decompose to trifluoroacetic acid (CF_3COOH).


Figure 6-15. Reductive dehalogenation of carbon tetrachloride to a trichloromethyl free radical that initiates lipid peroxidation.

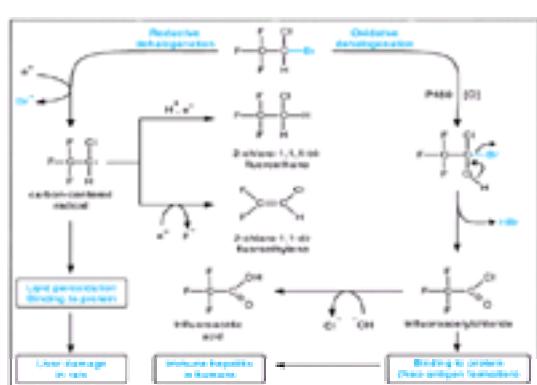
ABBREVIATIONS: RH, unsaturated lipid; R•, lipid dienyl radical; GSH, reduced glutathione; GSSG, oxidized glutathione.


Figure 6-16. Activation of halothane by reductive and oxidative dehalogenation and their role in liver toxicity in rats and humans.

Both the oxidative and reductive pathways of halothane metabolism generate reactive intermediates capable of binding to proteins and other cellular macromolecules. The relative importance of these two pathways to halothane-induced hepatotoxicity appears to be species-dependent. In rats, halothane-induced hepatotoxicity is promoted by those conditions favoring the reductive dehalogenation of halothane, such as moderate hypoxia (10 to 14% oxygen) plus treatment with the cytochrome P450 inducers phenobarbital and pregnenolone-16a-carbonitrile. In contrast to the situation in rats, halothane-induced hepatotoxicity in guinea pigs is largely the result of oxidative dehalogenation of halothane (Lunam et al., 1989). In guinea pigs, halothane hepatotoxicity is not enhanced by moderate hypoxia and is diminished by the use of deuterated halothane, which impedes the oxidative dehalogenation of halothane because the P450-dependent insertion of oxygen into a carbon–deuterium bond is energetically less favorable (and therefore slower) than inserting oxygen into a carbon–hydrogen bond.

Halothane hepatitis in humans is a rare but severe form of liver necrosis associated with repeated exposure to this volatile anesthetic. In humans as in guinea pigs, halothane hepatotoxicity appears to result from the oxidative dehalogenation of halothane, as shown in Fig. 6-16. Serum samples from patients suffering from halothane hepatitis contain antibodies directed against neoantigens formed by the trifluoroacetylation of proteins. These antibodies have been used to identify which specific proteins in the endoplasmic reticulum are targets for trifluoroacetylation during the oxidative dehalogenation of halothane (Pohl et al., 1989).

The concept that halothane is activated by cytochrome P450 to trifluoroacetylhalide, which binds covalently to proteins and elicits an immune response, has been extended to other volatile anesthetics, such as enflurane, methoxyflurane, and isoflurane. In other words, these halogenated aliphatic hydrocarbons, like halothane, may be converted to acylhalides that form immunogens by binding covalently to proteins. In addition to accounting for rare instances of enflurane hepatitis, this mechanism of hepatotoxicity can also account for reports of a *cross-sensitization* between enflurane and halothane, in which enflurane causes liver damage in patients previously exposed to halothane.

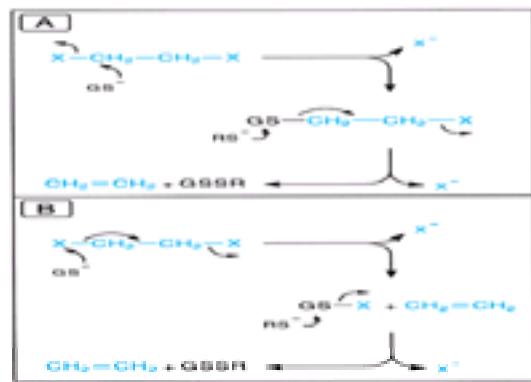
One of the metabolites generated from the reductive dehalogenation of halothane is 2-chloro-1,1-difluoroethylene (Fig. 6-16). The formation of this metabolite involves the loss of two halogens from adjacent carbon atoms with formation of a carbon–carbon double bond. This type of dehalogenation reaction can also be catalyzed by glutathione *S*-transferases. Glutathione initiates the reaction with a nucleophilic attack either on the electrophilic carbon to which the halogen is attached (mechanism A) or on the halide itself (mechanism B), as shown in Fig. 6-17 for the dehalogenation of 1,2-dihaloethane to ethylene. The insecticide DDT is detoxified by dehydrochlorination to DDE by DDT-dehydrochlorinase, as shown in Fig. 6-18. The activity of this glutathione-dependent reaction correlates well with resistance to DDT in houseflies.


Figure 6-17. Glutathione-dependent dehalogenation of 1,2-dihaloethane to ethylene.

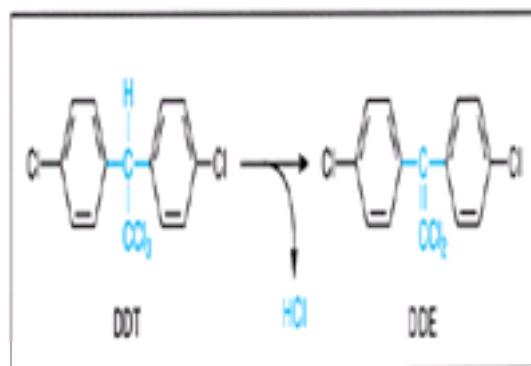

Figure 6-18. Dehydrochlorination of the pesticide DDT to DDE, a glutathione-dependent reaction.

Oxidation

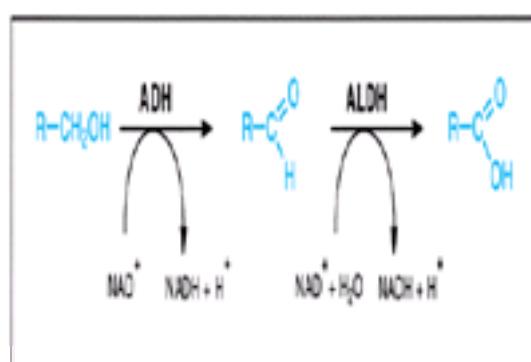
Alcohol, Aldehyde, Ketone Oxidation-Reduction Systems Alcohols, aldehydes, and ketones are oxidized or reduced by a number of enzymes, including alcohol dehydrogenase, aldehyde dehydrogenase, carbonyl reductase, dihydrodiol dehydrogenase, and the molybdenum-containing enzymes, aldehyde oxidase and xanthine dehydrogenase/oxidase. For example, simple alcohols (such as methanol and ethanol) are oxidized to aldehydes (namely formaldehyde and acetaldehyde) by alcohol dehydrogenase. These aldehydes are further oxidized to carboxylic acids (formic acid and acetic acid) by aldehyde dehydrogenase, as shown in   Fig. 6-19. NAD^+ is the preferred cofactor for both alcohol and aldehyde dehydrogenase.


Figure 6-19. Oxidation of alcohols to aldehydes and carboxylic acids by alcohol dehydrogenase (ADH) and aldehyde dehydrogenase (ALDH).

Alcohol Dehydrogenase Alcohol dehydrogenase (ADH) is a zinc-containing, cytosolic enzyme present in several tissues including the liver, which has the highest levels, the kidney, the lung, and the gastric mucosa (Agarwal and Goedde, 1992). Human ADH is a dimeric protein consisting of two 40-kDa subunits. The subunits (a, b, g, p c, and sixth subunit known as s or μ) are encoded by six different gene loci (ADH1 through ADH6). [Although the human ADH subunits a, b, g, p and c are consistently reported to be encoded by genes ADH1 to ADH5, respectively, the sixth subunit (s or μ) was originally reported to be encoded by gene ADH7. In this review, I have followed the recommendation of Jörnvall and Höög (1995) that the gene encoding the sixth subunit (s or μ) be designated ADH6.] Updates on ADH nomenclature can be found on the Internet (http://www.gene.ucl.ac.uk./nomenclature/ADH. shtml).

There are three allelic variants of the beta subunit (b $_1$, b$_2$, and b$_3$, which differ by a single amino acid) and two allelic variants of the gamma subunit (g $_1$ and g$_2$, which differ by two amino acids). Consequently, the human ADH enzymes comprise nine subunits, all of which can combine as homodimers. In addition, the a, b, and g subunits (and their allelic variants) can form heterodimers with each other (but not with the other subunits, none of which form heterodimers). The different molecular forms of ADH are divided into four major classes. Class I contains ADH1, ADH2, and ADH3, which can be considered isozymes. ADH1 contains either two alpha subunits or one alpha subunit plus a beta or gamma subunit. ADH2 contains either two beta subunits (which could be b $_1$, b$_2$, or b$_3$) or a beta subunit plus a gamma subunit (which could be g$_1$ or g$_2$). ADH3 contains two gamma subunits (which could be g$_1$ or g$_2$). ADH2 enzymes that differ in the type of b subunits are known as allelozymes, as are ADH3 enzymes that differ in the type of g subunit. Accordingly, ADH2*1 is an allelozyme composed of b $_1$ units; ADH2*2 is an allelozyme composed of b$_2$ subunits, and ADH2*3 is an allelozyme composed of b$_3$ subunits.

Class II contains ADH4, which is made up of two p subunits (named pi because this form of ADH is not inhibited by pyrazole). Class III contains ADH5, which is made up of two c subunits (for which reason it is also known as chi-ADH). Class IV contains ADH6 (originally named ADH7, as mentioned above), which is made up of two subunits designated s or μ (Agarwal and Goedde, 1992; Jörnvall and Höög, 1995; Edenberg, 2000).

The class I ADH isozymes (a-ADH, b-ADH, and g-ADH) are responsible for the oxidation of ethanol and other small aliphatic alcohols, and they are strongly inhibited by pyrazole and its 4-alkyl derivatives (e.g., 4-methylpyrazole). High levels of class I ADH isozymes are expressed in liver and adrenals, with lower levels in kidney, lung, blood vessels [in the case of ADH2 (i.e., b-ADH)] and other tissues, but not brain. Class II ADH (p-ADH) is primarily expressed in liver (with lower levels in stomach), where it preferentially oxidizes larger aliphatic and aromatic alcohols. Class II ADH differs from the class I ADH in that it plays little or no role in ethanol and methanol oxidation, and it is not inhibited by pyrazole. Long-chain alcohols (pentanol and larger) and aromatic alcohols (such as cinnamyl alcohol) are preferred substrates for class III ADH (c -ADH). Like class II ADH, class III ADH is not inhibited by pyrazole. However, in contrast to class II ADH, which is largely confined to the liver, class III ADH is ubiquitous, being present in virtually all tissues (including brain), where it appears to play an important role in detoxifying formaldehyde. In fact, class III ADH and formaldehyde dehydrogenase are identical enzymes (Koivusalo et al., 1989). Class IV ADH (s- or μ-ADH) is a low affinity (high K$_m$), high capacity ADH (high V$_{max}$), and is the most active of the medium-chain ADHs in oxidizing retinol. It is the major ADH expressed in human stomach and other areas of the gastrointestinal tract (esophagus, gingiva, mouth, and tongue). In contrast the other ADHs, class IV ADH is not expressed in adult human liver. Inasmuch as class IV ADH is expressed in the upper gastrointestinal tract, where chronic alcohol consumption leads to cancer development, there is growing interest in the role of class

IV ADH in the conversion of ethanol to acetaldehyde (a suspected upper GI tract carcinogen or cocarcinogen) and in its role in the metabolism of retinol (a vitamin required for epithelial cell growth and differentiation), which might be inhibited by alcohol consumption (Seitz and Oneta, 1998).

The class I isozymes of ADH differ in their capacity to oxidize ethanol. Even the allelozymes, which differ in a single amino acid, differ markedly in the affinity (K_m) and/or capacity (V_{max}) for oxidizing ethanol to acetaldehyde. The homodimer b_2b_2 and heterodimers containing at least one b_2 subunit (i.e., the ADH2*2 allelozymes) are especially active in oxidizing ethanol at physiologic pH. ADH2*2 is known as *atypical* ADH and is responsible for the unusually rapid conversion of ethanol to acetaldehyde in 90 percent of the Pacific Rim Asian population (Japanese, Chinese, Korean). The atypical ADH is expressed to a much lesser degree in Caucasians (<5 percent of Americans, ~8 percent of English, ~12 percent of Germans, and ~20 percent of Swiss), African Americans (<10 percent), Native Americans (0 percent) and Asian Indians (0 percent) (Agarwal and Goedde, 1992). The three ADH2 alleles, ADH2*1 (b_1-ADH), ADH2*2 (b_2-ADH), and ADH2*3 (b_3-ADH), are mainly expressed in Caucasians (up to 95 percent), Pacific Rim Asians (~90 percent) and Africans/African Americans (~24 percent), respectively. These population differences in ADH2 allelozyme expression contribute to ethnic differences in alcohol consumption and toxicity, as discussed in the next section, "Aldehyde Dehydrogenase."

Unlike the allelic variants of ADH2, the allelic variants of ADH3 do not differ markedly in their ability to oxidize ethanol. However, as in the case of the ADH2 allelozymes, the expression of the ADH3 allelozymes also varies from one ethnic group to the next. The two allelozymes of ADH3, namely ADH3*1 (g_1-ADH) and ADH3*2 (g_2-ADH) are respectively expressed 50:50 in Caucasians, but 90:10 in Pacific Rim Asians (Li, 2000).

The various class I ADHs in liver oxidize ethanol with a K_m of 50 μM to 4 mM. For comparison, legal intoxication in the United States is defined as a blood alcohol level of 0.1%, which corresponds to 22 mM (Edenberg, 2000). Therefore, during intoxication, the hepatic metabolism of ADH becomes saturated, and the kinetics of ethanol disappearance conform to zero-order kinetics, meaning that a constant amount of ethanol is metabolized per unit time. When the concentration of ethanol falls within the range of K_m, the kinetics of ethanol disappearance conform to a first-order process, meaning that a constant percentage of the remaining ethanol is metabolized per unit time.

Compared with hepatic ADH, gastric ADH has a lower affinity (higher K_m) but higher capacity (larger V_{max}) for oxidizing ethanol, the former being dominated by the class I ADHs, the latter by class IV ADH. Although ethanol is largely biotransformed by hepatic ADH, gastric ADH nevertheless can limit the systemic bioavailability of alcohol. This first-pass elimination of alcohol by gastric ADH can be significant, depending on the manner in which the alcohol is consumed; large doses over a short time produce high ethanol concentrations in the stomach, which compensate for the low affinity (high K_m) of gastric ADH. Young women have lower gastric ADH activity than do men, and gastric ADH activity tends to be lower in alcoholics (Frezza et al., 1990). Some alcoholic women have no detectable gastric ADH, and blood levels of ethanol after oral consumption of alcohol are the same as those that are obtained after intravenous administration. Gastric ADH activity decreases during fasting, which is one reason why alcohol is more intoxicating when it is consumed on an empty stomach. Several commonly used drugs (cimetidine, ranitidine, aspirin) are noncompetitive inhibitors of gastric ADH. Under certain circumstances these drugs increase the systemic availability of alcohol, although the effect is too small to have serious medical, social, or legal consequences (Levitt, 1993). About 30 percent of Asians appear to be genetically deficient in class IV ADH, the main gastric ADH. In addition to biotransforming ethanol and retinol, class IV ADH also detoxifies the dietary carcinogen nitrobenzaldehyde. It has been suggested that a lack of class IV ADH in Japanese subjects may impair their ability to detoxify nitrobenzaldehyde and may possibly be linked to the high rate of gastric cancer observed in the Japanese population (Seitz and Oneta, 1998).

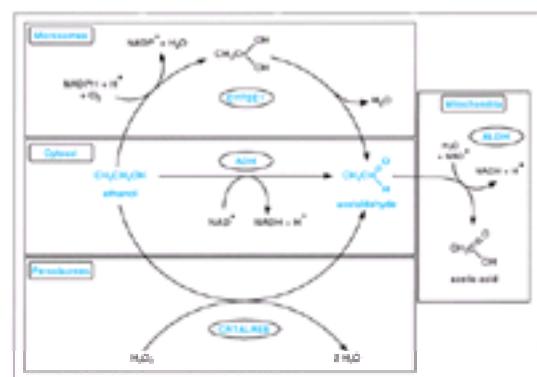
Alcohols can be oxidized to aldehydes by non-ADH enzymes in microsomes and peroxisomes, although these are quantitatively less important than ADH for ethanol oxidation (Lieber, 1999). The microsomal ethanol oxidizing system (formerly known as MEOS) is the cytochrome P450 enzyme CYP2E1. The corresponding peroxisomal enzyme is catalase. The oxidation of ethanol to acetaldehyde by these three enzyme systems is shown in Fig. 6-20.


Figure 6-20. Oxidation of ethanol to acetaldehyde by ethanol dehydrogenase (ADH), cytochrome P450 (CYP2E1), and catalase.

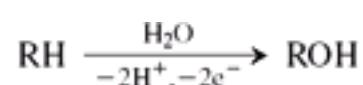
Note the oxidation of ethanol to acetic acid involves multiple organelles.

Aldehyde Dehydrogenase Aldehyde dehydrogenase (ALDH) oxidizes aldehydes to carboxylic acids with NAD^+ as the cofactor. Several ALDH enzymes are involved in the oxidation of xenobiotic aldehydes (Goedde and Agarwal, 1992). The enzymes also have esterase activity (Yoshida et al., 1998). Formaldehyde dehydrogenase, which specifically oxidizes formaldehyde complexed with glutathione, is not a member of the ALDH family but is a class III ADH (Koivusalo et al., 1989). Twelve ALDH genes (known as ALDH1 to 10, SSDH, and MMSDH) have been identified in humans, and a correspondingly large number of ALDH genes appear to be present in other mammalian species. The name, tissue distribution, subcellular location, and major substrate for the 12 human ALDHs are summarized in Table 6-2. The ALDHs differ in their primary amino acid sequences. They may also differ in the quaternary structure. For example, ALDH3 appears to be a dimer of two 85-kDa subunits, whereas ALDH1 and ALDH2 appear to be homotetramers of 54-kDa subunits (Goedde and Agarwal, 1992). In contrast to ALDH1 and ALDH2, which specifically reduce NAD^+, ALDH3 reduces both NAD^+ and $NADP^+$ due to its low affinity for these cofactors.

Table 6-2 Properties of the Human Aldehyde Dehydrogenases (ALDHs)

As shown in Fig. 6-20, ALDH2 is a mitochondrial enzymes that, by virtue of its high affinity, is primarily responsible for oxidizing simple aldehydes, such as acetaldehyde (K_m for acetaldehyde <5 μM at pH 7.4). A genetic polymorphism for ALDH2 has been documented in humans. A high percentage (45 to 53 percent) of Japanese, Chinese, Koreans, Taiwanese, and Vietnamese populations are deficient in ALDH2 activity due to a point mutation (Glu$_{487}$ ® Lys$_{487}$). This inactive allelic variant of ALDH2 is known as ALDH2*2, to distinguish it from the active, wild-type enzyme, ALDH2*1. This same population (i.e., Pacific Rim Asians) also has a high incidence of the atypical form of ADH (i.e., ADH2*2), which means that they rapidly convert ethanol to acetaldehyde but only slowly convert acetaldehyde to acetic

acid. (They also have a relatively high prevalence of a deficiency of class IV ADH activity, which impairs gastric metabolism of ethanol.) As a result, many Asian subjects experience a flushing syndrome after consuming alcohol due to a rapid buildup of acetaldehyde, which triggers the dilation of facial blood vessels through the release of catecholamines. Native Americans also experience a flushing syndrome after consuming alcohol, apparently because they express another allelic variant of ALDH2 and/or because acetaldehyde oxidation in blood erythrocytes is impaired in these individuals, possibly due to the expression of a variant form of ALDH1. The functional genetic variants of ADH that rapidly convert ethanol to acetaldehyde (i.e., ADH2*2), and the genetic variants of ALDH that slowly detoxify acetaldehyde both protect against heavy drinking and alcoholism. Inhibition of ALDH by disulfiram (Antabuse) causes an accumulation of acetaldehyde in alcoholics. The nauseating effect of acetaldehyde serves to deter continued ethanol consumption (Goedde and Agarwal, 1992). However, it is important to note that a predisposition toward alcoholism is not simply determined by factors that affect the pharmacokinetics of ethanol and its metabolites. Studies in humans and rodents implicate serotonin 1b receptor, dopamine D2 receptor, tryptophan hydroxylase, and neuropeptide Y as candidate targets of genetic susceptibility in the pharmacodynamic actions of ethanol (Li, 2000). Monoamine oxidase may also be a risk modifier for alcoholism, as discussed under "Monoamine Oxidase," further on.


Genetic deficiencies in other ALDHs impair the metabolism of other aldehydes, which is the underlying basis of certain diseases. For example, ALDH4 deficiency disturbs proline metabolism and causes type II hyperprolinemia, symptoms of which include mental retardation and convulsions. A deficiency of ALDH10, which detoxifies fatty aldehydes, disturbs the metabolism of membrane lipids. This is the underlying basis of Sjörgen-Larson syndrome, symptoms of which include ichthyosis, neurologic problems, and oligophrenia (Yoshida et al., 1998).

The toxicologic consequences of an inherited (i.e., genetic) or acquired (e.g., drug-induced) deficiency of ALDH illustrate that aldehydes are more cytotoxic than the corresponding alcohol. This is especially true of allyl alcohol ($CH_2 = CHCH_2OH$), which is converted by ADH to the highly hepatotoxic aldehyde acrolein ($CH_2 = CHCHO$). The oxidation of ethanol by ADH and ALDH leads to the formation of acetic acid, which is rapidly oxidized to carbon dioxide and water. However, in certain cases, alcohols are converted to toxic carboxylic acids, as in the case of methanol and ethylene glycol, which are converted via aldehyde intermediates to formic acid and oxalic acid, respectively. Formic and oxalic acids are considerably more toxic than acetic acid. For this reason, methanol and ethylene glycol poisoning are commonly treated with ethanol, which competitively inhibits the oxidation of methanol and ethylene glycol by ADH and ALDH. The potent inhibitor of ADH 4-methylpyrazole (fomepizole) is also used to treat methanol and ethylene glycol poisoning.

The reduction of aldehydes and ketones to primary and secondary alcohols by carbonyl reductases has already been discussed (see "Carbonyl Reduction," above). In contrast to ADH and ALDH, carbonyl reductases typically use NADPH as the source of reducing equivalents. Aldehydes can also be oxidized by aldehyde oxidase and xanthine oxidase, which are discussed below under "Molybdenum Hydroxylases."

Dihydrodiol Dehydrogenase In addition to several hydroxysteroid dehydrogenases and aldose reductases, the aldo-keto reductase (AKR) superfamily includes several forms of dihydrodiol dehydrogenase (Penning, 1997). As previously mentioned in the section on carbonyl reductase, dihydrodiol dehydrogenases are monomeric (~34 kDa), cytosolic, NADP(H)-requiring oxidoreductases that oxidize the *trans*-dihydrodiols of various polycyclic aromatic hydrocarbons to the corresponding *orthc*-quinones, as shown in Fig. 6-6 (Burczynski and Penning, 2000). The conversion of such dihydrodiols to *ortho*-quinones has toxicological implications, which were discussed earlier in the section on "Quinone Reduction."

Molybdenum Hydroxylases (Molybdozymes) Two major molybdenum hydroxylases or molybdozymes participate in the biotransformation of xenobiotics: aldehyde oxidase and xanthine dehydrogenase/xanthine oxidase (XD/XO) (Rettie and Fisher, 1999). Sulfite oxidase is third molybdozyme; it is not described here except to say that sulfite oxidase, as the name implies, oxidizes sulfite, an irritating air pollutant, to sulfate, which is relatively innocuous. All three molybdozymes are flavoprotein enzymes consisting of two identical ~150-kDa subunits, each of which contains FAD, molybdenum, in the form of a pterin molybdenum cofactor $\{[Mo^{VI} (=S) (=O)]^{2+}\}$ and two iron-sulfur (Fe_2S_2) centers (known as FeSI and FeSII). The catalytic cycle involves an interaction between the molybdenum center with a reducing substrate, which results in the reduction of the molybdenum cofactor. After this, reducing equivalents are transferred intramolecularly to the flavin and iron-sulfur centers, with reoxidation occurring via the flavin moiety by molecular oxygen (in the case of aldehyde oxidase and xanthine oxidase) or NAD^+ (in the case of xanthine dehydrogenase). During substrate oxidation, aldehyde oxidase and xanthine oxidase are reduced and then reoxidized by molecular oxygen; hence, they function as true oxidases. The oxygen incorporated into the xenobiotic is derived from water rather than oxygen, which distinguishes the oxidases from oxygenases. The overall reaction is as follows:

$$RH \xrightarrow[-2H^+, -2e^-]{H_2O} ROH$$

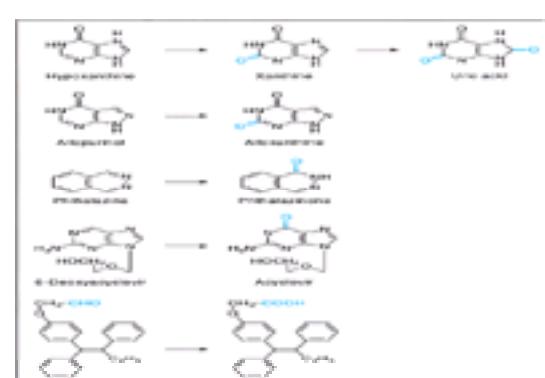
Additional details of the catalytic cycle are described below, under "Xanthine Dehydrogenase–Xanthine Oxidase." Xanthine oxidase and aldehyde oxidase catalyze the oxidation of electron-deficient sp^2-hybridized (i.e., double-bonded) carbon atoms found, more often than not, in nitrogen heterocycles, such as purines, pyrimidines, pteridines, and iminium ions. This contrasts with oxidation by cytochrome P450, which generally catalyzes the oxidation of carbon atoms with a high electron density. For this reason, xenobiotics that are good substrates for molybdozymes tend to be poor substrates for cytochrome P450, and vice versa (Rettie and Fisher, 1999). In nitrogen heterocycles, the carbon atom with lowest electron density is adjacent to the nitrogen atom, for which reason xanthine oxidase and aldehyde oxidase tend to hydroxylate the a-carbon atom to form a hydroximine that rapidly tautomerizes to the corresponding a-aminoketone. As the name implies, aldehyde oxidase can convert certain aldehydes to the corresponding carboxylic acid—a property that is also shared by xanthine oxidase, albeit with lower activity. Certain aromatic aldehydes, such as tamoxifen aldehyde and benzaldehyde, are good substrates for aldehyde oxidase and xanthine oxidase, whereas aliphatic aldehydes tend to be poor substrates. Consequently, aldehyde oxidase and xanthine oxidase contribute negligibly to the metabolism of acetaldehyde. Some reactions catalyzed by aldehyde oxidase and xanthine oxidase are shown in Fig. 6-21. Under certain conditions, both enzymes can also catalyze the reduction of xenobiotics containing one or more of the following functional groups: azo, nitro, *N*-oxide, nitrosamine, hydroxamic acid, oxime, sulfoxide, and epoxide. This is discussed further below, in the section entitled "Aldehyde Oxidase."


Figure 6-21. Examples of reactions catalyzed by the molybdozymes, xanthine oxidase, and aldehyde oxidase.

Xanthine Dehydrogenase–Xanthine Oxidase Xanthine dehydrogenase (XD) and xanthine oxidase (XO) are two forms of the same enzyme that differ in the electron acceptor used in the final step of catalysis. In the case of XD, the final electron acceptor is NAD^+ (dehydrogenase activity), whereas in the case of XO the final electron acceptor is oxygen (oxidase activity). XD is converted to XO by oxidation of cysteine residues (Cys_{993} and Cys_{1326} of the human enzyme) and/or proteolytic cleavage. The conversion of XD to XO by cysteine oxidation appears to be reversible. Under normal physiologic conditions, XD is the predominant form of the enzyme found in vivo. However, during tissue processing, the dehydrogenase form tends to be converted to the oxidase form, hence, most in vitro studies are conducted with XO or a combination of XO and XD. The induction (up-regulation) of XD and/or the conversion of XD to XO in vivo is thought to play an important role in ischemia-reperfusion injury, lipopolysaccharide (LPS)-mediated tissue injury, and alcohol-induced hepatotoxicity. During ischemia, XO levels increase because hypoxia induces XD/XO gene transcription and because XD is converted to XO. During reperfusion, XO contributes to oxidative stress and lipid peroxidation because the oxidase activity of XO involves the reduction of molecular oxygen, which can lead to the formation of reactive oxygen species of the type shown in Fig. 6-13. Similarly, treatment with LPS, a bacterial endotoxin that triggers an acute inflammatory response, increases XO activity both by inducing XD/XD transcription and by converting XD to XO. The associated increased in oxidative stress has been implicated in LPS-induced cytotoxicity. Ethanol facilitates the conversion of XD to XO, and the conversion of ethanol to acetaldehyde provides a substrate and, hence, a source of electrons for the reduction of oxygen.

Typical reactions catalyzed by XD/XO are shown in Fig. 6-21. XD/XO contributes significantly to the first-pass elimination of several purine derivatives (e.g., 6-mercaptopurine and 2,6-dithiopurine) and limits the therapeutic effects of these cancer chemotherapeutic agents. On the other hand, certain prodrugs are activated by xanthine oxidase. For example, the antiviral prodrugs 6-deoxyacyclovir and 2'-fluoroarabino-dideoxypurine, which are relatively well absorbed after oral dosing, are oxidized by xanthine oxidase to their respective active forms, acyclovir and 2'-fluoroarabino-dideoxyinosine, which are otherwise poorly absorbed (see Fig. 6-21). Furthermore, XD/XO has been implicated in the bioactivation of mitomycin C and related antineoplastic agents, although this bioactivation reaction is also catalyzed by DTdiaphorase (see section entitled "Quinone Reduction," below).

XD/XO catalyzes an important physiologic reaction, namely the sequential oxidation of hypoxanthine to xanthine and uric acid, as shown in Fig. 6-21 (Rajagopalan, 1980). By competing with hypoxanthine and xanthine for oxidation by XD/XO, allopurinol inhibits the formation of uric acid, making allopurinol a useful drug in the treatment of gout (a complication of hyperuricemia). Allopurinol can also be used to evaluate the contribution of XD/XO to xenobiotic biotransformation in vivo. Like allopurinol, hydroxylated coumarin derivatives, such as umbelliferone (7-hydroxycoumarin) and esculetin (7,8-dihydroxycoumarin), are potent inhibitors of XD/XO.

Monomethylated xanthines are preferentially oxidized to the corresponding uric acid derivatives by XD/XO. In contrast, dimethylated and trimethylated xanthines, such as theophylline (1,3-dimethylxanthine) and caffeine (1,3,7-trimethylxanthine), are oxidized to the corresponding uric acid derivatives primarily by cytochrome P450. Through two sequential *N*-demethylation reactions, cytochrome P450 converts caffeine to 1-methylxanthine, which is converted by XD/XO to 1-methyluric acid. The urinary ratio of 1-methylxanthine to 1-methyluric acid provides an in vivo marker of XD/XO activity.

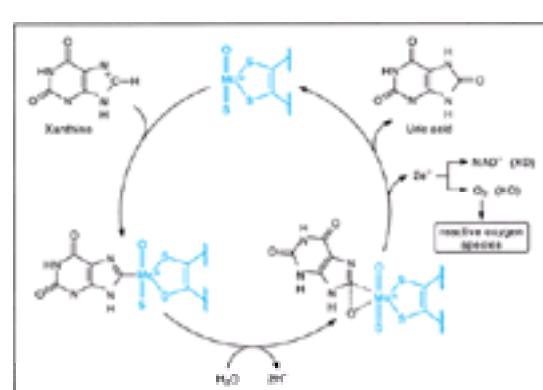
The mechanism of catalysis of xanthine oxidase has been reviewed by Bray et al. (1996). The pteridin molybdenum cofactor $\{[Mo^{VI} (=S) (=O)]^{2+}\}$ contains both a sulfido and oxo ligand. It was once thought that the oxo group was transferred and incorporated into the substrate, such as the C8-position of xanthine. More recent studies suggest that the oxo group does not participate directly in substrate oxidation. Instead, catalysis appears to involve the transient formation of a Mo–C bond between the molybdenum metal center and the C8 position of xanthine, as illustrated in Fig. 6-22. The formation of this Mo-C intermediate is preceded by deprotonation of xanthine (at the C8 position), which reduces the sulfido ligand (Mo = S) to Mo–SH. Deprotonation of xanthine produces a carbanion that reacts with molybdenum to form the Mo–C intermediate, which reacts with water to produce a three-ringed intermediate involving Mo, oxygen and the C8 position of xanthine, which rearranges to yield the hydroxylated substrate (uric acid). The catalytic cycle is completed by the transfer of electrons to NAD $^+$ (dehydrogenase activity) or oxygen (oxidase activity). A similar mechanism of catalysis likely holds true for aldehyde oxidase.


Figure 6-22. Catalytic cycle of xanthine dehydrogenase (XD) and xanthine oxidase (XO).

XD and XO are two forms of the same molybdozyme. During the final step of the catalytic cycle, the enzyme is reoxidized by transferring electrons to NAD $^+$ (in the case of XD) or oxygen (in the case of XO). The same mechanism of catalysis likely applies to aldehyde oxidase, although there is no dehydrogenase form of this molybdozyme.

In humans, XD/XO is a cytosolic enzyme that is widely distributed throughout the body, with the highest levels in heart, brain, liver, skeletal muscle, pancreas, small intestine, colon, and placenta. In humans, XD/XO appears to encoded by a single gene. Although the sequences of two enzymes have been reported in the literature, the first report is now known to describe the sequence of human aldehyde oxidase. A complete deficiency of XD/XO (which may also involve a deficiency of aldehyde oxidase) gives rise to the rare genetic disorder known as xanthinuria.

Aldehyde Oxidase Aldehyde oxidase is the second of two molybdozymes that play an important role in xenobiotic biotransformation, the other being xanthine oxidase (discussed in the preceding section). Whereas xanthine oxidase exists in two forms, a dehydrogenase form (XD) that relays electrons to NAD $^+$ and an oxidase form (XO) that relays electrons to molecular oxygen, aldehyde oxidase exists only in the oxidase form, apparently because it lacks an NAD $^+$ binding site (Terao et al., 1998). Another significant difference between these two molybdozymes is that high levels of xanthine oxidase appear to be widely distributed throughout the body, whereas high levels of aldehyde oxidase are found in the liver, with considerably less activity in other tissues, at least in humans. Aside from these differences, many of the features of xanthine oxidase apply to aldehyde oxidase, including subcellular location (cytosol), enzyme structure, and cofactor composition, mechanism of catalysis, preference for oxidizing carbon atoms adjacent to the nitrogen atoms in nitrogen heterocycles, and its preference for oxidizing aromatic aldehydes over aliphatic aldehydes. Furthermore, aldehyde oxidase also transfers electrons to molecular oxygen, which can generate reactive oxygen species and lead to oxidative stress and lipid peroxidation. Therefore, the pathophysiologic features described for xanthine oxidase may similarly apply to aldehyde oxidase, especially in the case of ethanol-induced liver damage.

As shown in Fig. 6-21, aldehyde oxidase can oxidize a number of substituted pyrroles, pyridines, pyrimidines, purines, pteridines, and iminium ions by a mechanism that is presumably similar to that described for xanthine oxidase in the previous section. Aldehyde oxidase can oxidize aldehydes to their corresponding carboxylic acids, but the enzyme shows a marked preference for aromatic aldehydes (e.g., benzaldehyde, tamoxifen aldehyde). Consequently, aldehyde oxidase contributes negligibly to the oxidation of aliphatic aldehydes, such as acetaldehyde. Rodrigues (1994) found that, in a bank of human liver samples, aldehyde oxidase activity toward N^1-methylnicotinamide varied more than 40-fold, whereas activity toward 6-methylpurine varied less than 3-fold. Although this suggests that human liver cytosol contains two or more forms of aldehyde oxidase, subsequent Southern blot analysis has provided evidence for only a single copy of the aldehyde oxidase gene in humans (Terao et al., 1998). On the other hand, two aldehyde oxidase genes have been identified in mice.

A number of physiologically important aldehydes are substrates for aldehyde oxidase, including homovanillyl aldehyde (formed from dopamine), 5-hydroxy-3-indoleacetaldehyde (formed from serotonin), and retinal, which is converted by aldehyde oxidase to retinoic acid, an important regulator of cell growth, differentiation, and morphogenesis. The catabolism of catecholamines by monoamine oxidase produces dihydromandelaldehyde, which is oxidized by aldehyde oxidase to dihydromandelic acid. Therefore, aldehyde oxidase plays an important role in the catabolism of biogenic amines and catecholamines. In humans, the gene for aldehyde oxidase has been mapped to chromosome 2q22-q33, placing it near a genetic marker that cosegregates with the recessive familial form of amyotrophic lateral sclerosis. In mouse brain, aldehyde oxidase is localized in the choroid plexus and motor neurons, which lends further support to the proposal that aldehyde oxidase is a candidate gene for this particular motor neuron disease (Bendotti et al., 1997). Furthermore, combined deficiency of molybdoproteins, which affects aldehyde oxidase and XD/XO, leads to an impairment in the development of the central nervous system and is accompanied by severe neurologic symptoms.

In general, xenobiotics that are good substrates for aldehyde oxidase are poor substrates for cytochrome P450, and vice versa (Rettie and Fisher, 1999). Naphthalene (with no nitrogen atoms) is oxidized by cytochrome P450 but not by aldehyde oxidase, whereas the opposite is true of pteridine (1,3,5,8-tetraazanaphthalene), which contains four nitrogen atoms. The intermediate structure, quinazolone (1,3-diazanaphthalene) is a substrate for both enzymes. This complementarity in substrate specificity reflects the opposing preference of the two enzymes for oxidizing carbon atoms; cytochrome P450 prefers to oxidize carbon atoms with high electron density, whereas aldehyde oxidase (and XD/XO) prefers to oxidize carbon atoms with low electron density. The substrate specificity of aldehyde oxidase differs among mammalian species, with substrate size being the main differentiating factor. The active site of human aldehyde oxidase accommodates much smaller substrates than rabbit or guinea pig aldehyde oxidase. Substituents on a substrate that increase electronegativity tend to enhance V $_{max}$, whereas substituents that increase lipophilicity tend to increase affinity (decrease K $_m$). Another interesting species difference is that dogs possess little or no aldehyde oxidase activity. However, aldehyde oxidase in human liver has proven to be rather unstable, which complicates an in vitro assessment of species differences in aldehyde oxidase activity (Rodrigues, 1994; Rettie and Fisher, 1999). A further complication is the observation of species differences in the relative roles of aldehyde

oxidase and XD/XO in xenobiotic biotransformation. For example, the 6-oxidation of antiviral deoxyguanine prodrugs is catalyzed exclusively in rats by XD/XO, but by aldehyde oxidase in humans (Rettie and Fisher, 1999).

Aldehyde oxidase is the second of two enzymes involved in the formation of cotinine, a major metabolite of nicotine excreted in the urine of cigarette smokers. The initial step in this reaction is the formation of a double bond (C = N) in the pyrrole ring, which produces nicotine D $^{1',5}$-iminium ion. Like nicotine, several other drugs are oxidized either sequentially or concomitantly by cytochrome P450 and aldehyde oxidase, including quinidine, azapetine, cyclophosphamide, carbazeran, and prolintane. Other drugs that are oxidized by aldehyde oxidase include bromonidine (an a$_2$-adrenoceptor agonist), O^6-benzylguanine (a cancer chemotherapeutic agent), quinine (an antimalarial), pyrazinamide (a tuberculostatic agent), methotrexate (an antineoplastic and immunosuppressive agent) and famciclovir (an antiviral prodrug that is converted by aldehyde oxidase to penciclovir). Several pyrimidine derivatives are oxidized by aldehyde oxidase, including 5-ethyl-2(1 H)-pyrimidone, which is converted by aldehyde oxidase to 5-ethynyluracil. Like Sorivudine, 5-ethynyluracil is a metabolism-dependent (suicide) inactivator of dihydropyrimidine dehydrogenase (see Fig. 6-14).

Menadione, hydralazine, methadone and proadifen are inhibitors of aldehyde oxidase. Menadione is a potent inhibitor of aldehyde oxidase (Ki ~0.1 µM) and can be used together with allopurinol to discriminate between aldehyde oxidase- and xanthine oxidase-catalyzed reactions. Hydralazine has been used to assess the role of aldehyde oxidase in human drug metabolism in vivo. The ability of proadifen to inhibit aldehyde oxidase is noteworthy because this methadone analog, commonly known as SKF 525A, is widely used as a cytochrome P450 inhibitor.

Under certain conditions, aldehyde oxidase and xanthine oxidase can also catalyze the reduction of xenobiotics, including azo-reduction (e.g., 4-dimethylaminoazobenzene), nitro-reduction (e.g., 1-nitropyrene), N-oxide reduction (e.g., S-(-)-nicotine-1'-N-oxide), nitrosamine reduction (e.g., N-nitrosodiphenylamine), hydroxamic acid reduction (e.g., N-hydroxy-2-acetylaminofluorene), sulfoxide reduction [e.g., sulindac (see Fig. 6-12)] and epoxide reduction [e.g., benzo(9a)pyrene 4,5-oxide]. Oximes (C = NOH) can also be reduced by aldehyde oxidase to the corresponding ketimines (C = NH), which may react nonenzymatically with water to produce the corresponding ketone or aldehyde (C = O) and ammonia. An analogous reaction allows aldehyde oxidase to catalyze the reductive ring-opening of Zonisamide and 1,2-benzisoxazole, which results in formation of an oxo-containing metabolite and ammonia (Sugihara et al., 1996). Xenobiotic reduction by aldehyde oxidase requires anaerobic conditions or the presence of a reducing substrate, such as N^1-methylnicotinamide, 2-hydroxypyrimidine or benzaldehyde. These "cosubstrates" reduce the enzyme, which in turn catalyzes azo-reduction, nitro-reduction, etc., by relaying electrons to xenobiotics (rather than molecular oxygen). These unusual requirements make it difficult to assess the degree to which aldehyde oxidase functions as a reductive enzyme in vivo.

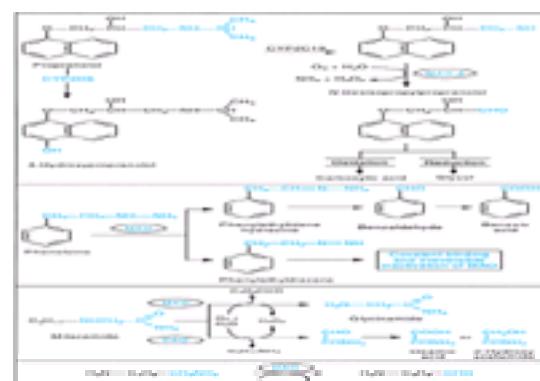
Monoamine Oxidase, Diamine Oxidase, and Polyamine Oxidase Monoamine oxidase (MAO), diamine oxidase (DAO), and polyamine oxidase (PAO) are all involved in the oxidative deamination of primary, secondary, and tertiary amines (Weyler et al., 1992; Benedetti and Dostert, 1994). Substrates for these enzymes include several naturally occurring amines, such as the monoamine serotonin (5-hydroxytryptamine), the diamines putrescine and histamine, and monoacetylated derivatives of the polyamines spermine and spermidine. A number of xenobiotics are substrates for these enzymes, particularly MAO. Oxidative deamination of a primary amine produces ammonia and an aldehyde, whereas oxidative deamination of a secondary amine produces a primary amine and an aldehyde. [The products of the former reaction (i.e., an aldehyde and ammonia) are those produced during the reductive biotransformation of certain oximes by aldehyde oxidase, as described in the preceding section on aldehyde oxidase]. The aldehydes formed by MAO are usually oxidized further by other enzymes to the corresponding carboxylic acids, although in some cases they are reduced to alcohols. Examples of reactions catalyzed by MAO, DAO, and PAO are shown in Fig. 6-23. Monoamine oxidase is located throughout the brain and is present in the liver, kidney, intestine, and blood platelets in the outer membrane of mitochondria. Its substrates include milacemide (Fig. 6-23), a dealkylated metabolite of propranolol (Fig. 6-23), primaquine, haloperidol, doxylamine, b-phenylethylamine, tyramine, catecholamines (dopamine, norepinephrine, epinephrine), tryptophan derivatives (tryptamine, serotonin), and tryptophan analogs known as triptans, which include the antimigraine drugs sumatriptan, zolmitriptan, and rizatriptan.


Figure 6-23. Examples of reactions catalyzed by monoamine oxidase (MAO), diamine oxidase (DAO), and polyamine oxidase (PAO).

Note that pheneizine is a metabolism-dependent (mechanism-based) inhibitor of MAO-A and MAO-B.

There are two forms of monoamine oxidase, called MAO-A and MAO-B. MAO-A preferentially oxidizes serotonin (5-hydroxy- tryptamine), norepinephrine, and the dealkylated metabolite of propranolol. It is preferentially inhibited by clorgyline, whereas MAO-B preferentially oxidizes b-phenylethylamine and benzylamine and is preferentially inhibited by ₋-deprenyl (selegiline). Species differences in the substrate specificity of MAO have been documented. For example, dopamine is oxidized by MAO-B in humans but by MAO-A in rats and by both enzymes in several other mammalian species. Most tissues contain both forms of the enzyme, each encoded by a distinct gene, although some tissues express only one MAO. In humans, for example, only MAO-A is expressed in the placenta, whereas only MAO-B is expressed in blood platelets and lymphocytes. The distribution of MAO in the brain shows little species variation, with the highest concentration of MAO-A in the locus ceruleus and the highest concentration of MAO-B in the raphe nuclei. MAO-A is expressed predominantly in catecholaminergic neurons, whereas MAO-B is expressed largely in serotonergic and histaminergic neurons and glial cells. The distribution of MAO throughout the brain does not always parallel that of its substrates. For example, serotonin is preferentially oxidized by MAO-A, but MAO-A is not found in serotonergic neurons.

MAO-A and -B are encoded by two distinct genes, both localized on the X-chromosome (Xp11.23) and both comprising 15 exons with an identical intron-exon organization, which suggests they are derived from a common ancestral gene (Shih et al., 1999). The amino acid sequence of MAO-A (Mr 59.7 kDa) is 70 percent identical to that of MAO-B (Mr 58.0 kDa). The deletion of both MAO-A and -B gives rise to Norrie disease, an X-linked recessive neurologic disorder characterized by blindness, hearing loss, and mental retardation (Shih et al., 1999). Selective loss of MAO-A (due a point mutation) gives rise to abnormal aggressiveness, whereas alterations in MAO-B have been implicated in Parkinson's disease (discussed later in this section).

The mechanism of catalysis by monoamine oxidase is illustrated below:

$$RCH_2NH_2 + FAD \circledR RCH=NH + FADH_2$$
$$RCH=NH + H_2O \circledR RCHO + NH_3$$
$$FADH_2 + O_2 \circledR FAD + H_2O_2$$

The substrate is oxidized by the enzyme, which itself is reduced (FAD $\circledR$ FADH$_2$). The oxygen incorporated into the substrate is derived from water, not molecular oxygen; hence the enzyme functions as a true oxidase. The catalytic cycle is completed by reoxidation of the reduced enzyme (FADH$_2$ $\circledR$ FAD) by oxygen, which generates hydrogen peroxide (which may be a cause of oxidative stress). The initial step in the catalytic cycle appears to be abstraction of hydrogen from the a-carbon adjacent to the nitrogen atom; hence, the oxidative deamination of xenobiotics by MAO is generally blocked by substitution of the a-carbon. For example, amphetamine and other phenylethylamine derivatives carrying a methyl group on the a-carbon atom are not oxidized well by MAO. (Amphetamines can undergo oxidative deamination, but the reaction is catalyzed by cytochrome P450.) The abstraction of hydrogen from the a-carbon adjacent to the nitrogen atom can occur stereospecifically; therefore, only one enantiomer of an a-substituted compound may be oxidized by MAO. For example, whereas MAO-B catalyzes the oxidative deamination of both R- and S-b-phenylethylamine, only the R-enantiomer is a substrate for MAO-A. The oxidative deamination of the dealkylated metabolite of propranolol is catalyzed stereoselectively by MAO-A, although in this case the preferred substrate is the S-enantiomer (which has the same absolute configuration as

the *R*-enantiomer of b-phenylethylamine) ([Benedetti and Dostert, 1994](#)).

Clorgyline and *r*-deprenyl (selegiline) are metabolism-dependent inhibitors (i.e., mechanism-based or suicide inactivators) of MAO-A and MAO-B, respectively. Both enzymes are irreversibly inhibited by phenelzine, a hydrazine that can be oxidized either by abstraction of hydrogen from the a-carbon atom, which leads to oxidative deamination with formation of benzaldehyde and benzoic acid, or by abstraction of hydrogen from the terminal nitrogen atom, which leads to formation of phenylethyldiazene and covalent modification of the enzyme, as shown in [Fig. 6-23](#).

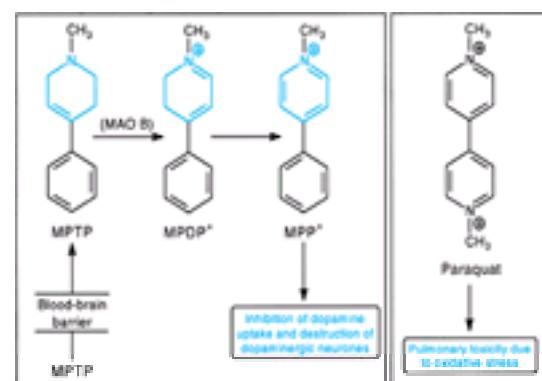
Monoamine oxidase has received considerable attention for its role in the activation of MPTP (1-methyl-4-phenyl-1,2,5,6-tetrahydropyridine) to a neurotoxin that causes symptoms characteristic of Parkinson's disease in humans and monkeys but not rodents ([Gerlach et al., 1991](#)). In 1983, Parkinsonism was observed in young individuals who, in attempting to synthesize and use a narcotic drug related to meperidine (demerol), instead synthesized and self-administered MPTP, which causes selective destruction of dopaminergic neurons in the substantia nigra. MPTP crosses the blood–brain barrier, where is it oxidized by MAO in the astrocytes (a type of glial cell) to 1-methyl-4-phenyl-2,3-dihydropyridine (MPDP$^+$), which in turn autooxidizes to the neurotoxic metabolite, 1-methyl-4-phenylpyridine MPP$^+$, as shown in [Fig. 6-24](#). Because it is transported by the dopamine transporter, MPP$^+$ concentrates in dopaminergic neurons, where it impairs mitochondrial respiration. The neurotoxic effects of MPTP can be blocked with pargyline (an inhibitor of both MAO-A and MAO-B) and by *r*-deprenyl (a selective inhibitor of MAO-B) but not by clorgyline (a selective inhibitor of MAO-A). This suggests that the activation of MPTP to its neurotoxic metabolite is catalyzed predominantly by MAO-B. This interpretation is consistent with the recent finding that MAO-B knockout mice (i.e., transgenic mice that lack MAO-B) do not sustain damage to the dopaminergic terminals of nigrostriatal neurons after MPTP treatment ([Shih et al., 1999](#)).


Figure 6-24. Activation of MPTP (1-methyl-4-phenyl-1,2,5,6-tetrahydropyridine) to the neurotoxic metabolite, MPP $^+$(1-methyl-4-phenylpyridine), by monoamine oxidase B.

The toxic pyridinium metabolite, MPP$^+$, is structurally similar to the herbicide paraquat. MPDP$^+$, 1-methyl-4-phenyl-2,3-dihydropyridine.

Genetic and environmental factors both appear to play important roles in the etiology of Parkinson's disease. Apart from MPTP, parkinsongenic neurotoxins to which humans are exposed have not been identified unequivocally, hence, the environmental factors that cause Parkinson's disease remain to be identified. It is interesting that the bipyridyl herbicide paraquat is similar in structure to the toxic metabolite of MPTP, as shown in [Fig. 6-24](#). Some epidemiologic studies have shown a positive correlation between herbicide exposure and the incidence of Parkinsonism in some but not all rural communities. Haloperidol can also be converted to a potentially neurotoxic pyridinium metabolite ([Subramanyam et al., 1991](#)).

MAO-B may be among the genetic factors that affect susceptibility to Parkinson's disease. MAO-B activity in the human brain increases with aging, perhaps due to a proliferation of glial cells. It has been proposed that increased oxidation of dopamine by MAO-B in the elderly may lead to a loss of dopaminergic neurons in the substantia nigra, which underlies Parkinson's disease. Such damage may be caused by the oxidative stress associated with the oxidative deamination of dopamine by MAO-B. In support of this proposal, it has been found that patients with Parkinson's disease have elevated MAO-B activity in the substantia nigra, and the MAO-B inhibitor *l*-deprenyl (selegiline) delays the progression of symptoms ([Sano et al., 1997](#)). Furthermore, there are allelic variants of MAO-B, some of which (such as allele 1 and allele B4) appear to be associated with an increased risk of developing Parkinson's disease ([Shih et al., 1999](#)). No such association has been found between Parkinson's disease and MAO-A gene polymorphisms. Recently, cigarette smoking, which carries a number of health risks, has been shown nevertheless to provide some protection against Parkinson's disease ([Gorell et al., 1999](#)). Although the mechanism of protection remains to be determined, it is interesting to note that cigarette smokers are known to have decreased levels of MAO-B (and MAO-A) ([Shih et al., 1999](#)), the degree of which is proportional to cigarette usage (i.e., it is dose-related) ([Whitfield et al., 2000](#)).

MAO-A knockout mice have elevated brain levels of serotonin and a distinct behavioral syndrome, including enhanced aggression in adult males. The enhanced aggressive behavior exhibited by MAO-A knockout mice is consistent with the abnormal aggressive behavior in individuals who lack MAO-A activity due to a point mutation in the MAO-A gene ([Shih et al., 1999](#)). Other polymorphisms in the MAO-A gene appear to be risk modifiers for alcoholism among Euro-Americans and Han Chinese ([Shih et al., 1999](#)). MAO-B may also be a factor in alcoholism, inasmuch as alcoholics (especially male type 2 alcoholics) tend to have lower MAO activity in platelets, which contain only MAO-B. However, MAO-B activity is not lower in alcoholics when cigarette smoking status is taken into account, which suggests that MAO-B activity tends to be lower in alcoholics because smoking and alcohol and dependence are strongly associated with each other ([Whitfield et al., 2000](#)).

Although not present in mitochondria, PAO resembles MAO in its cofactor requirement and basic mechanism of action. Both enzymes use oxygen as an electron acceptor, which results in the production of hydrogen peroxide. The MAO inhibitor pargyline also inhibits PAO. The anticonvulsant milacemide is one of the few xenobiotic substrates for PAO, although it is also a substrate for MAO ([Fig. 6-23](#)). By converting milacemide to glycine (via glycinamide), MAO plays an important role in anticonvulsant therapy with milacemide ([Benedetti and Dostert, 1994](#)).

Diamine oxidase is a cytosolic, copper-containing pyridoxal phosphate-dependent enzyme present in liver, kidney, intestine, and placenta. Its preferred substrates include histamine and simple alkyl diamines with a chain length of four (putrescine) or five (cadaverine) carbon atoms. Diamines with carbon chains longer than nine are not substrates for DAO, although they can be oxidized by MAO. DAO or a similar enzyme is present in cardiovascular tissue and appears to be responsible for the cardiotoxic effects of allylamine, which is converted by oxidative deamination to acrolein. Although histamine is a substrate for DAO, there is little or no DAO in brain (nor is there a receptor-mediated uptake system for histamine, in contrast to other neurotransmitters). For this reason, the major pathway of histamine metabolism in the brain is by methylation (see "[Methylation](#)," below).

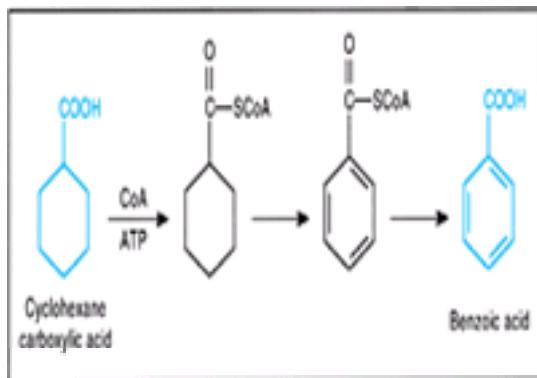
Aromatization The conversion of MPTP to MPP$^+$ ([Fig. 6-24](#)) is an example of a reaction involving the introduction of multiple double bonds to achieve some semblance of aromaticity (in this case, formation of a pyridinium ion). Aromatization of xenobiotics is an unusual reaction, but some examples have been documented. A mitochondrial enzyme in guinea pig and rabbit liver can oxidize certain cyclohexane derivatives to the corresponding aromatic hydrocarbon, as shown in [Fig. 6-25](#) for the aromatization of cyclohexane carboxylic acid (hexahydrobenzoic acid) to benzoic acid. Mitochondria from rat liver are less active, and those from cat, mouse, dog, monkey, and human are completely inactive. The reaction requires magnesium, coenzyme A, oxygen, and ATP. The first step appears to be the formation of hexahydrobenzoyl-CoA, which is then dehydrogenated to the aromatic product. Glycine stimulates the reaction, probably by removing benzoic acid through conjugation to form hippuric acid (a phase II reaction). The conversion of androgens to estrogens involves aromatization of the A-ring of the steroid nucleus. This reaction is catalyzed by CYP19, one of the cytochrome P450 enzymes involved in steroidogenesis.


Figure 6-25. Aromatization of cyclohexane carboxylic acid, a reaction catalyzed by rabbit and guinea pig liver mitochondria.

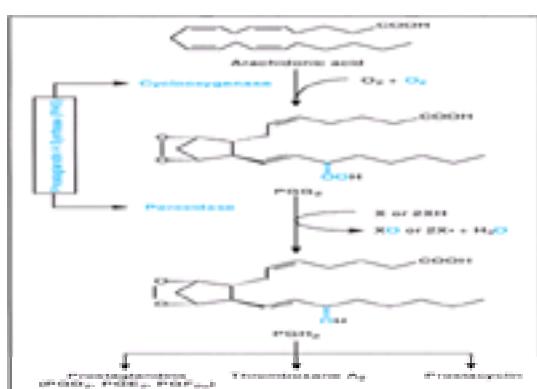
Peroxidase-Dependent Cooxidation The oxidative biotransformation of xenobiotics generally requires the reduced pyridine nucleotide cofactors NADPH and NADH. An exception is xenobiotic biotransformation by peroxidases, which couple the reduction of hydrogen peroxide and lipid hydroperoxides to the oxidation of other substrates—a process known as *cooxidation* (Eling et al., 1990). Several different peroxidases catalyze the biotransformation of xenobiotics, and these enzymes occur in a variety of tissues and cell types. For example, kidney medulla, platelets, vascular endothelial cells, the GI tract, brain, lung, and urinary bladder epithelium contain prostaglandin H synthase (PHS); mammary gland epithelium contains lactoperoxidase; and leukocytes contain myeloperoxidase. PHS is one of the most extensively studied peroxidase involved in the xenobiotic biotransformation. This enzyme possesses two catalytic activities: a *cyclooxygenase* that converts arachidonic acid to the cyclic endoperoxide-hydroperoxide PGG_2 (which involves the addition of two molecules of oxygen to each molecule of arachidonic acid) and a *peroxidase* that converts the hydroperoxide to the corresponding alcohol PGH_2 (which can be accompanied by the oxidation of xenobiotics). The conversion of arachidonic acid to PGH_2, which is subsequently converted to a variety of eicosanoids (prostaglandins, thromboxane, and prostacyclin), is shown in Fig. 6-26. PHS and other peroxidases play an important role in the activation of xenobiotics to toxic or tumorigenic metabolites, particularly in extrahepatic tissues that contain low levels of cytochrome P450 (Eling et al., 1990).


Figure 6-26. Cooxidation of xenobiotics (X) during the conversion of arachidonic acid to PGH $_2$ by prostaglandin H synthase.

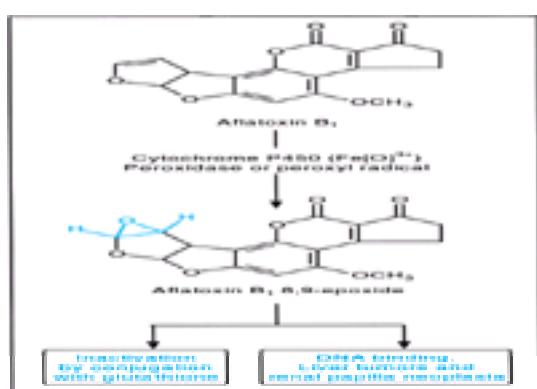
In certain cases, the oxidation of xenobiotics by peroxidases involves direct transfer of the peroxide oxygen to the xenobiotic, as shown in Fig. 6-26 for the conversion of substrate X to product XO. An example of this type of reaction is the PHS-catalyzed epoxidation of benzo[a]pyrene 7,8-dihydrodiol to the corresponding 9,10-epoxide (see Fig. 6-6). Although PHS can catalyze the final step (i.e., 9,10-epoxidation) in the formation of this tumorigenic metabolite of benzo[a]pyrene, it cannot catalyze the initial step (i.e., 7,8-epoxidation), which is catalyzed by cytochrome P450. The 9,10-epoxidation of benzo[a]pyrene 7,8-dihydrodiol can also be catalyzed by 15-lipoxygenase, which is present at high concentrations in human pulmonary epithelial cells, and by peroxyl radicals formed during lipid peroxidation in skin. Cytochrome P450 and peroxyl radicals formed by PHS, lipoxygenase, and/or lipid peroxidation may all play a role in activating benzo[a]pyrene to metabolites that cause lung and skin tumors. These same enzymes can also catalyze the 8,9-epoxidation of aflatoxin B $_1$, which is one of the most potent hepatotumorigens known. Epoxidation by cytochrome P450 is thought to be primarily responsible for the hepatotumorigenic effects of aflatoxin B $_1$. However, aflatoxin B_1 also causes neoplasia of rat renal papilla. This tissue has very low levels of cytochrome P450, but contains relatively high levels of PHS, which is suspected, therefore, of mediating the nephrotumorigenic effects of aflatoxin (Fig. 6-27).


Figure 6-27. Activation of aflatoxin B $_1$ by cytochrome P450, leading to liver tumor formation, and by peroxidases, leading to renal papilla neoplasia.

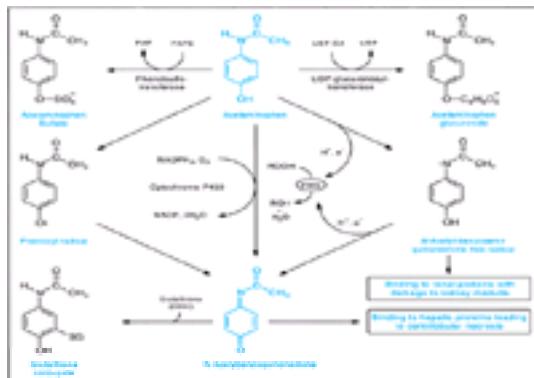
The direct transfer of the peroxide oxygen from a hydroperoxide to a xenobiotic is not the only mechanism of xenobiotic oxidation by peroxidases, nor is it the most common. As shown in Fig. 6-26, xenobiotics that can serve as electron donors, such as amines and phenols, can be oxidized to free radicals during the reduction of a hydroperoxide. In this case, the hydroperoxide is still converted to the corresponding alcohol, but the peroxide oxygen is reduced to water instead of being incorporated into the xenobiotic. For each molecule of hydroperoxide reduced (which is a two-electron process), two molecules of xenobiotic can be oxidized (each by a one-electron process). Important classes of compounds that undergo one-electron oxidation reactions by peroxidase include aromatic amines, phenols, hydroquinones, and polycyclic hydrocarbons. Many of the metabolites produced are reactive electrophiles. For example, polycyclic aromatic hydrocarbons, phenols, and hydroquinones are oxidized to electrophilic quinones. Acetaminophen is similarly converted to a quinoneimine, namely *N*-acetyl-benzoquinoneimine, a cytotoxic electrophile that binds to cellular proteins, as shown in Fig. 6-28. The formation of this toxic metabolite by cytochrome P450 causes centrilobular necrosis of the liver. However, acetaminophen can also damage the kidney medulla, which contains low levels of cytochrome P450 but relatively high levels of PHS; hence, PHS may play a significant role in the nephrotoxicity of acetaminophen. The two-electron oxidation of acetaminophen to *N*-acetyl-benzoquinoneimine by PHS likely involves the formation of a one-electron oxidation product, namely *N*-acetyl-benzosemiquinoneimine radical. Formation of this semiquinoneimine radical by PHS likely contributes to the nephrotoxicity of acetaminophen and related compounds, such as phenacetin and 4-aminophenol.


Figure 6-28. Activation of acetaminophen by cytochrome P450, leading to hepatotoxicity, and by prostaglandin H synthase (PHS), leading to nephrotoxicity.

Conjugation with sulfate, glucuronic acid, or glutathione represent detoxication reactions.

Like the kidney medulla, urinary bladder epithelium also contains low levels of cytochrome P450 but relatively high levels of PHS. Just as PHS in kidney medulla can activate aflatoxin and acetaminophen to nephrotoxic metabolites, so PHS in urinary bladder epithelium can activate certain aromatic amines—such as benzidine, 4-aminobiphenyl, and 2-aminonaphthalene—to DNA-reactive metabolites that cause bladder cancer in certain species, including humans and dogs. PHS can convert aromatic amines to reactive radicals, which can undergo nitrogen–nitrogen or nitrogen–carbon coupling reactions, or they can undergo a second one-electron oxidation to reactive diimines. Binding of these reactive metabolites to DNA is presumed to be the underlying mechanism by which several aromatic amines cause bladder cancer in humans and dogs. In some cases the one-electron oxidation of an amine leads to Λ-dealkylation. For example, PHS catalyzes the Λ-demethylation of aminopyrine, although in vivo this reaction is mainly catalyzed by cytochrome P450. In contrast to cytochrome P450, PHS does not catalyze the N-hydroxylation of aromatic amines.

Many of the aromatic amines known or suspected of causing bladder cancer in humans have been shown to cause bladder tumors in dogs. In rats, however, aromatic amines cause liver tumors by a process that involves Λ-hydroxylation by cytochrome P450, followed by conjugation with acetate or sulfate, as shown in Fig. 6-9. This species difference has complicated an assessment of the role of PHS in aromatic amine-induced bladder cancer, because such experiments must be carried out in dogs. However, another class of compounds, the 5-nitrofurans, such as N-[4-(5-nitro-2-furyl)-2-thiazole]formamide (FANFT) and its deformylated analog 2-amino-4-(5-nitro-2-furyl)thiazole (ANFT), are substrates for PHS and are potent bladder tumorigens in rats. The tumorigenicity of FANFT is thought to involve deformylation to ANFT, which is oxidized to DNA-reactive metabolites by PHS. The ability of FANFT to cause bladder tumors in rats is blocked by the PHS cyclooxygenase inhibitor aspirin, which suggests that PHS plays an important role in the metabolic activation and tumorigenicity of this nitrofuran. Unexpectedly, combined treatment of rats with FANFT and aspirin causes forestomach tumors, which are not observed when either compound is administered alone. This example underscores the complexity of chemically induced tumor formation. A further complication in interpreting this result is the recent finding that there are two forms of cyclooxygenase: COX-1, which is constitutively expressed in several tissues, and COX-2, which is inducible by growth factors and mediators of inflammation. Increased expression of the latter isozyme has been documented in a number of tumors, including human colorectal, gastric, esophageal, pulmonary, and pancreatic carcinomas (Gupta and DuBois, 1998; Molina et al., 1999). Aspirin and other NSAIDs block the formation of colon cancer in experimental animals, and there is epidemiological evidence that chronic NSAID usage decreases the incidence of colorectal cancer in humans (Gupta and DuBois, 1998). The incidence of intestinal neoplasms in Apc[D716] knockout mice is dramatically suppressed by crossing these transgenic animals with COX-2 knockout mice (Oshima et al., 1996). From these few examples it is apparent that cyclooxygenase may play at least two distinct roles in tumor formation—it may convert certain xenobiotics to DNA-reactive metabolites (and thereby *initiate* tumor formation), and it may somehow *promote* subsequent tumor growth, perhaps through formation of growth-promoting eicosanoids.

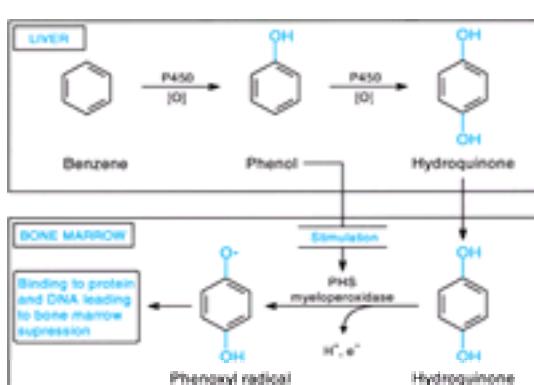
Many phenolic compounds can serve as reducing substrates for PHS peroxidase. The phenoxyl radicals produced by one-electron oxidation reactions can undergo a variety of reactions, including binding to critical nucleophiles, such as protein and DNA; reduction by antioxidants such as glutathione; and self-coupling. The reactions of phenoxyl radicals are analogous to those of the nitrogen-centered free radicals produced during the one-electron oxidation of aromatic amines by PHS. Peroxidases appear to play an important role in the bone marrow suppression produced by chronic exposure to benzene. Liver cytochrome P450 converts benzene to phenol, which in turn is oxidized to hydroquinone, which can be converted to DNA-reactive metabolites by PHS in bone marrow and by myeloperoxidase in bone marrow leukocytes. The myelosuppressive effect of benzene can be blocked by the PHS inhibitor indomethacin, which suggests an important role for peroxidase-dependent activation in the myelotoxicity of benzene. The formation of phenol and hydroquinone in the liver is also important for myelosuppression by benzene. However, such bone marrow suppression cannot be achieved simply by administering phenol or hydroquinone to mice, although it can be achieved by coadministering hydroquinone with phenol. Phenol stimulates the PHS-dependent activation of hydroquinone. Therefore, bone marrow suppression by benzene involves the cytochrome P450– dependent oxidation of benzene to phenol and hydroquinone in the liver, followed by phenol-enhanced peroxidative oxidation of hydroquinone to reactive intermediates that bind to protein and DNA in the bone marrow (Fig. 6-29). It is noteworthy that the cytochrome P450 enzyme responsible for hydroxylating benzene has been identified as CYP2E1 (see section on cytochrome P450, below). Although CYP2E1 was first identified in liver, this same enzyme has been identified in bone marrow, where it can presumably convert benzene to phenol and possibly hydroquinone (Bernauer et al., 2000). The importance of CYP2E1 in the metabolic activation of benzene was recently confirmed by the demonstration that CYP2E1 knockout mice (null mice) are relatively resistant to the myelosuppressive effects of benzene (Gonzalez and Kimura, 1999; Buters et al., 1999).


Figure 6-29. Role of cytochrome P450 and peroxidases in the activation of benzene to myelotoxic metabolites.

ABBREVIATION: PHS, prostaglandin H synthase.

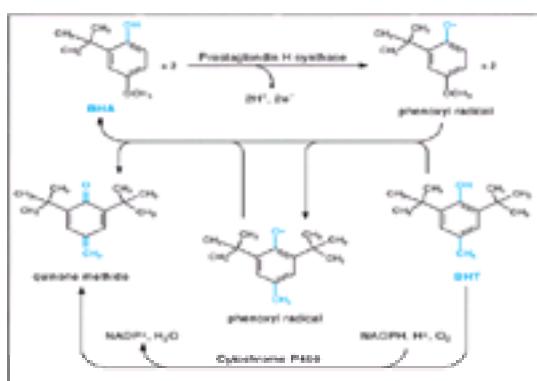
The ability of phenol to enhance the peroxidative metabolism of hydroquinone is analogous to the interaction between the phenolic antioxidants butylated hydroxytoluene (BHT), and butylated hydroxyanisole (BHA). In mice, the pulmonary toxicity of BHT, which is a relatively poor substrate for PHS, is enhanced by BHA, which is a relatively good substrate for PHS. The mechanism by which BHA enhances the pulmonary toxicity of BHT appears to involve the peroxidase-dependent conversion of BHA to a phenoxyl radical that interacts with BHT, converting it to a phenoxyl radical (by one-electron oxidation) or a quinone methide (by two-electron oxidation), as shown in Fig. 6-30. Formation of the toxic quinone methide of BHT can also be catalyzed by cytochrome P450, which is largely responsible for activating BHT in the absence of BHA.


Figure 6-30. Metabolite interaction between the phenolic antioxidants, butylated hydroxytoluene (BHT) and butylated hydroxyanisole (BHA).

Note that activation of BHT to a toxic quinone methide can be catalyzed by cytochrome P450 or, in the presence of BHA, by prostaglandin H synthase.

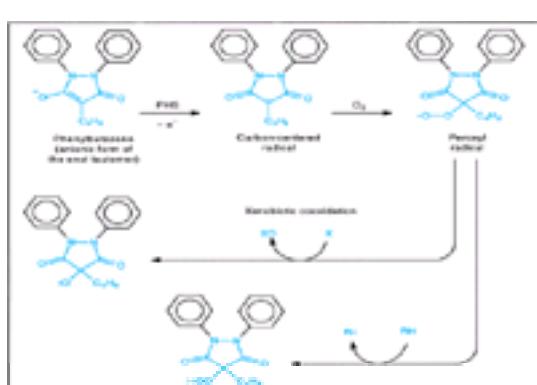
Several reducing substrates—such as phenylbutazone, retinoic acid, 3-methylindole, sulfite, and bisulfite—are oxidized by PHS to carbon- or sulfur-centered free radicals that can trap oxygen to form a peroxyl radical, as shown in Fig. 6-31 for phenylbutazone. The peroxyl radical can oxidize xenobiotics in a peroxidative manner. For example, the peroxyl radical of phenylbutazone can convert benzo[a]pyrene 7,8-dihydrodiol to the corresponding 9,10-epoxide.


Figure 6-31. Oxidation of phenylbutazone by prostaglandin H synthase (PHS) to a carbon-centered radical and peroxyl radical.

Note that the peroxyl radical can oxidize xenobiotics (X) in a peroxidative manner.

PHS is unique among peroxidases because it can both generate hydroperoxides and catalyze peroxidase-dependent reactions, as shown in Fig. 6-26. Xenobiotic biotransformation by PHS is controlled by the availability of arachidonic acid. The biotransformation of xenobiotics by other peroxidases is controlled by the availability of hydroperoxide substrates. Hydrogen peroxide is a normal product of cellular respiration, and lipid peroxides can form during lipid peroxidation. The levels of these peroxides and their availability for peroxidase reactions depends on the efficiency of hydroperoxide scavenging by glutathione peroxidase and catalase.

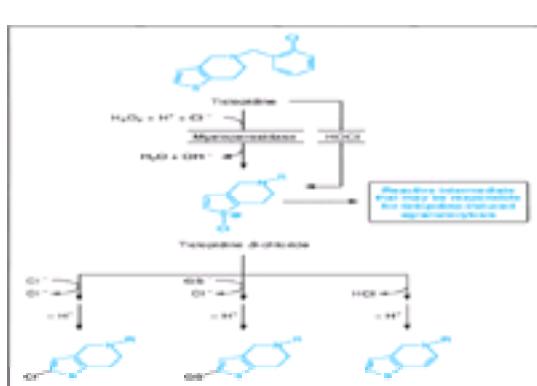
Uetrecht and others have implicated myeloperoxidase in the formation of reactive metabolites of drugs that cause agranulocytosis, including clozapine, aminopyrine, vesnarinone, propylthiouracil, dapsone, sulfonamides, procainamide, amodiaquine, and ticlopidine (references to this large body of work can be found in Liu and Uetrecht, 2000). Activation of these drugs involves their oxidation by HOCl, which is the principal oxidant produced by myeloperoxidase (in the presence of hydrogen peroxide and chloride ion) in activated neutrophils and monocytes. In the case of ticlopidine, myeloperoxidase converts the thiophene ring of this antiplatelet drug to a thiophene-*S*-chloride, a reactive metabolite that rearranges to 2-chloroticlopidine (minor) and dehydro-ticlopidine (major), or reacts with glutathione, as shown in Fig. 6-32. When catalyzed by activated neutrophils, ticlopidine oxidation is inhibited by low concentrations of azide and catalase. When catalyzed by purified myeloperoxidase, ticlopidine oxidation requires hydrogen peroxide and chloride, although all components of this purified system can be replaced with HOCl. It is not known whether drugs that cause agranulocytosis are activated in the bone marrow by neutrophils or their precursors that contain myeloperoxidase or are activated in neutrophils in the general circulation. In the latter case, agranulocytosis would presumably involve an immune response triggered by neoantigens formed in neutrophils by the covalent modification of cellular component by one or more of the reactive metabolites formed by myeloperoxidase.


Figure 6-32. Activation of ticlopidine to a reactive thiophene **S**-*chloride by myeloperoxidase.*

Flavin Monooxygenases Liver, kidney, and lung contain one or more FAD-containing monooxygenases (FMO) that oxidize the nucleophilic nitrogen, sulfur, and phosphorus heteroatom of a variety of xenobiotics (Ziegler, 1993; Lawton et al., 1994; Cashman, 1995; Rettie and Fisher, 1999; Cashman, 1999). The mammalian FMO gene family comprises five enzymes (designated FMO1 to FMO5) that contain about 550 amino acid residues each and are 50 to 58 percent identical in amino acid sequence across species lines. Each FMO enzyme contains a highly conserved glycine-rich region (residues 4 to 32) that binds 1 mole of FAD (noncovalently) near the active site, which is adjacent to a second highly conserved glycine-rich region (residues 186 to 213) that binds NADPH.

Like cytochrome P450, the FMOs are microsomal enzymes that require NADPH and O_2, and many of the reactions catalyzed by FMO can also be catalyzed by cytochrome P450. Several in vitro techniques have been developed to distinguish reactions catalyzed by FMO from those catalyzed by cytochrome P450. In contrast to cytochrome P450, FMO is heat-labile and can be inactivated in the absence of NADPH by warming microsomes to 50°C for 1 min. By comparison, cytochrome P450 can be inactivated with nonionic detergent, such as 1% Emulgen 911, which has a minimal effect on FMO activity. The pH optimum for FMOcatalyzed reactions (pH 8 to 10) tends to be higher than that for most (but not all) P450 reactions (pH 7 to 8). Antibodies raised against purified P450 enzymes can be used not only to establish the role of cytochrome P450 in a microsomal reaction but also to identify which particular P450 enzyme catalyzes the reaction. In contrast, antibodies raised against purified FMO do not inhibit the enzyme. The use of chemical inhibitors to ascertain the relative contribution of FMO and cytochrome P450 to microsomal reactions is often complicated by a lack of specificity. For example, cimetidine and SKF 525A, which are well-recognized cytochrome P450 inhibitors, are both substrates for FMO. Conversely, the FMO inhibitor methimazole is known to inhibit several of the P450 enzymes in human liver microsomes (namely CYP2B6, CYP2C9, and CYP3A4). The situation is further complicated by the observation that the various forms of FMO differ in their thermal stability and sensitivity to

detergents and other chemical modulators (examples of which are described later in this section).

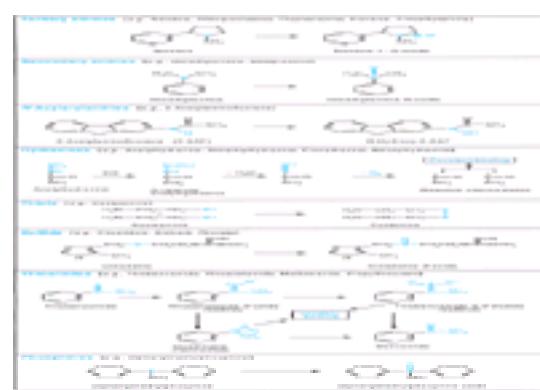
FMO catalyzes the oxidation of nucleophilic tertiary amines to *N*-oxides, secondary amines to hydroxylamines and nitrones, and primary amines to hydroxylamines and oximes. Amphetamine, benzydamine, chlorpromazine, clozapine, guanethidine, imipramine, methamphetamine, olanzapine, and tamoxifen are examples of nitrogen-containing drugs that are *N*-oxygenated by FMO (and by cytochrome P450 in most cases). FMO also oxidizes several sulfur-containing xenobiotics (such as thiols, thioethers, thiones, and thiocarbamates) and phosphines to *S*- and *F*-oxides, respectively. Cimetidine and sulindac sulfide are examples of sulfur-containing drugs that are converted to sulfoxides by FMO. (Fig. 6-12 shows how sulindac is reduced to sulindac sulfide, only to be oxidized by FMO back to the parent drug in what is often called a futile cycle.) Hydrazines, iodides, selenides, and boron-containing compounds are also substrates for FMO. Examples of FMOcatalyzed reactions are shown in Fig. 6-33*A* and Fig. 6-33*B*.


Figure 6-33. A. *Examples of reactions catalyzed by flavin monooxygenases (FMO): Nitrogen-containing xenobiotics.* **B.** *Examples of reactions catalyzed by flavin monooxygenases (FMO): Sulfur- and phophorus-containing xenobiotics.*

In general, the metabolites produced by FMO are the products of a chemical reaction between a xenobiotic and a peracid or peroxide, which is consistent with the mechanism of catalysis of FMO (discussed later in this section). The reactions catalyzed by FMO are generally detoxication reactions, although there are exceptions to this rule, described below (this section). Inasmuch as FMO attacks nucleophilic heteroatoms, it might be assumed that substrates for FMO could be predicted simply from their pKa values (i.e., from a measure of their basicity). Although there is some truth to this—for example, xenobiotics containing an sp ^{3} hybridized nitrogen atom with a pKa of 5 to 10 are generally good substrates for FMO—predictions of substrate specificity based on pKa alone are not very reliable, presumably because steric effects influence access of substrates to the FMO active site (Rettie and Fisher, 1999).

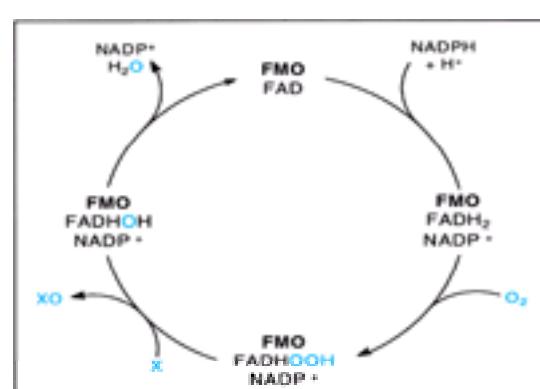
With few exceptions, FMO acts as an electrophilic oxygenating catalyst, which distinguishes it from most other flavoprotein oxidases and monooxygenases (which will be discussed further in the section on cytochrome P450). The mechanism of catalysis by FMO is depicted in Fig. 6-34. After the FAD moiety is reduced to $FADH_2$ by NADPH, the oxidized cofactor, $NADP^+$, remains bound to the enzyme. $FADH_2$ then binds oxygen to produce a peroxide (i.e., the 4a-hydroperoxyflavin of FAD). The peroxide is relatively stable, probably because the active site of FMO comprises nonnucleophilic, lipophilic amino acid residues. During the oxygenation of xenobiotics, the 4a-hydroperoxyflavin is converted to 4ahydroxyflavin with transfer of the flavin peroxide oxygen to the substrate (depicted as X ® XO in Fig. 6-34). From this latter step, it is understandable why the metabolites produced by FMO are generally the products of a chemical reaction between a xenobiotic and a peroxide or peracid. The final step in the catalytic cycle involves dehydration of 4a-hydroxyflavin (which restores FAD to its resting, oxidized state) and release of $NADP^+$. This final step is important because it is rate-limiting, and it occurs after substrate oxygenation. Consequently, this step determines the upper limit of the rate of substrate oxidation. Therefore all good substrates for FMO are converted to products at the same maximum rate (i.e., V $_{max}$ is determined by the final step in the catalytic cycle). Binding of $NADP^+$ to FMO during catalysis is important because it prevents the reduction of oxygen to H_2O_2. In the absence of bound $NADP^+$, FMO would function as an NADPH-oxidase that would consume NADPH and cause oxidative stress through excessive production of H_2O_2.


Figure 6-34. Catalytic cycle of flavin monooxygenase (FMO).

X and XO are the xenobiotic substrate and oxygenated product, respectively. The 4a-hydroperoxyflavin and 4a-hydroxyflavin of FAD are depicted as FADHOOH and FADHOH, respectively.

The oxygenation of substrates by FMO does not lead to inactivation of the enzyme, even though some of the products are strong electrophiles capable of binding covalently to critical and noncritical nucleophiles such as protein and glutathione, respectively. The products of the oxygenation reactions catalyzed by FMO and/or the oxygenation of the same substrates by cytochrome P450 can inactivate cytochrome P450. For example, the FMOdependent *S*-oxygenation of spironolactone thiol (which is formed by the deacetylation of spironolactone by carboxylesterases, as shown in Fig. 6-2) leads to the formation of an electrophilic sulfenic acid (R– SH ® R – SOH), which inactivates cytochrome P450 and binds covalently to other proteins.

In humans, FMO plays an important role in the biotransformation of several drugs (e.g., benzydamine, cimetidine, clozapine, guanethidine, methimazole, olanzapine, sulindac sulfide, tamoxifen and various dimethylaminoalkyl phenothiazine derivatives such as chlorpromazine and imipramine), xenobiotics (e.g., cocaine, methamphetamine, nicotine, tyramine), and endogenous substrates (e.g., trimethylamine, cysteamine). The major flavin monooxygenase in human liver microsomes, FMO3, is predominantly if not solely responsible for converting (*S*)-nicotine to (*S*)-nicotine *N*-1'-oxide (which is one of the reactions shown in Fig. 6-33*A*). The reaction proceeds stereospecifically; only the *trans* isomer is produced by FMO3, and this is the only isomer of (*S*)-nicotine *N*-1'-oxide excreted in the urine of cigarette smokers or individuals wearing a nicotine patch. Therefore, the urinary excretion of *trans*-(*S*)-nicotine *N*-1'-oxide can be used as an in vivo probe of FMO3 activity in humans. FMO3 is also the principal enzyme involved in the *S*-oxygenation of cimetidine, an H_2 antagonist widely used in the treatment of gastric ulcers and other acid-related disorders (this reaction is shown in Fig. 6-33*B*). Cimetidine is stereoselectively sulfoxidated by FMO3 to an 84:16 mixture of (+) and (–) enantiomers, which closely matches the 75:25 enantiomeric composition of cimetidine *S*-oxide in human urine. Therefore, the urinary excretion of cimetidine *S*-oxide, like that of (*S*)-nicotine *N*-1'-oxide, is an in vivo indicator of FMO3 activity in humans.

Sulindac is a sulfoxide that exists in two stereochemical forms (as do most sulfoxides), and a racemic mixture of *R*- and *S*-sulindac is used therapeutically as a NSAID. As shown in Fig. 6-12, the sulfoxide group in sulindac is reduced to the corresponding sulfide (which is achiral), which is then oxidized back to sulindac (a process often described as futile cycling). In human liver, the sulfoxidation of sulindac sulfide is catalyzed by FMO3 with little or no contribution from cytochrome P450. At low substrate concentrations (30 μM), FMO3 converts sulindac sulfide to *R*- and *S*-sulindac in an 87:13 ratio (Hamman et al., 2000). Consequently, although sulindac is administered as a racemic mixture (i.e., a 1:1 mixture of *R*- and *S*-enantiomers), the reduction of this drug to the corresponding sulfide and its preferential

sulfoxidation by FMO3 to *R*-sulindac results in stereoselective enrichment of *R*-sulindac in serum and urine.

In the case of sulindac sulfide, stereoselective sulfoxidation occurs not only with human FMO3 (the major FMO in human liver) but also with porcine FMO1 (the major form expressed in pig liver) and rabbit FMO2 (the major form expressed in rabbit lung) (Hamman et al., 2000). However, this conformity is the exception rather than the rule. For example, in contrast to the stereoselective oxygenation of (*S*)-nicotine and cimetidine by human FMO3 (see above), FMO1 (which is the major FMO expressed in pig, rat, and rabbit liver) converts (*S*)-nicotine to a 1:1 mixture of *cis*- and *trans*-(*S*)-nicotine *N*-1'-oxide and similarly converts cimetidine to a 1:1 mixture of (+) and (–) cimetidine *S*-oxide, respectively. Therefore, statements concerning the role of FMO in the disposition of xenobiotics in humans may not apply to other species, or vice versa.

Several sulfur-containing xenobiotics are oxygenated by FMO to electrophilic reactive intermediates. Such xenobiotics include various thiols, thioamides, 2-mercaptoimidazoles, thiocarbamates, and thiocarbamides. The electrophilic metabolites of these xenobiotics do not inactivate FMO, but they can covalently modify and inactivate neighboring proteins, including cytochrome P450. Some of these same xenobiotics are substrates for cytochrome P450, and their oxygenation to electrophilic metabolites leads to inactivation of cytochrome P450, a process known variously as metabolism-dependent inhibition, mechanism-based inhibition and suicide inactivation. 2-Mercaptoimidazoles undergo sequential *S*-oxygenation reactions by FMO, first to sulfenic acids and then to sulfinic acids (R–SH ® R–SOH ® R–SO$_2$H). These electrophilic metabolites, like the sulfenic acid metabolite produced from spironolactone thiol (see above), bind to critical nucleophiles (such as proteins) or interact with glutathione to form disulfides. The thiocarbamate functionality present in numerous agricultural chemicals is converted by FMO to *S*-oxides (sulfoxides), which can be further oxygenated to sulfones. These reactions involve *S*-oxygenation adjacent to a ketone, which produces strong electrophilic acylating agents, which may be responsible for the toxicity of many thiocarbamate herbicides and fungicides. The hepatotoxicity of thiobenzamide is dependent on *S*-oxidation by FMO and/or cytochrome P450. As shown in Fig. 6-33*B*, the *S*-oxidation of thiobenzamide can lead to the formation of an oxathiirane (a three-membered ring of carbon, sulfur, and oxygen) that can bind covalently to protein (which leads to hepatocellular necrosis) or rearrange to benzamide, a reaction known as *oxidative group transfer*.

Endogenous FMO substrates include cysteamine, which is oxidized to the disulfide, cystamine, and trimethylamine (TMA), which is converted to TMA *N*-oxide (Fig. 6-33*B*). By converting cysteamine to cystamine, FMO may serve to produce a low-molecular-weight disulfide-exchange agent, which may participate in the formation of disulfide bridges during peptide synthesis or the renaturation of proteins. By converting TMA to TMA *N*-oxide, FMO converts a malodorous and volatile dietary product of choline, lecithin, and carnitine catabolism to an inoffensive metabolite. TMA smells of rotting fish, and people who are genetically deficient in FMO3 suffer from trimethylaminuria or *fish-odor syndrome,* which is caused by the excretion of TMA in urine, sweat, and breath (Ayesh and Smith, 1992). The underlying genetic basis of trimethylaminuria is a mutation (Pro$_{153}$ ® Leu$_{153}$) in exon 4 of the FMO3 gene (Dolphin et al., 1997). Although this mutation (and hence trimethylaminuria) occurs only rarely, it is now known to be just one of several mutations that decrease or eliminate FMO3 activity; these other mutations include missense mutations (Met$_{66}$ ® Ile$_{66}$, Met$_{82}$ ® Thr$_{82}$, Arg$_{492}$ ® is Trp$_{492}$) and the nonsense mutation Glu$_{305}$ ® X$_{305}$ (Cashman et al., 2000). As might be expected, trimethylaminuria is associated with an impairment of nicotine *N*-oxidation and other pathways of drug biotransformation that are primarily catalyzed by FMO3 (Rettie and Fisher, 1999).

Humans and other mammals express five different flavin monooxygenases (FMO1, FMO2, FMO3, FMO4, and FMO5) in a species- and tissue-specific manner, as shown in Table 6-3 (adapted from Cashman, 1995). For example, the major FMO expressed in human and mouse liver microsomes is FMO3, whereas FMO1 is the major FMO expressed in rat, rabbit, and pig liver. (Although FMO3 is the major FMO in *adult* human liver, the major FMO in *fetal* human liver is FMO1.) In humans, high levels of FMO1 are expressed in the kidney, and low levels of FMO2 are expressed in the lung. However, lung microsomes from other species, particularly rabbit, mouse, and monkey, contain high levels of FMO2. The uncharacteristically low levels of FMO2 in human lung are due to a mutation (a C ® T transition at codon 472) in the major human FMO2 allele, which results in the synthesis of a nonfunctional, truncated protein (one lacking the last 64–amino acid residues from the C-terminus) (Dolphin et al., 1998). FMO4 appears to be expressed at low levels in the brain of several mammalian species, where it might terminate the action of several centrally active drugs and other xenobiotics.

	FMO1	FMO2	FMO3	FMO4	FMO5
Liver					
Mouse	Low	NP*	High	?	Low
Rat	High	**	Low	?	Low
Rabbit	High	NP	Low	?	Low
Human	Very low	Low	High	Very low	Low
Kidney					
Mouse	High	?	High	?	Low
Rat	High	?	High	High	Low

Human	High	Low	?	?	?
Lung					
Mouse	?	High	Very low	NP	Low
Rat	?	?	?	NP	Low
Rabbit	?	Very high	?	NP	NP
Human	?	Low	?	NP	?

* NP, apparently not present. A question mark indicates that no data are available on the presence of an FMO form. Adapted from Cashman, 1995.

Table 6-3 Putative Tissue Levels of FMO Forms Present in Animals and Humans

The various forms of FMO are distinct gene products with different physical properties and substrate specificities. For example, FMO2 *N*-oxygenates *n*-octylamine, whereas such long aliphatic primary amines are not substrates for FMO1, although they stimulate its activity toward other substrates (in some cases causing a change in stereospecificity). Conversely, short-chain tertiary amines, such as chlorpromazine and imipramine, are substrates for FMO1 but not FMO2. Certain substrates are oxygenated stereospecifically by one FMO enzyme but not another. For example, FMO2 and FMO3 convert (*S*)-nicotine exclusively to *trans*-(*S*)-nicotine *N*-1'-oxide, whereas the *N*-oxides of (*S*)-nicotine produced by FMO1 are a 1:1 mixture of *cis* and *trans* isomers. FMO2 is heat-stable under conditions that completely inactivate FMO1, and FMO2 is resistant to anionic detergents that inactivate FMO1. Low concentrations of bile salts, such as cholate, stimulate FMO activity in rat and mouse liver microsomes but inhibit FMO activity in rabbit and pig liver.

The FMO enzymes expressed in liver microsomes are not under the same regulatory control as cytochrome P450. In rats, the expression of FMO1 is repressed rather than induced by treatment with phenobarbital or 3-methylcholanthrene (although some studies point to of a modest [~3-fold] induction of rat FMO1 by 3-methylcholanthrene). Indole-3-carbinol, which induces the same P450 enzymes as 3-methylcholanthrene, causes a marked decrease in FMO activity in rat liver and intestine. A similar decrease in FMO3 activity occurs in human volunteers following the consumption of large amounts of Brussels sprouts, which contain high levels of indole-3-carbinol and related indoles. The decrease in FMO3 activity may result from direct inhibition of FMO3 by indole-3-carbinol and its derivatives rather than from an actual decrease in enzyme levels (Cashman et al., 1999). The levels of FMO3 and, to a lesser extent, of FMO1 in mouse liver microsomes are sexually differentiated (female > male) due to suppression of expression by testosterone. The opposite is true of FMO1 levels in rat liver microsomes, the expression of which is positively regulated by testosterone and negatively regulated by estradiol. In pregnant rabbits, lung FMO2 is positively regulated by progesterone and/or corticosteroids.

Species differences in the relative expression of FMO and cytochrome P450 appear to determine species differences in the toxicity of the pyrrolizidine alkaloids, senecionine, retrorsine, and monocrotaline. These compounds are detoxified by FMO, which catalyzes the formation of tertiary amine *N*-oxides, but they are activated by cytochrome P450, which oxidizes these alkaloids to pyrroles that generate toxic electrophiles through the loss of substituents on the pyrrolizidine nucleus (details of which appear in the section on cytochrome P450). Rats have a high pyrrole-forming cytochrome P450 activity and a low *N*-oxide forming FMO activity, whereas the opposite is true of guinea pigs. This likely explains why pyrrolizidine alkaloids are highly toxic to rats but not to guinea pigs. Many of the reactions catalyzed by FMO are also catalyzed by cytochrome P450, but differences in the oxidation of pyrrolizidine alkaloids by FMO and cytochrome P450 illustrate that this is not always the case.

Cytochrome P450 Among the phase I biotransforming enzymes, the cytochrome P450 system ranks first in terms of catalytic versatility and the sheer number of xenobiotics it detoxifies or activates to reactive intermediates (Guengerich, 1987; Waterman and Johnson, 1991). The highest concentration of P450 enzymes involved in xenobiotic biotransformation is found in liver endoplasmic reticulum (microsomes), but P450 enzymes are present in virtually all tissues. The liver microsomal P450 enzymes play a very important role in determining the intensity and duration of action of drugs, and they also play a key role in the detoxication of xenobiotics. P450 enzymes in liver and extrahepatic tissues play important roles in the activation of xenobiotics to toxic and/or tumorigenic metabolites. Microsomal and mitochondrial P450 enzymes play key roles in the biosynthesis or catabolism of steroid hormones, bile acids, fat-soluble vitamins, fatty acids, and eicosanoids,

which underscores the catalytic versatility of cytochrome P450.

All P450 enzymes are heme-containing proteins. The heme iron in cytochrome P450 is usually in the ferric (Fe^{2+}) state. When reduced to the ferrous (Fe^{2+}) state, cytochrome P450 can bind ligands such as O_2 and carbon monoxide (CO). The complex between ferrous cytochrome P450 and CO absorbs light maximally at 450 nm, from which cytochrome P450 derives its name. The absorbance maximum of the CO complex differs slightly among different P450 enzymes and ranges from 447 to 452 nm. All other hemoproteins that bind CO absorb light maximally at ~420 nm. The unusual absorbance maximum of cytochrome P450 is due to an unusual fifth ligand to the heme (a cysteine-thiolate). The amino acid sequence around the cysteine residue that forms the thiolate bond with the heme moiety is highly conserved in all P450 enzymes (Negishi et al., 1996). When this thiolate bond is disrupted, cytochrome P450 is converted to a catalytically inactive form called cytochrome P420. By competing with oxygen, CO inhibits cytochrome P450. The inhibitory effect of carbon monoxide can be reversed by irradiation with light at 450 nm, which photodissociates the cytochrome P450–CO complex.

These properties of cytochrome P450 are of historical importance. The observation that treatment of rats with certain chemicals, such as 3-methylcholanthrene, causes a shift in the peak absorbance of cytochrome P450 (from 450 to 448 nm) provided some of the earliest evidence for the existence of multiple forms of cytochrome P450 in liver microsomes. The conversion of cytochrome P450 to cytochrome P420 by detergents and phospholipases helped to establish the hemoprotein nature of cytochrome P450. The inhibition of cytochrome P450 by CO and the reversal of this inhibition by photodissociation of the cytochrome P450–CO complex established cytochrome P450 as the microsomal and mitochondrial enzyme involved in drug biotransformation and steroid biosynthesis (Omura, 1999).

The basic reaction catalyzed by cytochrome P450 is monooxygenation in which one atom of oxygen is incorporated into a substrate, designated RH, and the other is reduced to water with reducing equivalents derived from NADPH, as follows:

Substrate (RH) + O_2 + NADPH + H^+ ®
Product (ROH) + H_2O + NADP$^+$

Although cytochrome P450 functions as a monooxygenase, the products are not limited to alcohols and phenols due to rearrangement reactions (Guengerich, 1991). During catalysis, cytochrome P450 binds directly to the substrate and molecular oxygen, but it does not interact directly with NADPH or NADH. The mechanism by which cytochrome P450 receives electrons from NAD(P)H depends on the subcellular localization of cytochrome P450. In the endoplasmic reticulum, which is where most of the P450 enzymes involved in xenobiotic biotransformation are localized, electrons are relayed from NADPH to cytochrome P450 via a flavoprotein called NADPH–cytochrome P450 reductase. Within this flavoprotein, electrons are transferred from NADPH to cytochrome P450 via FMN and FAD. In mitochondria, which house many of the P450 enzymes involved in steroid hormone biosynthesis and vitamin D metabolism, electrons are transferred from NAD(P)H to cytochrome P450 via two proteins; an iron-sulfur protein called ferredoxin and an FMN-containing flavoprotein called ferredoxin reductase (these proteins are also known as adrenodoxin and adrenodoxin reductase). In bacteria such as *Pseudomonas putida,* electron flow is similar to that in mitochondria (NADH ® flavoprotein ® putidaredoxin ® P450).

There are some notable exceptions to the general rule that cytochrome P450 requires a second enzyme (i.e., a flavoprotein) for catalytic activity. One exception applies to two P450 enzymes involved in the conversion of arachidonic acid to eicosanoids, namely thromboxane synthase and prostacyclin synthase. These two P450 enzymes convert the endoperoxide PGH_2 to thromboxane (TXA_2) and prostacyclin (PGI_2) in platelets and the endothelial lining of blood vessels, respectively. In both cases, cytochrome P450 functions as an isomerase and catalyzes a rearrangement of the oxygen atoms introduced into arachidonic acid by cyclooxygenase. The plant cytochrome P450, allene oxide synthase, and certain invertebrate P450 enzymes also catalyze the rearrangement of oxidized chemicals. The second exception are two cytochrome P450 enzymes expressed in the bacterium *Bacillus megaterium,* which are known as BM-1 and BM-3 (or CYP106 and CYP102, respectively). These P450 enzymes are considerably larger than most P450 enzymes because they are linked directly to a flavoprotein. In other words, the P450 moiety and flavoprotein are expressed in a single protein encoded by a single gene. Through recombinant DNA techniques, mammalian P450 enzymes have been linked directly to NADPH–cytochrome P450 reductase and, like the bacterial enzyme, the resultant fusion protein is catalytically active. Most mammalian P450 enzymes are not synthesized as a single enzyme containing both the hemoprotein and flavoprotein moieties, but this arrangement is found in nitric oxide (NO) synthase. In addition to its atypical structure, the P450 enzyme expressed in *B. megaterium,* CYP102, is unusual for another reason: It is inducible by phenobarbital, as are some of the mammalian P450 enzymes (see "Induction of Cytochrome P450," below).

Phospholipids and cytochrome b_5 also play an important role in cytochrome P450 reactions. Cytochrome P450 and NADPH– cytochrome P450 reductase are embedded in the phospholipid bilayer of the endoplasmic reticulum, which facilitates their interaction. When the *C*-terminal region that anchors NADPH– cytochrome P450 reductase in the membrane is cleaved with trypsin, the truncated flavoprotein can no longer support cytochrome P450 reactions, although it is still capable of reducing cytochrome *c* and other soluble electron acceptors. The ability of phospholipids to facilitate the interaction between NADPH– cytochrome P450 reductase and cytochrome P450 does not appear to depend on the nature of the polar head group (serine, choline, inositol, ethanolamine), although certain P450 enzymes (those in the CYP3A subfamily) have a requirement for phospholipids containing unsaturated fatty acids.

Cytochrome b_5 can donate the second of two electrons required by cytochrome P450. Although this would be expected simply to increase the rate of catalysis of cytochrome P450, cytochrome b_5 can also increase the apparent affinity with which certain P450 enzymes bind their substrates; hence, cytochrome b_5 can increase V_{max} and/or decrease the apparent K_m of cytochrome P450 reactions. In both cases, cytochrome b_5 increases V_{max}/K_m, which is a measure of catalytic efficiency and intrinsic clearance. Liver microsomes contain numerous forms of cytochrome P450 but only a single form of NADPH–cytochrome P450 reductase and cytochrome b_5. For each molecule of NADPH–cytochrome P450 reductase in rat liver microsomes, there are 5 to 10 molecules of cytochrome b_5 and 10 to 20 molecules of cytochrome P450. NADPH–cytochrome P450 reductase will reduce electron acceptors other than cytochrome P450, which enables this enzyme to be measured based on its ability to reduce cytochrome-c (which is why NADPH–cytochrome P450 reductase is often called NADPH–cytochrome-c reductase). NADPH–cytochrome P450 reductase can transfer electrons much faster than cytochrome P450 can use them, which more than likely accounts for the low ratio of NADPH–cytochrome P450 reductase to cytochrome P450 in liver microsomes. Low levels of NADPH–cytochrome P450 reductase may also be a safeguard to protect cells from the often deleterious one-electron reduction reactions catalyzed by this flavoprotein (see Fig. 6-13).

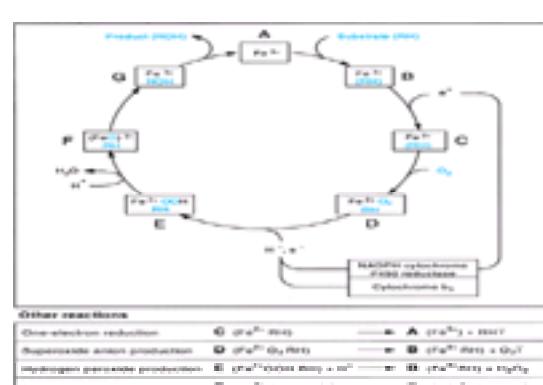
The catalytic cycle of cytochrome P450 is shown in Fig. 6-35 (Dawson, 1988; Schlichting et al., 2000). The first part of the cycle involves the activation of oxygen, and the final part involves substrate oxidation, which entails the abstraction of a hydrogen atom or an electron from the substrate followed by oxygen rebound (radical recombination). Following the binding of substrate to the P450 enzyme, the heme iron is reduced from the ferric (Fe^{3+}) to the ferrous (Fe^{2+}) state by the addition of a single electron from NADPH–cytochrome P450 reductase. The reduction of cytochrome P450 is facilitated by substrate binding, possibly because binding of the substrate in the vicinity of the heme moiety converts the heme iron from a low-spin to a high-spin state. Oxygen binds to cytochrome P450 in its ferrous state, and the $Fe^{2+}O_2$ complex is converted to an $Fe^{2+}OOH$ complex by the addition of a proton (H^+) and a second electron, which is derived from NADPH–cytochrome P450 reductase or cytochrome b_5. Introduction of a second proton cleaves the $Fe^{2+}OOH$ complex to produce water and an $(FeO)^{3+}$ complex, which transfers its oxygen atom to the substrate. Release of the oxidized substrate returns cytochrome P450 to its initial state. If the catalytic cycle is interrupted (uncoupled) following introduction of the first electron, oxygen is released as superoxide anion (O_2^-). If the cycle is interrupted after introduction of the second electron, oxygen is released as hydrogen peroxide (H_2O_2). The final oxyge nating species, $(FeO)^{3+}$, can be generated directly by the transfer of an oxygen atom from hydrogen peroxide and certain other hydroperoxides, a process known as the peroxide shunt. For this reason certain P450 reactions can be supported by hydroperoxides in the absence of NADPH–cytochrome P450 reductase and NADPH.


Figure 6-35. Catalytic cycle of cytochrome P450.

Cytochrome P450 catalyzes several types of oxidation reactions, including:

1. Hydroxylation of an aliphatic or aromatic carbon
2. Epoxidation of a double bond
3. Heteroatom (*S*-, *N*-, and *I*-) oxygenation and *N*-hydroxylation
4. Heteroatom (*O*-, *S*-, *N*- and *Si*-) dealkylation
5. Oxidative group transfer
6. Cleavage of esters
7. Dehydrogenation

In the first three cases, oxygen from the $(FeO)^{3+}$ complex is incorporated into the substrate, which otherwise remains intact. In the fourth case, oxygenation of the substrate is followed by a rearrangement reaction leading to cleavage of an amine (*N*-dealkylation) or an ether (*O*- and *S*-dealkylation). Oxygen from the $(FeO)^{3+}$ complex is incorporated into the alkyl-leaving group, producing an aldehyde or ketone. In the fifth case, oxygenation of the substrate is followed by a rearrangement reaction leading to loss of a heteroatom (oxidative group transfer). The sixth case, the cleavage of esters, resembles heteroatom dealkylation in that the functional group is cleaved with incorporation of oxygen from the $(FeO)^{3+}$ complex into the leaving group, producing an aldehyde. In the seventh case, two hydrogens are abstracted from the substrate with the formation of a double bond (C=C, C = O, or C = N), with the reduction of oxygen from the $(FeO)^{3+}$ complex to water. It should be noted that this long list of reactions does not encompass all of the reactions catalyzed by cytochrome P450. As noted above (this section), cytochrome P450 can catalyze reductive reactions (such as azo reduction, nitro reduction, and reductive dehalogenation) and isomerization reactions (such as the conversion of PGH_2 to thromboxane and prostacyclin). During the synthesis of steroid hormones, cytochrome P450 catalyzes the cleavage of carbon–carbon bonds, which occurs during the conversion of cholesterol to pregnenolone by side-chain cleavage enzyme (also known as P450$_{scc}$ and CYP11A1) and the aromatization of a substituted cyclohexane, which occurs during the conversion of androgens to estrogens by aromatase (also known as P450$_{aro}$ and CYP19).

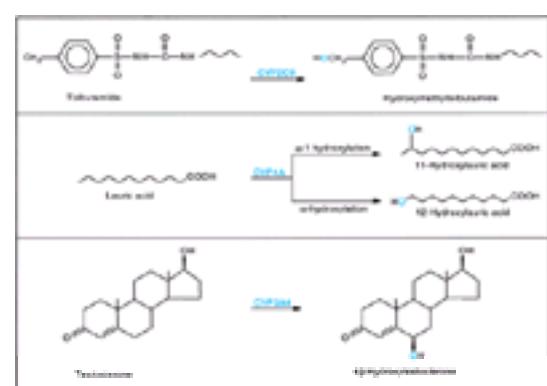
Examples of aliphatic and aromatic hydroxylation reactions catalyzed by cytochrome P450 are shown in Fig. 6-36 and Fig. 6-37, respectively. The hydroxylation of aromatic hydrocarbons may proceed via an oxirane intermediate (i.e., an arene oxide) that isomerizes to the corresponding phenol. Alternatively aromatic hydroxylation can proceed by a mechanism known as direct insertion. The *ortho*-hydroxylation and *para*-hydroxylation of chlorobenzene proceed via 2,3- and 3,4-epoxidation, whereas *meta*-hydroxylation proceeds by direct insertion, as shown in Fig. 6-38. When aromatic hydroxylation involves direct insertion, hydrogen abstraction (i.e., cleavage of the C–H bond) is the rate-limiting step, so that substitution of hydrogen with deuterium or tritium considerably slows the hydroxylation reaction. This *isotope effect* is less marked when aromatic hydroxylation proceeds via an arene oxide intermediate. Arene oxides are electrophilic and therefore potentially toxic metabolites that are detoxified by such enzymes as epoxide hydrolase (see Fig. 6-6) and glutathione *S*-transferase. Depending on the ring substituents, the rearrangement of arene oxides to the corresponding phenol can lead to an intramolecular migration of a substituent (such as hydrogen or a halogen) from one carbon to the next. This intramolecular migration occurs at the site of oxidation and is known as the NIH shift—so named for its discovery at the National Institutes of Health.


Figure 6-36. Examples of reactions catalyzed by cytochrome P450: Hydroxylation of aliphatic carbon.
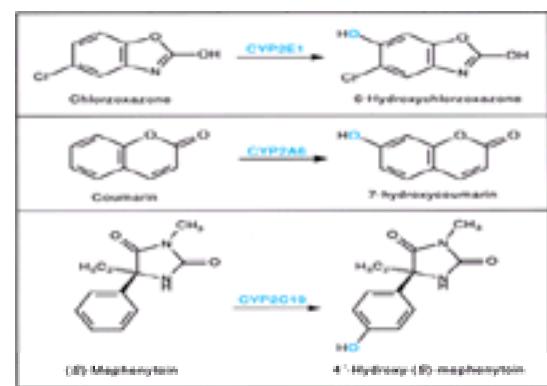

Figure 6-37. Examples of reactions catalyzed by cytochrome P450: Hydroxylation of aromatic carbon.
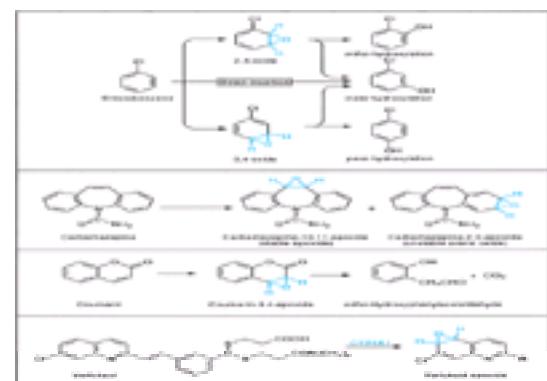

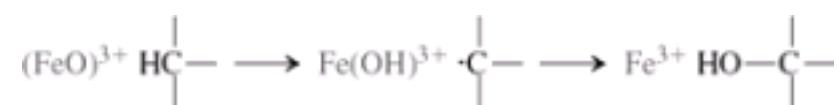

Figure 6-38. Examples of reactions catalyzed by cytochrome P450: Epoxidation.

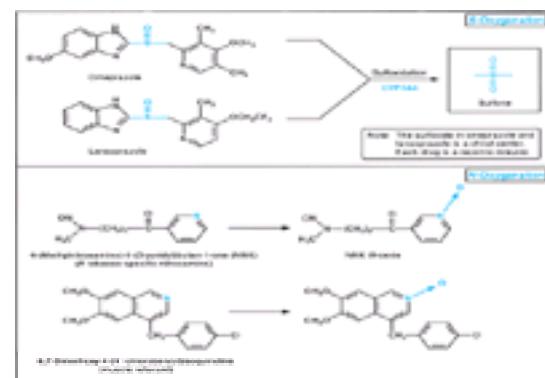
Aliphatic hydroxylation involves insertion of oxygen into a C–H bond. As in the case of aromatic hydroxylation by direct insertion, cleavage of the C–H bond by

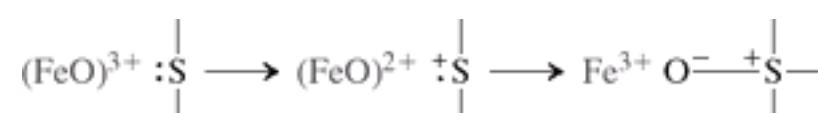
hydrogen abstraction is the rate-limiting step, as shown below:

$$(FeO)^{3+} \; HC{-} \longrightarrow Fe(OH)^{3+} \; \cdot C{-} \longrightarrow Fe^{3+} \; HO{-}C{-}$$

In the case of simple, straight-chain hydrocarbons, such as n-hexane, aliphatic hydroxylation occurs at both the terminal methyl groups and the internal methylene groups. In the case of fatty acids and their derivatives (i.e., eicosanoids such as prostaglandins and leukotrienes), aliphatic hydroxylation occurs at the w-carbon (terminal methyl group) and the w-carbon (penultimate carbon), as shown for lauric acid in Fig. 6-36. Most P450 enzymes preferentially catalyze the w-1 hydroxylation of fatty acids and their derivatives, but one group of P450 enzymes (those encoded by the *CYP4A* genes) preferentially catalyzes the w-hydroxylation of fatty acids, which can be further oxidized to dicarboxylic acids.

Xenobiotics containing a carbon–carbon double bond (i.e., alkenes) can be epoxidated (i.e., converted to an oxirane) in an analogous manner to the oxidation of aromatic compounds to arene oxides. Just as arene oxides can isomerize to phenols, so aliphatic epoxides can isomerize to the corresponding ene-ol, the formation of which may involve an intramolecular migration (NIH shift) of a substituent at the site of oxidation. Like arene oxides, aliphatic epoxides are also potentially toxic metabolites that are inactivated by other xenobiotic-metabolizing enzymes. Oxidation of some aliphatic alkenes and alkynes produces metabolites that are sufficiently reactive to bind covalently to the heme moiety of cytochrome P450, a process variously known as metabolism-dependent inhibition, suicide inactivation, or mechanism-based inhibition. As previously discussed in the section on epoxide hydrolase, not all epoxides are highly reactive electrophiles. Although the 3,4-epoxidation of coumarin produces an hepatotoxic metabolite, the 10,11-epoxidation of carbamazepine produces a stable, relatively nontoxic metabolite (Fig. 6-38).

In the presence of NADPH and O_2, liver microsomes catalyze the oxygenation of several *S*-containing xenobiotics, including chlorpromazine, cimetidine, lansoprazole, and omeprazole. Sulfur-containing xenobiotics can potentially undergo two consecutive sulfoxidation reactions: one that converts the sulfide (S) to the sulfoxide (SO), which occurs during the sulfoxidation of chlorpromazine and cimetidine, and one that converts the sulfoxide (SO) to the sulfone (SO$_2$), which occurs during the sulfoxidation of omeprazole and lansoprazole, as shown in Fig. 6-39. Albendazole is converted first to a sulfoxide and then to a sulfone. All of these reactions are catalyzed by FMO (as shown in Fig. 6-33*B*) and/or cytochrome P450 (as shown in Fig. 6-39). Both enzymes are efficient catalysts of *S*-oxygenation, and both contribute significantly to the sulfoxidation of various xenobiotics. For example, the sulfoxidation of omeprazole, lansoprazole, chlorpromazine, and phenothiazine by human liver microsomes is primarily catalyzed by a P450 enzyme (namely CYP3A4), whereas the sulfoxidation of cimetidine and sulindac sulfide is primarily catalyzed by a flavin monooxygenase (namely FMO3). In the presence of NADPH and O$_2$, liver microsomes catalyze the oxygenation of several *N*-containing xenobiotics—including chlorpromazine, doxylamine, oflaxacin, morphine, nicotine, MPTP, methapyrilene, methaqualone, metronidazole, pargyline, pyridine, senecionine, strychnine, trimethylamine, trimipramine, and verapamil—all of which are converted to stable *N*-oxides. Whereas *S*-oxygenation might be catalyzed by both cytochrome P450 and FMO, *N*-oxygenation is more likely to be catalyzed by just one of these enzymes. For example, the conversion of (*S*)-nicotine to *trans* (*S*)-nicotine *N*-1'-oxide by human liver microsomes is catalyzed by FMO3, with little or no contribution from cytochrome P450. Conversely, the conversion of pyridine to its *N*-oxide is primarily catalyzed by cytochrome P450. Both enzymes can participate in the *N*-oxygenation of certain xenobiotics. For example, the *N*-oxygenation of chlorpromazine is catalyzed by FMO3 and, to a lesser extent, by two P450 enzymes (CYP2D6 and CYP1A2). In general, FMO catalyzes the *N*-oxygenation of xenobiotics containing electron-deficient nitrogen atoms, whereas cytochrome P450 catalyzes the *N*-oxygenation of xenobiotics containing electron-rich nitrogen atoms. Therefore, substrates primarily *N*-oxygenated by cytochrome P450 are somewhat limited to pyridine-containing xenobiotics, such as the tobacco-specific nitrosamine NNK and the antihistamine temelastine, and to xenobiotics containing a quinoline or isoquinoline group, such as the muscle relaxant 6,7-dimethoxy-4-(4'-chlorobenzyl)isoquinoline. The initial step in heteroatom oxygenation by cytochrome P450 involves the abstraction of an electron from the heteroatom (*N*, *S* or *I*) by the (FeO)$^{3+}$ complex, as shown below for sulfoxidation.




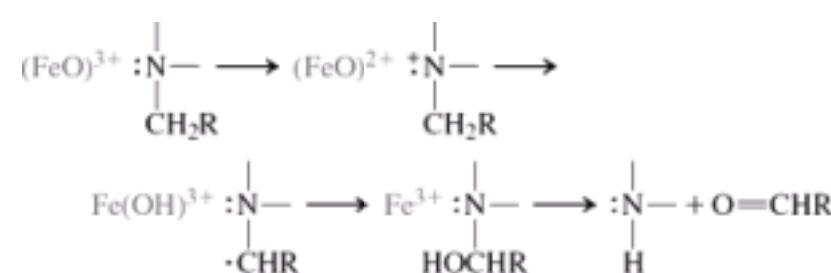


Figure 6-39. Examples of reactions catalyzed by cytochrome P450: Heteroatom oxygenation.

$$(FeO)^{3+} \; :S \longrightarrow (FeO)^{2+} \; \overset{\cdot}{:}S \longrightarrow Fe^{3+} \; O^{-}\overset{+}{=}S{-}$$

Abstraction of an electron from *N*, *O*, or *S* by the (FeO)$^{3+}$ complex is also the initial step in heteroatom dealkylation, but in this case abstraction of the electron from the heteroatom is quickly followed by abstraction of a proton (H$^+$) from the a-carbon atom (the carbon atom attached to the heteroatom). Oxygen rebound leads to hydroxylation of the a-carbon, which then rearranges to form the corresponding aldehyde or ketone with cleavage of the a-carbon from the heteroatom, as shown below for the *N*-dealkylation of an *N*-alkylamine:

$$(FeO)^{3+} \; :N{-} \longrightarrow (FeO)^{2+} \; \overset{\cdot}{:}N{-} \longrightarrow$$
$$\underset{CH_2R}{} \qquad \underset{CH_2R}{}$$
$$Fe(OH)^{3+} \; :N{-} \longrightarrow Fe^{3+} \; :N{-} \longrightarrow :N{-} + O{=}CHR$$
$$\underset{\cdot CHR}{} \qquad \underset{HOCHR}{} \qquad \underset{H}{}$$

Although the initial steps in heteroatom oxygenation and heteroatom dealkylation are the same (abstraction of an electron from the heteroatom to produce a radical cation), the nature of the radical cation determines whether the xenobiotic will undergo oxygenation or dealkylation. The sulfur radical cations of numerous xenobiotics are sufficiently stable to allow oxygen rebound with the heteroatom itself, which results in *S*-oxygenation. However, this is not generally the case with nitrogen radical cations, which undergo rapid deprotonation at the a-carbon, which in turn results in *N*-dealkylation. In general, therefore, cytochrome P450 catalyzes the *N*-dealkylation, not the *N*-oxygenation, of amines. *N*-Oxygenation by cytochrome P450 can occur if the nitrogen radical cation is stabilized by a nearby electron-donating group (making the nitrogen electron rich) or if a-protons are either absent (e.g., aromatic amines) or inaccessible (e.g., quinidine). In the case of primary and secondary aromatic amines, *N*-oxygenation by cytochrome P450 usually results in the formation of hydroxylamines, as illustrated in Fig. 6-9. *N*-Hydroxylation of aromatic amines with subsequent conjugation with sulfate or acetate is one mechanism by which tumorigenic aromatic amines, such as 2-acetylaminofluorene, are converted to electrophilic reactive intermediates that bind covalently to DNA (Anders, 1985).

In contrast to cytochrome P450, which oxidizes nitrogen-containing xenobiotics by a radicaloid mechanism involving an initial one-electron oxidation of the heteroatom, the flavin monooxygenases oxidize nitrogen-containing xenobiotics by a heterolytic mechanism involving a two-electron oxidation by the 4ahydroperoxide of FAD (see Fig. 6-34). These different mechanisms explain why the *N*-oxygenation of xenobiotics by cytochrome P450 generally results in *N*-dealkylation, whereas *N*-oxygenation by the flavin monooxygenases results in *N*-oxide formation. In contrast to cytochrome P450, the flavin monooxygenases do not catalyze *N*-, *O*-, or *S*-dealkylation reactions.

Numerous xenobiotics are *N*-, *O*-, or *S*-dealkylated by cytochrome P450, and some examples of these heteroatom dealkylation reactions are shown in Fig. 6-40. Cytochrome P450 has been shown to catalyze the demethylation of octamethylcyclotetrasiloxane, which is an example of *Si*-demethylation, as shown in Fig. 6-40.

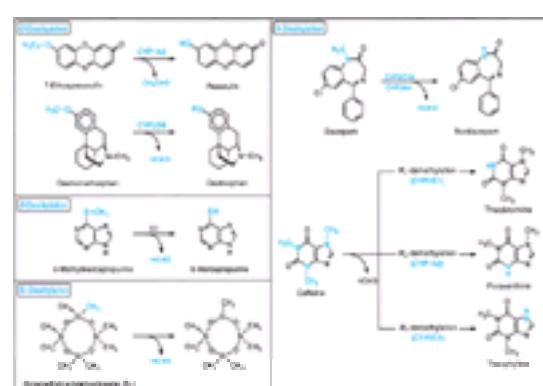
The dealkylation of xenobiotics containing an *N*-, *O*-, or *S*-methyl group results in the formation of formaldehyde, which can easily be measured by a simple colorimetric assay to monitor the demethylation of substrates in vitro. The expiration of ^{13}C- or ^{14}C-labeled carbon dioxide following the demethylation of drugs containing a ^{13}C- or ^{14}C-labeled methyl group has been used to probe cytochrome P450 activity in vivo (Watkins, 1994). The activity of the human P450 enzymes involved in the *N*-demethylation of aminopyrine, erythromycin, and caffeine can be assessed by this technique. Although caffeine has three *N*-methyl groups, all of which can be removed by cytochrome P450, the major pathway in humans involves *N3*-demethylation of caffeine to paraxanthine (see Fig. 6-40).


Figure 6-40. Examples of reactions catalyzed by cytochrome P450: Heteroatom dealkylation.

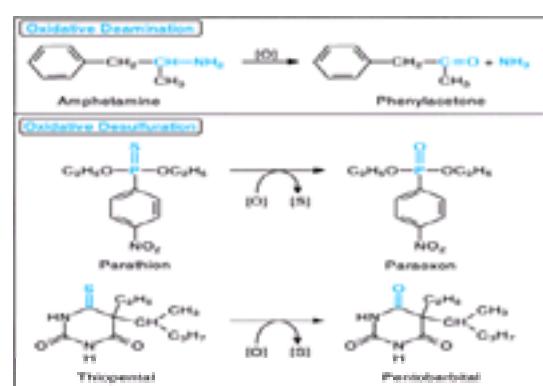
In addition to *N*-dealkylation, primary amines can also undergo oxidative deamination by cytochrome P450, which is an example of oxidative group transfer. The mechanism is similar to that of *N*-dealkylation: The a-carbon adjacent to the primary amine is hydroxylated, which produces an unstable intermediate that rearranges to eliminate ammonia with the formation of an aldehyde or ketone. The conversion of amphetamine to phenylacetone is an example of oxidative deamination, as shown in Fig. 6-41. Oxidative deamination is also catalyzed by monoamine oxidase (MAO). In the example given above, however, the substrate, amphetamine, contains an a-methyl group which renders it a poor substrate for MAO (as described earlier under *"Monoamine Oxidase, Diamine Oxidase, and Polyamine Oxidase'*).


Figure 6-41. Examples of reactions catalyzed by cytochrome P450: Oxidative group transfer.

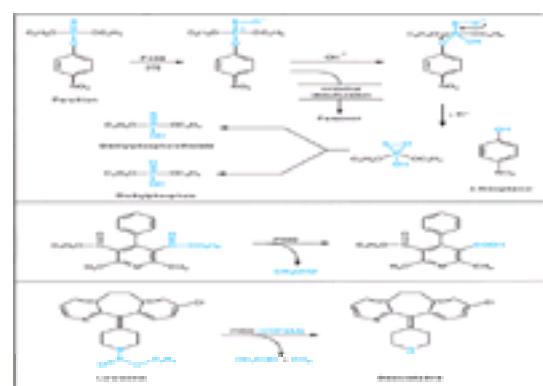
In addition to oxidative deamination, cytochrome P450 catalyzes two other types of oxidative group transfer, namely oxidative desulfuration and oxidative dehalogenation. In all cases the heteroatom (*N*, *S*, or halogen) is replaced with oxygen. As shown in Fig. 6-42, oxidative desulfuration converts parathion, which has little insecticidal activity, to paraoxon, which is a potent insecticide. The same reaction converts thiopental to pentobarbital. Diethyldithiocarbamate methyl ester, a metabolite of disulfiram, also undergoes oxidative desulfuration. The initial reaction involves *S*-oxidation by cytochrome P450 or FMO to a sulfine ($R_1R_2C = S + [O]$ ® R_1R_2C ® S^+ —O^-). In the presence of glutathione (GSH) and glutathione *S*-transferase, this sulfine is either converted back to the parent compound ($R_1R_2C = S^+$ —O^- + 2 GSH ® $R_1R_2C = S + GSSG + H_2O$) or it undergoes desulfuration ($R_1R_2C = S^+$ —O^- + 2 GSH ® $R_1R_2C = O + GSSG + H_2S$) (Madan et al., 1994).


Figure 6-42. Examples of reactions catalyzed by cytochrome P450: Cleavage of esters.

Cytochrome P450 catalyzes both reductive and oxidative dehalogenation reactions (Guengerich, 1991). During oxidative dehalogenation, a halogen and hydrogen from the same carbon atom are replaced with oxygen (R_1R_2CHX ® R_1R_2CO) to produce an aldehyde or acylhalide, as shown in Fig. 6-16 for the conversion of halothane ($CF_3CHClBr$) to trifluoroacetylchloride (CF_3COCl). Oxidative dehalogenation does not involve a direct attack on the carbon–halogen bond, but it involves the formation of an unstable halohydrin by oxidation of the carbon atom bearing the halogen substituent. The carbon–halogen bond is broken during the rearrangement of the unstable halohydrin. When the carbon atom contains a single halogen, the resulting product is an aldehyde, which can be further oxidized to a carboxylic acid or reduced to a primary alcohol. When the carbon atom contains two halogens, the dihalohydrin intermediate rearranges to an acylhalide, which can be converted to the corresponding carboxylic acid (see Fig. 6-16). As discussed previously, aldehydes and, in particular, acylhalides are reactive compounds that can bind covalently to protein and other critical cellular molecules. The immune hepatitis caused by repeated exposure of humans to halothane and related volatile anesthetics is dependent on oxidative dehalogenation by cytochrome P450, with neoantigens produced by the trifluoroacetylation of proteins, as shown in Fig. 6-16.

As shown in Fig. 6-15 and Fig. 6-16, cytochrome P450 also can catalyze the reductive dehalogenation of halogenated alkanes and the reduction of certain azo- and nitro-containing xenobiotics (Fig. 6-8). The ability of cytochrome P450 to reduce xenobiotics can be understood from the catalytic cycle shown in Fig. 6-35. Binding of a substrate to cytochrome P450 is followed by a one-electron reduction by NADPH–cytochrome P450 reductase. Under aerobic conditions, reduction of the heme iron to the ferrous state permits binding of oxygen. Anaerobic conditions, in contrast, interrupt the cycle at this point, which allows cytochrome P450 to reduce those substrates capable of accepting an electron. Therefore, cytochrome P450 can catalyze reduction reactions, such as azo-reduction, nitro-reduction, and reductive dehalogenation, particularly under conditions of low oxygen tension. In effect, the substrate rather than molecular oxygen accepts electrons and is reduced. In fact, oxygen acts as an inhibitor of these reactions because it competes with the substrate for the reducing equivalents. The toxicity of many halogenated alkanes is dependent on their biotransformation by reductive dehalogenation. The first step in reductive dehalogenation is a one-electron reduction catalyzed by cytochrome P450, which produces a potentially toxic, carbon-centered radical and inorganic halide. The conversion of CCl_4 to a trichloromethyl radical and other toxic metabolites

is shown in Fig. 6-15.

The oxidative desulfuration of parathion involves the production of an intermediate that rearranges to paraoxon (see Fig. 6-41). This same intermediate can decompose to *para*-nitrophenol and diethylphosphorothioic acid, which are the same products formed by the hydrolysis of parathion (Fig. 6-42). In addition to facilitating the hydrolysis of phosphoric acid esters, cytochrome P450 also catalyzes the cleavage of carboxylic acid esters, as shown in Fig. 6-42. Carboxylic acid esters typically are cleaved by carboxylesterases, which results in the formation of an acid and an alcohol ($R_1COOCH_2R_2 + H_2O \circledR R_1COOH + R_2CH_2OH$). In contrast, cytochrome P450 converts carboxylic acid esters to an acid plus aldehyde ($R_1COOCH_2 R_2 + [O] \circledR R_1COOH + R_2CHO$), as shown in Fig. 6-42. The deacylation of loratadine is the major route of biotransformation of this nonsedating antihistamine. The reaction is catalyzed predominantly by cytochrome P450 (namely CYP3A4 with a minor contribution from CYP2D6), with little contribution from carboxylesterases.

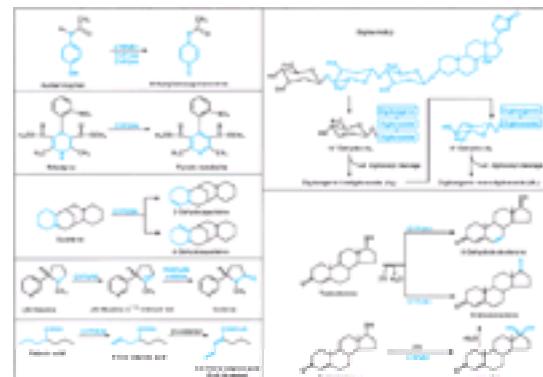
Cytochrome P450 can also catalyze the dehydrogenation of a number of compounds, including acetaminophen, nifedipine, and related dihydropyridine calcium-channel blockers, sparteine, nicotine, valproic acid, digitoxin, and testosterone, as shown in Fig. 6-43. Dehydrogenation by cytochrome P450 converts acetaminophen to its hepatotoxic metabolite, *N*-acetylbenzoquinoneimine, as shown in Fig. 6-28. Dehydrogenation of digitoxin (dt $_3$) to 15'-dehydro-dt$_3$ leads to cleavage of the terminal sugar residue to produce digitoxigenin bisdigitoxoside (dt $_2$), which can similarly be converted to 9'-dehydro-dt$_2$, which undergoes digitoxosyl cleavage to digitoxigenin monodigitoxoside (dt$_1$). In contrast to digitoxin, this latter metabolite is an excellent substrate for glucuronidation. In rats, the P450 enzymes responsible for converting digitoxin to dt $_1$ (namely the CYP3A enzymes) and the UDP-glucuronosyltransferase responsible for glucuronidating dt $_1$ are inducible by dexamethasone, pregnenolone-16a-carbonitrile, and spironolactone, all of which protect rats from the toxic effects of digitoxin. The dehydrogenation of nicotine produces nicotine $D^{1',5'}$-iminium ion, which is oxidized by cytosolic aldehyde oxidase to cotinine, a major metabolite of nicotine excreted in the urine of cigarette smokers.


Figure 6-43. Examples of reactions catalyzed by cytochrome P450: Dehydrogenation.

Testosterone is dehydrogenated by cytochrome P450 to two metabolites: 6-dehydrotestosterone, which involves formation of a carbon–carbon double bond, and androstenedione, which involves formation of a carbon–oxygen double bond. The conversion of testosterone to androstenedione is one of several cases where cytochrome P450 converts a primary or secondary alcohol to an aldehyde or ketone, respectively. The reaction can proceed by formation of a *gem*-diol (two hydroxyl groups on the same carbon atom), with subsequent dehydration to a keto group, as shown in Fig. 6-20 for the conversion of ethanol to acetaldehyde. However, *gem*-diols are not obligatory intermediates in the oxidation of alcohols by cytochrome P450, and in fact the conversion of testosterone to androstenedione by CYP2B1 (the major phenobarbital-inducible P450 enzyme in rats) does not involve the intermediacy of a *gem*-diol but proceeds by direct dehydrogenation (Fig. 6-43). In contrast, a *gem*-diol is involved in the formation of androstenedione from *epi*-testosterone (which is identical to testosterone except the hydroxyl group at C17 is in the a-configuration, not the b-configuration). The fact that formation of androstenedione from *epi*-testosterone involves formation of a *gem*-diol, whereas its formation from testosterone does not, makes it difficult to generalize the mechanism by which cytochrome P450 converts alcohols to aldehydes and ketones.

Liver microsomes from all mammalian species contain numerous P450 enzymes, each with the potential to catalyze the various types of reactions shown in Fig. 6-36, Fig. 6-37, Fig. 6-38, Fig. 6-39, Fig. 6-40, Fig. 6-41, Fig. 6-42 and Fig. 6-43. In other words, all of the P450 enzymes expressed in liver microsomes have the potential to catalyze xenobiotic hydroxylation, epoxidation, dealkylation, oxygenation, dehydrogenation, and so forth. The broad and often overlapping substrate specificity of liver microsomal P450 enzymes precludes the possibility of naming these enzymes for the reactions they catalyze. The amino acid sequence of numerous P450 enzymes has been determined, largely by recombinant DNA techniques, and such sequences now form the basis for classifying and naming P450 enzymes (Gonzalez, 1989; Nelson et al., 1993). In general, P450 enzymes with less than 40 percent amino acid sequence identity are assigned to different gene families (gene families 1, 2, 3, 4, etc.). P450 enzymes that are 40 to 55 percent identical are assigned to different subfamilies (e.g., 2A, 2B, 2C, 2D, 2E, etc.). P450 enzymes that are more than 55 percent identical are classified as members of the same subfamily (e.g., 2A1, 2A2, 2A3, etc.). The liver microsomal P450 enzymes involved in xenobiotic biotransformation belong to three main P450 gene families, namely CYP1, CYP2, and CYP3. Liver microsomes also contain P450 enzymes encoded by the CYP4 gene family, substrates for which include several fatty acids and eicosanoids but relatively few xenobiotics. The liver microsomal P450 enzymes in each of these gene families belong to a single subfamily (i.e., CYP3A and CYP4A), two subfamilies (i.e., CYP1A and CYP1B) or five subfamilies (i.e., CYP2A, CYP2B, CYP2C, CYP2D, and CYP2E). The number of P450 enzymes in each subfamily differs from one species to the next.

Human liver microsomes can contain 15 or more different P450 enzymes (CYP1A1, 1A2, 1B1, 2A6, 2B6, 2C8, 2C9, 2C18, 2C19, 2D6, 2E1, 3A4, 3A5, 3A7, 4A9, and 4A11) that biotransform xenobiotics and/or endogenous substrates (Guengerich, 1994; Wrighton and Stevens, 1992). Other P450 enzymes in human liver microsomes have been described, but they appear to be allelic variants of the aforementioned enzymes rather than distinct gene products. For example, CYP2C10 is an allelic variant of CYP2C9. Unfortunately, a nomenclature system based on structure does not guarantee that structurally related proteins in different species will perform the same function (examples of such functional differences are given later). Some P450 enzymes have the same name in all mammalian species, whereas others are named in a species-specific manner. For example, all mammalian species contain two P450 enzymes belonging to the CYP1A subfamily, and in all cases these are known as CYP1A1 and CYP1A2 because the function and regulation of these enzymes are highly conserved among mammalian species. The same is true of CYP1B1 and CYP2E1. In other words, CYP1A1, CYP1A2, CYP1B1, and CYP2E1 are not species-specific names but rather names given to proteins in all mammalian species. In all other cases, functional or evolutionary relationships are not immediately apparent; hence, the P450 enzymes are named in a species-specific manner and the names are assigned in chronological order regardless of the species of origin. For example, human liver microsomes express CYP2A6, but this is the only functional member of the CYP2A subfamily found in the human liver. The other members of this subfamily (i.e., CYP2A1 to CYP2A5) are the names given to rat and mouse proteins, which were sequenced before the human enzyme. With the exception of CYP1A1, CYP1A2, CYP1B1, and CYP2E1, the names of all of the other P450 enzymes in human liver microsomes refer specifically to human P450 enzymes.

Without exception, the levels and activity of each P450 enzyme have been shown to vary from one individual to the next, due to environmental and/or genetic factors (Meyer, 1994; Shimada et al., 1994). Decreased P450 enzyme activity can result from (1) a genetic mutation that either blocks the synthesis of a P450 enzyme or leads to the synthesis of a catalytically compromised or inactive enzyme, (2) exposure to an environmental factor (such as an infectious disease or a xenobiotic) that suppresses P450 enzyme expression, or (3) exposure to a xenobiotic that inhibits or inactivates a preexisting P450 enzyme. By inhibiting cytochrome P450, one drug can impair the biotransformation of another, which may lead to an exaggerated pharmacologic or toxicologic response to the second drug. In this regard, inhibition of cytochrome P450 mimics the effects of a genetic deficiency in P450 enzyme expression. Increased P450 enzyme activity can result from (1) gene duplication leading to over expression of a P450 enzyme; (2) exposure to environmental factors, such as xenobiotics, that induce the synthesis of cytochrome P450; or (3) stimulation of preexisting enzyme by a xenobiotic.

Although activation of cytochrome P450 has been documented in vitro, it appears to occur in vivo only under special circumstances. Although duplication of functional P450 genes has been documented, induction of cytochrome P450 by xenobiotics is the most common mechanism by which P450 enzyme activity is increased. By inducing cytochrome P450, one drug can stimulate the metabolism of a second drug and thereby decrease or ameliorate its therapeutic effect. A dramatic effect of this type of drug interaction is the induction of ethinylestradiol metabolism by phenobarbital and rifampin, which can ameliorate the contraceptive effect of the former drug and lead to unplanned pregnancy. Allelic variants, which arise by point mutations in the wild-type gene, are another source of interindividual variation in P450 activity. Amino acid substitutions can increase or, more commonly, decrease P450 enzyme activity, although the effect may be substrate-dependent. Examples of genetic factors that influence P450 activity are given later in this section. The environmental factors known to affect P450 levels include medications (e.g., barbiturates, anticonvulsants, rifampin, troglitazone, isoniazid), foods (e.g., cruciferous vegetables, charcoal-broiled beef), social habits (e.g., alcohol consumption, cigarette

smoking), and disease status (diabetes, inflammation, viral and bacterial infection, hyperthyroidism, and hypothyroidism). When environmental factors influence P450 enzyme levels, considerable variation may be observed during repeated measures of xenobiotic biotransformation (e.g., drug metabolism) in the same individual. Such variation is not observed when alterations in P450 activity are determined genetically.

Due to their broad substrate specificity, it is possible that two or more P450 enzymes can contribute to the metabolism of a single compound. For example, two P450 enzymes, designated CYP2D6 and CYP2C19, both contribute significantly to the metabolism of propranolol in humans: CYP2D6 oxidizes the aromatic ring to give 4-hydroxypropranolol, whereas CYP2C19 oxidizes the isopropanolamine side chain to give naphthoxylactic acid (see Fig. 6-23). Consequently, changes in either CYP2D6 or CYP2C19 do not markedly affect the disposition of propranolol. Three human P450 enzymes, CYP1A2, CYP2E1, and CYP3A4, can convert the commonly used analgesic, acetaminophen, to its hepatotoxic metabolite, *N*-acetylbenzoquinoneimine (Fig. 6-43). It is also possible for a single P450 enzyme to catalyze two or more metabolic pathways for the same drug. For example, CYP2D6 catalyzes both the *O*-demethylation and 5-hydroxylation (aromatic ring hydroxylation) of methoxyphenamine, and CYP3A4 catalyzes the 3-hydroxylation and *N*-oxygenation of quinidine, the M1-, M17-, and M21-oxidation of cyclosporine, the 1- and 4-hydroxylation of midazolam, the *tert*-butyl-hydroxylation and *N*-dealkylation of terfenadine, and several pathways of testosterone oxidation, including 1b-, 2b-, 6b-, and 15b-hydroxylation and dehydrogenation to 6-dehydrotestosterone (Fig. 6-36 and Fig. 6-43).

The pharmacologic or toxic effects of certain drugs are exaggerated in a significant percentage of the population due to a heritable deficiency in a P450 enzyme (Tucker, 1994; Meyer, 1994; Smith et al., 1998). The two major polymorphically expressed P450 enzymes are CYP2D6 and CYP2C19, although allelic variants have been described for nearly all of the human P450 enzymes involved in xenobiotic biotransformation (Smith et al., 1998). Individuals lacking CYP2D6 or CYP2C19 were initially identified as poor metabolizers of debrisoquine and *S*-mephenytoin, respectively. However, because each P450 enzyme has a broad substrate specificity, each genetic defect affects the metabolism of several drugs. The incidence of the poor-metabolizer phenotype varies among different ethnic groups. For example, 5 to 10 percent of Caucasians are poor metabolizers of debrisoquine (an antihypertensive drug metabolized by CYP2D6), whereas less than 1 percent of Japanese subjects are defective in CYP2D6 activity. In contrast, ~20 percent of Japanese subjects are poor metabolizers of *S*-mephenytoin (an anticonvulsant metabolized by CYP2C19), whereas less than 5 percent of Caucasians are so affected. On Vanuatu and some other Pacific islands, as many as 70 percent of the population are CYP2C19 poor metabolizers (Kaneko et al., 1999). Some individuals have been identified as poor metabolizers of tolbutamide and phenytoin, both of which are metabolized by CYP2C9, or as poor metabolizers of coumarin or phenacetin, which are metabolized by CYP2A6 and CYP1A2, respectively. However, the incidence of each of these phenotypes is apparently less than 1 percent of the populations examined to date.

The observation that individuals who are genetically deficient in a particular P450 enzyme are poor metabolizers of one or more drugs illustrates a very important principle—namely that the rate of elimination of drugs can be largely determined by a single P450 enzyme. This observation seems to contradict the fact that P450 enzymes have broad and overlapping substrate specificities. The resolution to this apparent paradox lies in the fact that, although more than one human P450 enzyme can catalyze the biotransformation of a xenobiotic, they may do so with markedly different affinities. Consequently, xenobiotic biotransformation in vivo, where only low substrate concentrations are usually achieved, is often determined by the P450 enzyme with the highest affinity (lowest apparent K_m) for the xenobiotic. For example, the *N*-demethylation of diazepam (shown in Fig. 6-40) and the 5-hydroxylation of omeprazole are both catalyzed by two human P450 enzymes, namely CYP2C19 and CYP3A4. However, these reactions are catalyzed by CYP3A4 with such low affinity that the *N*-demethylation of diazepam and the 5-hydroxylation of omeprazole in vivo appear to be dominated by CYP2C19 (Kato and Yamazoe, 1994a). When several P450 enzymes catalyze the same reaction, their relative contribution to xenobiotic biotransformation is determined by the kinetic parameter, V_{max}/K_m, which is a measure of in vitro intrinsic clearance at low substrate concentrations (<10 percent of K_m) (Houston, 1994).

Inasmuch as the biotransformation of a xenobiotic in humans is frequently dominated by a single P450 enzyme, considerable attention has been paid to defining the substrate specificity of the P450 enzymes expressed in human liver microsomes (a process commonly referred to as *reaction phenotyping* or *enzyme mapping*). Three in vitro approaches have been developed for reaction phenotyping. Each has its advantages and disadvantages, and a combination of approaches is usually required to identify which human P450 enzyme is responsible for metabolizing a xenobiotic (Wrighton et al., 1993; Rodrigues 1999; Madan et al., 2000). The three approaches to reaction phenotyping are as follows:

1. *Correlation analysis,* which involves measuring the rate of xenobiotic metabolism by several samples of human liver microsomes and correlating reaction rates with the variation in the level or activity of the individual P450 enzymes in the same microsomal samples. This approach is successful because the levels of the P450 enzymes in human liver microsomes vary enormously from sample to sample (up to 100-fold) but vary independently from each other.
2. *Chemical and antibody inhibition,* which involves an evaluation of the effects of known P450 enzyme inhibitors or inhibitory antibodies on the metabolism of a xenobiotic by human liver microsomes. Chemical inhibitors of cytochrome P450, which are discussed later, must be used cautiously because most of them can inhibit more than one P450 enzyme. Some chemical inhibitors are metabolism-dependent (mechanism-based) inhibitors that require biotransformation to a metabolite that inactivates or noncompetitively inhibits cytochrome P450.
3. *Biotransformation by purified or recombinant human P450 enzymes,* which can establish whether a particular P450 enzyme can or cannot biotransform a xenobiotic, but it does not address whether that P450 enzyme contributes substantially to reactions catalyzed by human liver microsomes. The information obtained with purified or recombinant human P450 enzymes can be improved by taking into account large differences in the extent to which the individual P450 enzymes are expressed in human liver microsomes, which is summarized in Table 6-4. Some P450 enzymes, such as CYP1A1 and CYP1B1, are expressed at such low levels in human liver microsomes that they contribute negligibly to the hepatic biotransformation of xenobiotics. Other P450 enzymes are expressed in some but not all livers. For example, CYP3A5 is expressed in ~25 percent of human livers.

P450 ENZYME	Specific Content (pmol/mg protein)		
	SOURCE (1)	SOURCE (2)	SOURCE (3)
CYP1A2	45	42	15

Table 6-4 Concentration of Individual P450 Enzymes in Human Liver Microsomes

These in vitro approaches have been used to characterize the substrate specificity of several of the P450 enzymes expressed in human liver microsomes. Examples of reactions catalyzed by human P450 enzymes are shown in Fig. 6-36, Fig. 6-37, Fig. 6-38, Fig. 6-39, Fig. 6-40, Fig. 6-41, Fig. 6-42 and Fig. 6-43, and examples of substrates, inhibitors, and inducers for each P450 enzyme are given in Table 6-5. Additional examples appear in a comprehensive review by Rendic and Di Carlo (1997), and clinically important examples can be found on the Internet at http://www.dml.georgetown.edu/depts/pharmacology/davetab.html (Abernathy and Flockhart, 2000). It should be emphasized that reaction phenotyping in vitro is not always carried out with pharmacologically or toxicologically relevant substrate concentrations. As a result, the P450 enzyme that appears responsible for biotransforming the drug in vitro may not be the P450 enzyme responsible for biotransforming the drug in vivo. This may be particularly true of CYP3A4, which metabolizes several drugs with high capacity but low affinity. The salient features of the major P450 enzymes in human liver microsomes are summarized below (subsequent sections, this chapter).

Table 6-5 Examples of Substrates, Inhibitors, and Inducers of the Major Human Liver Microsomal P450 Enzymes Involved in Xenobiotic Biotransformation

CYP1A1/2 All mammalian species apparently possess two inducible CYP1A enzymes, namely CYP1A1 and CYP1A2. Human liver microsomes contain relatively high levels of CYP1A2 but not of CYP1A1, even though this enzyme is readily detectable in the human lung, intestine, skin, lymphocytes, and placenta, particularly from cigarette smokers. In addition to cigarette smoke, inducers of the CYP1A enzymes include charcoal-broiled meat (a source of polycyclic aromatic hydrocarbons), cruciferous vegetables (a source of various indoles), and omeprazole, a proton-pump inhibitor used to suppress gastric acid secretion. In contrast to CYP1A1, CYP1A2 is not expressed in extrahepatic tissues. CYP1A1 and CYP1A2 both catalyze the *O*-dealkylation of 7-methoxyresorufin and 7-ethoxyresorufin (see Fig. 6-40). Reactions preferentially catalyzed by CYP1A1 include the hydroxylation and epoxidation of benzo[a]pyrene (see Fig. 6-6) and the epoxidation of the leukotriene D_4 receptor antagonist, verlukast (Fig. 6-38). CYP1A2 catalyzes the *N*-hydroxylation of aromatic amines, such as 4-aminobiphenyl and 2-aminonaphthalene, which in many cases represents the initial step in the conversion of aromatic amines to tumorigenic metabolites (see Fig. 6-9). CYP1A2 also catalyzes the *O*-dealkylation of phenacetin and the 4-hydroxylation of acetanilide, both of which produce acetaminophen, which can be converted by CYP1A2 and other P450 enzymes to a toxic benzoquinoneimine (Fig. 6-28). The anticholinesterase agent tacrine, which is used in the treatment of Alzheimer's disease, is similarly converted by CYP1A2 to a reactive quinoneimine/ quinone methide (Pirmohamed and Park, 1999). As shown in Fig. 6-40, CYP1A2 catalyzes the *N3*-demethylation of caffeine to paraxanthine. By measuring rates of formation of paraxanthine in blood, urine, or saliva or by measuring the exhalation of isotopically labeled CO_2 from ^{13}C- or ^{14}C-labeled caffeine, the *N3*-demethylation of caffeine can be used as an in vivo probe of CYP1A2 activity, which varies enormously from one individual to the next. CYP1A1 and CYP1A2 are both inhibited by a-naphthoflavone. Ellipticine preferentially inhibits CYP1A1, whereas the metabolism-dependent inhibitor furafylline is a specific inhibitor of CYP1A2.

Although CYP1A1 and CYP1A2 are expressed in all mammals, there are species differences in their function and regulation. For example, although CYP1A1 is not expressed in human liver (or in the liver of most other mammalian species), it appears to be constitutively expressed in rhesus monkey and guinea pig liver. Conversely, although CYP1A2 is expressed in human liver (and in most other mammalian species), it does not appear to be constitutively expressed in cynomolgus monkey liver. Polycyclic and polyhalogenated aromatic hydrocarbons appear to induce CYP1A enzymes in all mammalian species. In contrast, omeprazole is an inducer of CYP1A enzymes in humans, but not in mice or rabbits (Diaz et al., 1990). The function of the CYP1A enzymes is fairly well conserved across species, although there are subtle differences. For example, in some species, such as the rat, CYP1A1 is considerably more effective than CYP1A2 as a catalyst of 7-ethoxyresorufin *O*-dealkylation, whereas the opposite is true in other species, such as rabbit. In mice, CYP1A1 and CYP1A2 catalyze the *O*-dealkylation of 7-ethoxyresorufin at comparable rates. In the rat, CYP1A1 preferentially catalyzes the *O*-dealkylation of 7-ethoxyresorufin whereas CYP1A2 preferentially catalyzes the *O*-dealkylation of 7-methoxyresorufin. However, in other species, such as the mouse and the human, CYP1A2 catalyzes the *O*-dealkylation of 7-ethoxyresorufin and 7-methoxyresorufin at about the same rate. There are also species differences in the affinity with which CYP1A2 interacts with xenobiotics. For example, furafylline is a potent, metabolism-dependent inhibitor of human CYP1A2 but a weak inhibitor of rat CYP1A2. Although the levels of CYP1A2 vary enormously from one individual to the next, genetic defects in CYP1A2 are rare (<1 percent).

CYP2A6 Enzymes belonging to the *CYP2A* gene family show marked species differences in catalytic function. For example, the two CYP2A enzymes expressed in rat liver, namely CYP2A1 and CYP2A2, primarily catalyze the 7a- and 15a-hydroxylation of testosterone, respectively. In contrast, the CYP2A enzyme expressed in human liver, namely CYP2A6, catalyzes the 7-hydroxylation of coumarin, as shown in Fig. 6-37. Just as rat CYP2A1 and CYP2A2 have little or no capacity to 7-hydroxylate coumarin, human CYP2A6 has little or no capacity to hydroxylate testosterone. Mouse liver microsomes contain three CYP2A enzymes: a testosterone 7a-hydroxylase (CYP2A1), a testosterone 15a-hydroxylase (CYP2A4), and a coumarin 7-hydroxylase (CYP2A5). Functionally, CYP2A5 can be converted to CYP2A4 by a single amino acid substitution ($Phe_{209} \circledR Leu_{209}$). In other words, this single amino substitution converts CYP2A5 from a coumarin 7-hydroxylating to a testosterone 15a-hydroxylating enzyme (Lindberg and Negishi, 1989). The fact that a small change in primary structure can have a dramatic effect on substrate specificity makes it difficult to predict whether orthologous proteins in different species (which are structurally similar but never identical) will catalyze the same reactions.

Differences in CYP2A function have important implications for the adverse effects of coumarin, which is hepatotoxic to rats but not humans. Whereas coumarin is detoxified in humans by conversion to 7-hydroxycoumarin, which is subsequently conjugated with glucuronic acid and excreted, a major pathway of coumarin biotransformation in rats involves formation of the hepatotoxic metabolite, coumarin 3,4-epoxide, as shown in Fig. 6-38. In addition to catalyzing the 7-hydroxylation of coumarin, CYP2A6 converts 1,3-butadiene to butadiene monoxide and nicotine to nicotine $D^{1,5}$-iminium ion, which is further oxidized by aldehyde oxidase to cotinine, as shown in Fig. 6-43. 8-Methoxypsoralen, a structural analog of coumarin, is a potent, metabolism-dependent inhibitor of CYP2A6. Although the levels of CYP2A6 vary enormously from one individual to the next, genetic defects in this enzyme are rare (<1 percent). Nevertheless, those individuals who lack CYP2A6 appear to have an aversion to cigarette smoking, presumably because they are poor metabolizers of nicotine (Pianezza et al., 1998).

CYP2B6 Enzymes belonging to the CYP2B subfamily have been studied extensively in many species, although only recently was it appreciated that, despite its low levels in human liver, CYP2B6 contributes significantly to the biotransformation of certain xenobiotics (Ekins and Wrighton, 1999). CYP2B6 appears to be the functional gene expressed in human, with CYP2B7 (a splice variant of CYP2B6) unable to encode for a functional enzyme. CYP2B6 catalyzes the *O*-dealkylation of 7-ethoxy-4-trifluromethylcoumarin, the *N*-demethylation of benzphetamine, and the *O*-dealkylation of benzyloxyresorufin; however, these reactions are not selective for CYP2B6. More specific reactions are *S*-mephenytoin *N*-demethylation and the cyclopentyl ring hydroxylation of the phosphodiester inhibitor 3-cyclopentyloxy *N*-(3,5-dichloro-4-pyridyl)-4-methoxybenzamide (RP 73401). Orphenadrine inhibits CYP2B6, but not selectively. 9-Ethynylphenanthrene has been shown to be a potent metabolism-dependent (mechanism-based) inhibitor of CYP2B6, and appears to be selective. CYP2B6 levels in adult human liver are low, but the enzyme is inducible by rifampin, troglitazone and various anticonvulsant drugs (phenobarbital, phenytoin), which also induce CYP3A4. Phenobarbital (and a host of other xenobiotics) primarily induce the corresponding CYP2B enzymes in other species. For example, CYP2B10, CYP2B1/2, CYP2B11 and CYP2B17 are the major phenobarbital-inducible P450 enzymes in mouse, rat, dog, and cynomolgus monkey, respectively.

CYP2C8 The 6a-hydroxylation of the taxane ring of paclitaxel (which generates a metabolite known as M5, VIII' and HM3) is a specific marker for CYP2C8 (Rahman et al., 1994). Another pathway of paclitaxel metabolism, aromatic hydroxylation (3'-p-hydroxylaton) to M4 (also known as VII'), is catalyzed by CYP3A enzymes. CYP2C8 catalyzes the 10,11-epoxidation of carbamazepine, although this reaction in human liver microsomes is dominated by CYP3A4/5. The 4-hydroxylation of all-*trans* retinoic acid appears to be catalyzed primarily by CYP2C8, however, members of the CYP3A subfamily may be minor participants as well. CYP2C8 also metabolizes endogenous arachidonic acid to form epoxyeicosatrienoic acids, which are converted by cytosolic epoxide hydrolase dihydroeicosatrienoic acids. It has been speculated that the biologically active eicosanoids may be important in maintaining homeostasis in the liver. The multidrug resistance (MDR) reversing agents *R*-verapamil, tamoxifen, and etoposide (VP-16) inhibit the CYP2C8-dependent metabolism of paclitaxel but also inhibit its metabolism by CYP3A4. Quercetin has been shown to inhibit the CYP2C8-dependent hydroxylation of paclitaxel; however, it may not inhibit CYP2C8 selectively.

CYP2C9 A genetic polymorphism for tolbutamide metabolism was first described in 1978–1979, although its incidence is still unknown (Back and Orme, 1992). Poor metabolizers are defective in CYP2C9, which catalyzes the methyl-hydroxylation of this hypoglycemic agent. Poor metabolizers of tolbutamide are also poor metabolizers of phenytoin, which is consistent with in vitro data suggesting that CYP2C9 catalyzes both the methyl-hydroxylation of tolbutamide and the 4-hydroxylation of phenytoin. The antimalarial naphthoquinone 58C80 is converted to a *t*-butyl hydroxylated metabolite by CYP2C9. CYP2C9 also catalyzes the 7-hydroxylation and, to a lesser extent, the 6-hydroxylation of *S*-warfarin; it also appears to catalyze the 7-hydroxylation of D^1-tetrahydrocannabinol. Although CYP2C9 (Arg_{144}, Tyr_{358}, Ile_{359}, Gly_{417}) and its allelic variant CYP2C9 ($Arg_{144} \circledR Cys_{144}$) both catalyze the methyl-hydroxylation of tolbutamide (the former being twice as active as the latter), the latter enzyme is virtually devoid of *S*-warfarin 6- and 7-hydroxylase activity (Rettie et al., 1994). This suggests that individuals who express the allelic variant CYP2C9 ($Arg_{144} \circledR Cys_{144}$) could be poor metabolizers of warfarin but near normal metabolizers of tolbutamide. CYP2C9 also appears to be

responsible for metabolizing several NSAIDs, including the 4'-hydroxylation of diclofenac and the 5'-hydroxylation of piroxicam and tenoxicam. Tienilic acid is also metabolized by CYP2C9, but with potentially deleterious effects. CYP2C9 converts tienilic acid to an electrophilic thiophene sulfoxide, which can react either with water to give 5-hydroxytienilic acid or with a nucleophilic amino acid (Ser $_{365}$) in CYP2C9 to form a covalent adduct, which inactivates the enzyme (Koenigs et al., 1999). Antibodies directed against the adduct between CYP2C9 and tienilic acid are thought to be responsible for the immunoallergic hepatitis that develops in about 1 out of every 10,000 patients treated with this uricosuric diuretic drug. Sulfaphenazole is a potent inhibitor of CYP2C9, both in vitro and in vivo.

CYP2C18 The functions of CYP2C18 are largely unknown. The mRNA encoding this protein is expressed in all human livers, although the mean value is one-seventh to one-eighth that of the mRNAs encoding CYP2C8 and CYP2C9. The levels of CYP2C18 mRNA vary widely from one liver to the next and vary independently of the mRNAs encoding CYP2C8 and CYP2C9, which tend to be coregulated.

CYP2C19 A genetic polymorphism for the metabolism of *S*-mephenytoin was first described in 1984 (reviewed in Wilkinson et al., 1989). The deficiency affects the 4'-hydroxylation (aromatic ring hydroxylation) of this anticonvulsant drug. The other major pathway of *S*-mephenytoin metabolism, namely *N*-demethylation to *S*-nirvanol, is catalyzed by CYP2B6, so it is not affected. Consequently, poor metabolizers excrete little or no 4'-hydroxymephenytoin in their urine but excrete increased amounts of the *N*-demethylated metabolite, *S*-nirvanol (*S*-phenylethylhydantoin). Interestingly, the P450 enzyme responsible for this genetic polymorphism, namely cytochrome CYP2C19, is highly stereoselective for the *S*-enantiomer of mephenytoin. In contrast to the *S*-enantiomer, the *R*-enantiomer is not converted to 4'-hydroxymephenytoin but is *N*-demethylated to *R*-nirvanol (*R*-phenylethylhydantoin). The formulation of mephenytoin used clinically is mesantoin, which is a racemic mixture of *S*- and *R*-enantiomers. An exaggerated central response has been observed in poor metabolizers administered mephenytoin at doses that were without effect in extensive metabolizers of mephenytoin.

There is considerable interethnic variation in the incidence of the poor-metabolizer phenotype for *S*-mephenytoin. In Caucasians, CYP2C19 is defective in 2 to 5 percent of the population, but it is defective in 12 to 23 percent of Japanese, Chinese, and Korean subjects. On Vanuatu and some other Pacific islands, CYP2C19 is deficient in ~70 percent of the population (Kaneko et al., 1999). Based on clinical observations and/or in vitro analysis, CYP2C19 also appears to metabolize diphenylhydantoin (dilantin), mephobarbital, hexobarbital, propranolol, imipramine, diazepam, omeprazole, and lansoprazole. CYP2C19 also converts proguanil to cycloguanil, its active antimalarial metabolite. Artemisinin, another antimalarial drug, is an effective inducer of CYP2C19 and dramatically induces its own metabolism (Mihara et al., 1999). The monoamine oxidase inhibitor tranylcypromine is a potent but not specific inhibitor of CYP2C19.

CYP2C Enzymes in Other Species The multiplicity, function, and regulation of the CYP2C enzymes vary enormously from one species to the next. For example, whereas the 4'-hydroxylation of *S*-mephenytoin in humans is catalyzed by CYP2C19, this same reaction in rats is catalyzed by a CYP3A enzyme, not a CYP2C enzyme. Conversely, one of the reactions catalyzed by rat CYP2C11, namely the 2a-hydroxylation of testosterone, is not catalyzed by the human CYP2C enzymes (or any of the other P450 enzymes in human liver microsomes).

CYP2D6 In the late 1950s, clinical trials in the United States established that sparteine was as potent as oxytocin for inducing labor at term. However, the duration and intensity of action of sparteine were dramatically increased in ~7 percent of all patients tested. The exaggerated response to sparteine included prolonged (tetanic) uterine contraction and abnormally rapid labor. In some cases, sparteine caused the death of the fetus. The drug was not recommended for clinical use because these side effects were unpredictable and occurred at doses of 100 to 200 mg/kg, which were well tolerated by other patients. The antihypertensive drug debrisoquine was subsequently found to cause a marked and prolonged hypotension in 5 to 10 percent of patients, and a genetic polymorphism for the metabolism of debrisoquine and sparteine was discovered in 1977–1979 (Gonzalez, 1989; Meyer, 1994). Poor metabolizers lack CYP2D6, which catalyzes the 4-hydroxylation of debrisoquine and the D^2- and D^2-oxidation of sparteine (see Fig. 6-43).

In addition to debrisoquine and sparteine, CYP2D6 biotransforms a large number of drugs, as shown in Table 6-5. Individuals lacking CYP2D6 have an exaggerated response to most but not all of these drugs. For example, even though debrisoquine and propranolol are both biotransformed by CYP2D6, the effects of propranolol are not exaggerated in poor metabolizers of debrisoquine for two reasons. First, 4-hydroxypropranolol is a b-adrenoceptor antagonist, so the 4-hydroxylation of propranolol by CYP2D6 does not terminate the pharmacologic effects of the drug. Second, CYP2D6 is not the only P450 enzyme to biotransform propranolol. As mentioned above, CYP2C19 catalyzes the side-chain oxidation of propranolol to naphthoxylactic acid (see Fig. 6-23). Because CYP2D6 and CYP2C19 both contribute significantly to the biotransformation of propranolol, a deficiency in either one of these enzymes does not markedly alter the pharmacokinetics of this beta blocker. However, in one individual who lacked both enzymes, the total oral clearance of propranolol was markedly reduced (Wilkinson et al., 1989). CYP2D6 catalyzes the *O*-demethylation of codeine to the potent analgesic morphine. Pain control with codeine is reduced in individuals lacking CYP2D6. The biotransformation of substrates for CYP2D6 occurs 5 to 7.5Å from a basic nitrogen, which interacts with an anionic residue (Glu $_{301}$) in the enzyme's substrate-binding site (Strobl et al., 1993). Quinidine is a potent inhibitor of CYP2D6 because it interacts favorably with the anionic site on CYP2D6, but it cannot be oxidized at sites 5 to 7.5Å from its basic nitrogen atoms. Fluoxetine (and several other selective serotonin-reuptake inhibitors), ajmalicine, and yohimbine are also potent competitive inhibitors of CYP2D6. A poor-metabolizer phenotype can be induced pharmacologically with these potent inhibitors of CYP2D6. Quinine, the levorotatory diasteriomer of quinidine, is not a potent inhibitor of CYP2D6, and neither drug is a potent inhibitor of the CYP2D enzymes expressed in rats. CYP2D6 is one of the few P450 enzymes that efficiently uses the peroxide shunt, so that reactions catalyzed by CYP2D6 can be supported by cumene hydroperoxide.

As shown in Fig. 6-40, CYP2D6 catalyzes the *O*-demethylation of dextromethorphan to dextrorphan, which is glucuronidated and excreted in urine. Dextromethorphan can also be *N*-demethylated, a reaction catalyzed predominantly by CYP3A4 and CYP2B6, but this metabolite is not glucuronidated and excreted in urine. Because the urinary excretion of dextromethorphan is dependent on *O*-demethylation, this over-the-counter antitussive drug can be used to identify individuals lacking CYP2D6, although most poor metabolizers can be identified by DNA analysis (genotyping). There is considerable interethnic variation in the incidence of the poor metabolizer phenotype for debrisoquine/sparteine. In Caucasians, CYP2D6 is defective in 5 to 10 percent of the population, but it is defective in less than 2 percent of African Americans, Africans, Thai, Chinese, and Japanese subjects. Individuals lacking CYP2D6 have an unusually low incidence of some chemically induced neoplastic diseases, such as lung cancer, bladder cancer, hepatocellular carcinoma, and endemic Balkan nephropathy (Idle, 1991; Taningher et al., 1999). It has been hypothesized that CYP2D6 may play a role in the metabolic activation of chemical carcinogens, such as those present in the environment, in the diet, and/or in cigarette smoke. According to this hypothesis, individuals lacking CYP2D6 have a low incidence of cancer because they fail to activate chemical carcinogens. However, CYP2D6 appears to play little or no role in the activation of known chemical carcinogens to DNA-reactive or mutagenic metabolites with the possible exception of the tobacco-smoke specific nitrosamine, 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK), which is also activated by other P450 enzymes. Therefore, it remains to be determined whether a deficiency of CYP2D6 is causally or coincidentally related to a low incidence of certain cancers.

CYP2E1 As shown in Fig. 6-20, CYP2E1 was first identified as MEOS, the microsomal ethanol oxidizing system (Lieber, 1999). In addition to ethanol, CYP2E1 catalyzes the biotransformation of a large number halogenated alkanes (Guengerich et al., 1991). CYP2E1 is expressed constitutively in human liver and possibly in extrahepatic tissues, such as the kidney, lung, lymphocytes, and bone marrow, and the enzyme is inducible by ethanol and isoniazid. CYP2E1 catalyzes the *N1*- and *N7*-demethylation of caffeine to theobromine and theophylline, as shown in Fig. 6-40, and it can activate acetaminophen to the hepatotoxic metabolite *N*-acetylbenzoquinoneimine, as shown in Fig. 6-28 and Fig. 6-43. The mechanism by which alcohol potentiates the hepatotoxic effects of acetaminophen (Tylenol) is thought to involve increased activation of acetaminophen due to the induction of CYP2E1 and decreased inactivation due to a lowering of glutathione levels. However, the degree to which ethanol consumption increases the risk of acetaminophen-induced hepatotoxicity remains a controversial issue (Prescott, 1999). Induction of CYP2E1 by isoniazid stimulates the dehalogenation of the volatile anesthetics enflurane and isoflurane. In human liver microsomes, CYP2E1 activity can be conveniently measured by the 6-hydroxylation of chlorzoxazone and the hydroxylation of 4-nitrophenol. The 6-hydroxylation of chlorzoxazone can also be catalyzed by CYP1A1, but this enzyme is rarely expressed in human liver. Chlorzoxazone is an FDA-approved muscle relaxant (Paraflex), and the urinary excretion of 6-hydroxychlorzoxazone and the plasma ratio of 6-hydroxychlorzoxazone to chlorzoxazone have been used as noninvasive in vivo probes of CYP2E1. The levels of CYP2E1 are by no means constant among individuals, but they do not exhibit the marked interindividual variation characteristic of other P450 enzymes. CYP2E1 is one of the P450 enzymes that requires cytochrome b$_5$, which lowers the apparent K$_m$ for several substrates biotransformed by CYP2E1. The function and regulation of CYP2E1 are well conserved among mammalian species.

CYP3A The most abundant P450 enzymes in human liver microsomes belong to the CYP3A gene subfamily, which includes CYP3A4, CYP3A5, and CYP3A7. CYP3A7 is considered a fetal enzyme, whereas the others are considered to be adult forms, although livers from some adults contain CYP3A7 and some fetal livers contain CYP3A5. All human livers appear to contain CYP3A4, although the levels vary enormously (> 10-fold) among individuals (Wrighton and Stevens, 1992; Shimada et al., 1994). CYP3A5 is expressed in relatively few livers (10 to 30 percent). One or more of these enzymes is expressed in extrahepatic tissues. For example, CYP3A4 is expressed in the small intestine, whereas CYP3A5 is expressed in 80 percent of all human kidneys.

The CYP3A enzymes biotransform an extraordinary array of xenobiotics and steroids, as shown in Table 6-5 (Thummel and Wilkinson, 1998; Dresser et al., 2000). CYP3A enzymes also catalyze the oxidation of hydroxyarginine to citrulline and nitric oxide. Factors that influence the levels and/or activity of the CYP3A enzymes influence the biotransformation of many of the drugs listed in Table 6-5, and many of these drugs have been shown to inhibit each other's metabolism (Pichard et al.,

In humans, CYP3A enzymes are inducible by numerous drugs, such as rifampin, phenobarbital, phenytoin, and troglitazone (Pichard et al., 1990). Inhibitors of human CYP3A include azole-type antimycotics (e.g., ketoconazole and clotrimazole), macrolide antibiotics (e.g., erythromycin and troleandomycin), HIV protease inhibitors (especially ritonavir), the ethynylprogesterone analog gestodene, and certain flavones or other component(s) present in grapefruit juice (although other flavones, such as a-naphthoflavone, are activators of CYP3A4). Several noninvasive clinical tests of CYP3A activity have been proposed, including the [^{14}C-N-methyl]-erythromycin breath test, the plasma clearance of midazolam and nifedipine, and the urinary excretion of 6b-hydroxycortisol (Watkins, 1994). However, for reasons that are not yet understood, there can be marked differences in the results obtained with different tests in the same individuals. Nevertheless, the various noninvasive tests suggest that CYP3A activity varies widely among individuals (> 10-fold), but there appear to be no individuals who are completely devoid of CYP3A activity, possibly due to the multiplicity of enzymes in the human CYP3A subfamily.

The function and regulation of the CYP3A enzymes is fairly well conserved among mammalian species, with some notable exceptions. For example, rifampin is an inducer of the CYP3A enzymes in humans and rabbits but not rats or mice, whereas the opposite appears to be true of pregnenolone-16a-carbonitrile (Pichard et al., 1990). In adult rats, the levels of CYP3A2 in males are much greater (> 10-fold) than in females, whereas no marked sex difference in CYP3A levels is observed in humans (if anything, the levels of CYP3A enzymes are higher in females than in males).

CYP4A9/11 The CYP4A enzymes in human and other species catalyze the w- and w-1 hydroxylation of fatty acids and their derivatives, including prostaglandins, thromboxane, prostacyclin, and leukotrienes. With lauric acid as substrate, the CYP4A enzymes preferentially catalyze the w-hydroxylation to 12-hydroxylauric acid (see Fig. 6-36), which can be further oxidized to form a dicarboxylic acid. Although CYP4A enzymes also catalyze the w-1 hydroxylation of lauric acid, other P450 enzymes, including CYP2E1, can contribute significantly to the formation of 11-hydroxylauric acid. The CYP4A enzymes are unusual for ability to preferentially catalyze the w-hydroxylation of fatty acids over the thermodynamically more favorable reaction leading to w-1 hydroxylation. Despite their physiologic importance, the CYP4A enzymes appear to play a very limited role in the metabolism of drugs and other xenobiotics.

Activation of Xenobiotics by Cytochrome P450

Biotransformation by cytochrome P450 does not always lead to detoxication, and several examples have been given previously where the toxicity or tumorigenicity of a chemical depends on its activation by cytochrome P450. The role of individual human P450 enzymes in the activation of procarcinogens and protoxicants is summarized in Table 6-6 (adapted from Guengerich and Shimada, 1991). A variety of cytochrome P450–dependent reactions are involved in the activation of the chemicals listed in Table 6-6. The conversion of polycyclic aromatic hydrocarbons to tumor-forming metabolites involves the formation of bay-region diolepoxides, as shown in Fig. 6-6 for the conversion of benzo[a]pyrene to benzo[a]pyrene 7,8-dihydrodiol-9,10, epoxide. Epoxidation generates hepatotoxic metabolites of chlorobenzene and coumarin (Fig. 6-38), and generates an hepatotumorigenic metabolite of aflatoxin B1 (Fig. 6-27).

Table 6-6 Examples of Xenobiotics Activated by Human P450 Enzymes

The initial step in the conversion of aromatic amines to tumor-forming metabolites involves N-hydroxylation, as shown for 2-amino-6-nitrobenzylalcohol (Fig. 6-9) and 2-acetylaminofluorene (Fig. 6-33A). In the case of acetaminophen, activation to an hepatotoxic metabolite involves dehydrogenation to N-acetylbenzoquinoneimine, as shown in Fig. 6-28. A similar reaction converts butylated hydroxytoluene to a toxic quinone methide, as shown in Fig. 6-30. The myelotoxicity of benzene depends on its conversion to phenol and hydroquinone (Fig. 6-29). The toxicity of several organophosphorus insecticides involves oxidative group transfer to the corresponding organophosphate, as shown for the conversion of parathion to paraoxon in Fig. 6-41 and Fig. 6-42. The hepatotoxicity of carbon tetrachloride involves reductive dechlorination to a trichloromethyl free radical, which binds to protein and initiates lipid peroxidation, as shown in Fig. 6-15. The hepatotoxicity and nephrotoxicity of chloroform involves oxidative dechlorination to phosgene (Fig. 6-15). Oxidative and reductive dehalogenation both play a role in the activation of halothane, although hepatotoxicity in rats is more dependent on reductive dehalogenation, whereas the immune hepatitis in humans is largely a consequence of oxidative dehalogenation, which leads to the formation of neoantigens (Pohl et al., 1989). Formation of neoantigens (by covalent binding to CYP2C9) is also the mechanism by which the uricosuric diuretic drug tienilic acid causes immune hepatitis (Koenigs et al., 1999).

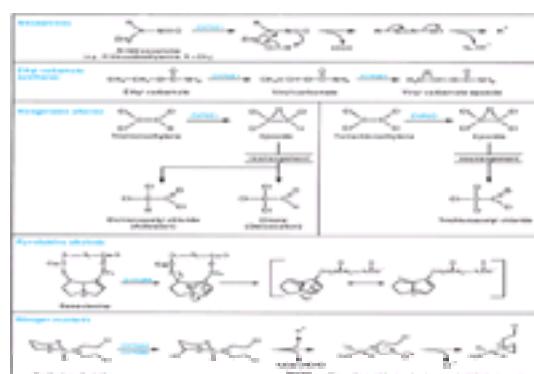
Some of the chemicals listed in Table 6-6 are activated to toxic or tumorigenic metabolites by mechanisms not mentioned previously. For example, N-nitrosodimethylamine, which is representative of a large class of tumorigenic nitrosamines, is activated to an alkylating electrophile by N-demethylation, as shown in Fig. 6-44. The activation of ethyl carbamate (urethan) involves two sequential reactions catalyzed by cytochrome P450 (CYP2E1): dehydrogenation to vinyl carbamate followed by epoxidation, as shown in Fig. 6-44. CYP2E1 is one of several P450 enzymes that can catalyze the epoxidation of tetrachloroethylene. The rearrangement of this epoxide to a carbonyl is accompanied by migration of chlorine, which produces the highly reactive metabolite, trichloroacetylchloride, as shown in Fig. 6-44. The toxic pyrrolizidine alkaloids, such as senecionine, are cyclic arylamines that are dehydrogenated by cytochrome P450 (CYP3A4) to the corresponding pyrroles. Pyrroles themselves are nucleophiles, but electrophiles are generated through the loss of substituents on the pyrrolizidine nucleus, as shown in Fig. 6-44 (Mabic et al, 1999).


Figure 6-44. Additional mechanisms of cytochrome P450–dependent activation of xenobiotics to reactive (electrophilic) metabolites.

Cyclophosphamide and ifosphamide are examples of chemicals designed to be activated to toxic electrophiles for the treatment of malignant tumors and other proliferative diseases. These drugs are nitrogen mustards, which have a tendency to undergo intramolecular nucleophilic displacement to form an electrophilic aziridinium species. In the case of cyclophosphamide and ifosphamide, the nitrogen mustard is stabilized by the presence of a phosphoryl oxygen, which delocalizes the lone pair of nitrogen electrons required for intramolecular nucleophilic displacement. For this reason, formation of an electrophilic aziridinium species requires hydroxylation by cytochrome P450, as shown in Fig. 6-44 for cyclophosphamide. Hydroxylation of the carbon atom next to the ring nitrogen leads spontaneously to

ring opening and elimination of acrolein. In the resultant phosphoramide mustard, delocalization of the lone pair of nitrogen electrons to the phosphoryl oxygen is now disfavored by the presence of the lone pair of electrons on the oxygen anion, hence the phosphoramide undergoes an intramolecular nucleophilic elimination to generate an electrophilic aziridinium species. This reaction is catalyzed by CYP3A4 and CYP2B6. Cyclophosphamide is also activated by CYP2B enzymes in rats, one of which (CYP2B12) is expressed in the skin (Friedberg et al., 1992). Activation of cyclophosphamide by P450 enzymes in the skin would generate a cytotoxic metabolite at the base of hair follicles, which may be the reason why hair loss is one of the side effects of cyclophosphamide treatment.

Many of the chemicals listed in Table 6-6 are also detoxified by cytochrome P450 by biotransformation to less toxic metabolites. In some cases, the same P450 enzyme catalyzes both activation and detoxication reactions. For example, CYP3A4 activates aflatoxin B_1 to the hepatotoxic and tumorigenic 8,9-epoxide, but it also detoxifies aflatoxin B_1 by 3-hydroxylation to aflatoxin Q_1. Similarly, CYP3A4 activates senecionine by converting this pyrrolizidine alkaloid to the corresponding pyrrole, but it also detoxifies senecionine through formation of an N-oxide (a reaction mainly catalyzed by FMO3). Epoxidation of trichloroethylene by CYP2E1 appears to be both an activation and detoxication pathway, as shown in Fig. 6-44. Rearrangement of trichloroethylene epoxide can be accompanied by migration of chlorine, which produces chloral (trichloroacetaldehyde), or hydrogen, which produces dichloroacetylchloride. Chloral is much less toxic than dichloroacetylchloride, hence, migration of the chlorine during epoxide rearrangement is a detoxication reaction, whereas migration of the hydrogen is an activation reaction. These few examples serve to underscore the complexity of factors that determine the balance between xenobiotic activation and detoxication. Further details of xenobiotic activation are available in recent review articles (Bolton et al., 2000; Mabic et al., 1999; Pirmohamed and Park, 1999; Purohit and Basu, 2000).

P450 Knockout Mice

Several strategies have been developed to explore the role of cytochrome P450 enzymes in the activation of xenobiotics. Cytochrome P450 levels in rodents can be increased by a variety of inducers, which would be expected to enhance xenobiotic toxicity. Alternatively, cytochrome P450 activity can be decreased by various inhibitors, which would be expected to have a protective effect. (Inducers and inhibitors of cytochrome P450 are discussed later in this section.) Various in vitro techniques can be employed, similar to those described earlier in this section for determining the role of human P450 enzymes in drug metabolism. Transgenic mice that lack one or more P450 enzymes, which are commonly referred to as knockout mice or null mice, provide a relatively new strategy to evaluate the role of specific P450 enzymes in xenobiotic activation (Gonzalez and Kimura, 1999; Buters et al., 1999). It should be noted, however, that such transgenic mice often have abnormal phenotypes due to disruption of genes other than the target gene. Moreover, deletion of the same gene can produce markedly different phenotypes, as has been observed in different transgenic mice lacking the Ah receptor.

Knockout mice have confirmed the role of several P450 enzymes in the activation of specific xenobiotics. For example, CYP2E1 knockout mice are relatively resistant to the myelotoxic effects of benzene (as previously discussed under "Peroxidase-Dependent Cooxidation"). These same mice are relatively resistant to the toxic effects of chloroform and the lethal effects of acetaminophen. CYP1A2 knockout mice are also relatively more resistant to acetaminophen toxicity, whereas mice lacking both CYP1A2 and CYP2E1 are highly resistant. These results were largely expected based on other evidence implicating CYP2E1 in the activation of benzene, chloroform, and acetaminophen and CYP1A2 in the activation of acetaminophen. However, some results with knockout mice were unexpected. For example, contrary to expectation, CYP1A2 knockout mice were not resistant to hepatotumorigenic effect of 4-aminobiphenyl, even though CYP1A2 was thought to be primarily responsible for catalyzing the initial step in the activation of this carcinogenic amine (i.e., N-hydroxylation). On the other hand, the demonstration that CYP1B1 knockout mice are resistant to the toxic and tumorigenic effects of 7,12-dimethylbenzanthracene provides compelling evidence that CYP1B1, which is expressed in numerous extrahepatic tissues, plays a major role in the activation of polycyclic aromatic hydrocarbons to carcinogenic metabolites (Buters et al., 1999).

These studies in knockout mice are relevant to humans because their counterpart can be found in those individuals who lack certain P450 enzymes or other xenobiotic-biotransforming enzymes. Experiments in knockout mice underscore how genetic polymorphisms in the human population are risk modifiers for the development of chemically induced disease.

Inhibition of Cytochrome P450

In addition to predicting the likelihood of some individuals being poor metabolizers due to a genetic deficiency in P450 expression, information on which human P450 enzyme metabolizes a drug can help predict or explain drug interactions (Peck et al., 1993). For example, when administered with azole antifungals (e.g., ketoconazole and itraconazole) or macrolide antibiotics (e.g., erythromycin and troleandomycin), the antihistamine terfenadine (Seldane) can cause torsades de pointes, which in some individuals has apparently led to lethal ventricular arrhythmias (Kivsito et al., 1994). This drug interaction can be rationalized on the basis that terfenadine is normally converted by intestinal and liver CYP3A4 to a tertiary-butyl alcohol, which is further oxidized to a carboxylic acid metabolite. This latter metabolite blocks H1 receptors and does not cross the blood–brain barrier, which is why terfenadine is a nonsedating antihistamine. When formation of the carboxylic acid metabolite is blocked by CYP3A4 inhibitors—such as ketoconazole, itraconazole, erythromycin, or troleandomycin—the plasma levels of the parent drug, terfenadine, become sufficiently elevated to block cardiac potassium channels, which can lead to arrhythmias. In some cases, inhibition of cytochrome P450 is advantageous. For example, ritonavir blocks the CYP3A-dependent metabolism of sequinavir and thereby improves its pharmacokinetic profile. Both these drugs are HIV protease inhibitors, and combined therapy is better than monotherapy in helping to curtail the development of drug-resistant strains of HIV. Ketoconazole and erythromycin inhibit the biotransformation of cyclosporine by intestinal and liver CYP3A4 and consequently increase the bioavailability of cyclosporine and decrease the rate of elimination of this expensive immunosuppressant. However, much higher doses of cyclosporine must be given to patients taking the CYP3A4 inducer rifampin in order to achieve therapeutic levels and immune suppression.

Inhibitory drug interactions generally fall into three categories. The first involves competition between two drugs that are metabolized by the same P450 enzyme. For example, omeprazole and diazepam are both metabolized by CYP2C19. When the two drugs are administered simultaneously, omeprazole decreases the plasma clearance of diazepam and prolongs its plasma half-life. The inhibition of diazepam metabolism by omeprazole is presumed to involve competition for metabolism by CYP2C19 because no such inhibition occurs in individuals who, for genetic reasons, lack this polymorphically expressed P450 enzyme. The second inhibitory drug interaction is also competitive in nature, but the inhibitor is not a substrate for the affected P450 enzyme. The inhibition of dextromethorphan biotransformation by quinidine is a good example of this type of drug interaction. Dextromethorphan is O-demethylated by CYP2D6, and the clearance of dextromethorphan is impaired in individuals lacking this polymorphically expressed enzyme. The clearance of dextromethorphan is similarly impaired when this antitussive agent is taken with quinidine, a potent inhibitor of CYP2D6. However, quinidine is not biotransformed by CYP2D6, even though it binds to this enzyme with high affinity ($K_i \sim 100$ nM). Quinidine is actually biotransformed by CYP3A4, and is a weak competitive inhibitor of this enzyme ($K_i > 100$ μM). The COX-2 inhibitor celecoxib (Celebrex) is also a CYP2D6 inhibitor, even though it is metabolized by other P450 enzymes.

The third type of drug interaction results from noncompetitive inhibition of cytochrome P450, and it often involves metabolism-dependent inhibition of cytochrome P450 (also known as mechanism-based or suicide inactivation) (Halpert et al., 1994). The inhibition of terfenadine metabolism by macrolide antibiotics appears to be an example of this type of drug interaction. CYP3A4 converts macrolide antibiotics to a metabolite that binds so tightly (but noncovalently) to the heme moiety of CYP3A4 that it is not released from the enzyme's active site. The noncompetitive inhibition of a P450 enzyme by a metabolism-dependent inhibitor can completely block the metabolism of a drug. As the fatal interactions between macrolide antibiotics and terfenadine indicate, noncompetitive inhibition of cytochrome P450 can have profound consequences. Numerous compounds are activated by cytochrome P450 to metabolites that bind covalently to the heme moiety or surrounding protein. These compounds, known as suicide inactivators, include various halogenated alkanes (CCl_4), halogenated alkenes (vinyl chloride, trichloroethylene), allylic compounds (allylisopropylacetamide and secobarbital), and acetylenic compounds (ethinylestradiol and the ethynylprogesterone, gestodene). Ethinyl derivatives of various P450 substrates have been synthesized as potential selective metabolism-dependent inhibitors of individual P450 enzymes. For example, polycyclic aromatic hydrocarbons are preferred substrates for CYP1A1, and this enzyme can be inactivated by various ethynyl derivatives of naphthalene and pyrene. 9-Ethynylphenanthrene is a metabolism-dependent inhibitor of CYP2B6. Furafylline is a metabolism-dependent inhibitor of CYP1A2, for which the structurally related xanthine, caffeine, is a substrate. Similarly, tienilic acid is metabolism-dependent inhibitor of CYP2C9, whereas 8-methoxypsoralen, which is a derivative of coumarin, is a metabolism-dependent inhibitor of CYP2A6 (Table 6-5).

Induction of Cytochrome P450

In contrast to inhibitors, inducers of cytochrome P450 increase the rate of xenobiotic biotransformation (Conney, 1967, 1982; Batt et al., 1992). Some of the P450 enzymes in human liver microsomes are inducible, as summarized in Table 6-5 (Pichard et al., 1990). Clinically important consequences of P450 enzyme induction include the enhanced biotransformation of cyclosporine, warfarin, and contraceptive steroids by inducers of the CYP3A and CYP2C enzymes and enhanced activation of acetaminophen to its hepatotoxic metabolite N-acetylbenzoquinoneimine, by the CYP2E1 inducers ethanol and isoniazid, and possibly by CYP3A enzyme inducers. As an underlying cause of serious adverse effects, P450 induction is generally less important than P450 inhibition, because the latter can cause a rapid and profound increase in blood levels of a drug, which can cause toxic effects and symptoms of drug overdose. In contrast, cytochrome P450 induction lowers blood levels, which compromises the therapeutic goal of drug therapy but does not cause an exaggerated response to the drug. An exception to this rule is the potentiating effect of

alcohol and isoniazid on acetaminophen hepatotoxicity, which is in part because of cytochrome P450 induction.

However, even this drug interaction is complicated by the fact that ethanol and isoniazid are inhibitors as well as inducers of CYP2E1 (Zand et al., 1993). Consequently, increased activation of acetaminophen by ethanol and isoniazid is a delayed response, due to the time required for increased synthesis of CYP2E1 and for the inducers to be cleared to the point where they no longer cause an overall inhibition of CYP2E1 activity. CYP3A4 and CYP1A2 are also inducible enzymes capable of activating acetaminophen to a reactive quinoneimine. By inducing CYP3A4, rifampin and barbiturates would be expected to enhance the hepatotoxicity of acetaminophen, and there is some clinical evidence that this does occur. In contrast, induction of CYP1A2 by cigarette smoking or dietary exposure to polycyclic aromatic hydrocarbons (in charcoal-broiled beef) or indole-3-carbinol derivatives (in cruciferous vegetables) has been reported to have no effect on the hepatotoxicity of acetaminophen, even though CYP1A2 induction in rodents potentiates the hepatocellular necrosis caused by acetaminophen.

Induction of cytochrome P450 would be expected to increase the activation of procarcinogens to DNA-reactive metabolites, leading to increased tumor formation. Contrary to expectation, there is little evidence from either human epidemiologic studies or animal experimentation that P450 induction enhances the incidence or multiplicity of tumors caused by known chemical carcinogens. In fact, most evidence points to a protective role of enzyme induction against chemical-induced neoplasia (Parkinson and Hurwitz, 1991). On the other hand, transgenic (knockout) mice lacking the *Ah* receptor were recently shown to be resistant to the carcinogenic effects of benzo[a]pyrene (Shimizu et al., 2000), which suggests that induction of CYP1A1 plays an important role in the carcinogenicity of polycyclic aromatic hydrocarbons (PAH). However, the *Ah* receptor may be critical to PAH carcinogenicity for reasons other than its role in CYP1A1 induction. For example, the *Ah* receptor may transport DNA-reactive metabolites, such as *ortho*-quinones, to the nucleus (see Fig. 6-6; Burczynski and Penning, 2000), or it might regulate the expression of genes that influence tumor promotion, as has been proposed for other receptors that mediate cytochrome P450 induction (discussed later in this section). In this regard it is significant that benzo[a]pyrene is a complete carcinogen (both an initiator and promoter), and that TCDD and other *Ah* receptor ligands are potent tumor promoters.

Cytochrome P450 induction can cause pharmacokinetic tolerance, as in the case of artemisinin [which induces CYP2C19 (Mihara et al., 1999)], in which case larger doses of drug must be administered to achieve therapeutic blood levels due to increased drug biotransformation. In many instances, however, P450 induction does not necessarily enhance the biotransformation of the inducer, in which case the induction is said to be gratuitous. Drugs are also known to induce enzymes that play no role in their biotransformation. For example, omeprazole induces CYP1A2, even though the disposition of this acid-suppressing drug is largely determined by CYP2C19. Some of the most effective inducers of cytochrome P450 are polyhalogenated aromatic hydrocarbons, such as polychlorinated derivatives of dibenzo-*p*-dioxin (PCDDs), dibenzofurans (PCDFs), azobenzenes and azoxybenzenes, biphenyl (PCBs), and naphthalene. In general, highly chlorinated compounds are resistant to biotransformation and cause a prolonged induction of cytochrome P450 and other enzymes. Due to the increased demand for heme, persistent induction of cytochrome P450 can lead to porphyria, a disorder characterized by excessive accumulation of intermediates in the heme biosynthetic pathway. In 1956, widespread consumption of wheat contaminated with the fungicide hexachlorobenzene caused an epidemic of porphyria cutanea tarda in Turkey. Another outbreak occurred in 1964 among workers at a factory in the United States manufacturing 2,4,5-trichlorophenoxyacetic acid (the active ingredient in several herbicides and in the defoliant Agent Orange). The outbreak of porphyria cutanea tarda was caused not by the herbicide itself but by a contaminant, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin, also known as dioxin and TCDD. Drugs that cause P450 induction have not been shown to cause porphyria cutanea tarda under normal circumstances, but phenobarbital, phenytoin, and alcohol are recognized as *precipitating factors* because they cause episodes of porphyria cutanea tarda in individuals with an inherited deficiency in the heme-biosynthetic enzyme uroporphyrinogen decarboxylase.

The mechanism of P450 induction has been studied extensively in rats and other laboratory animals (Gonzalez, 1989; Okey, 1990; Ryan and Levin, 1990; Porter and Coon, 1991). Currently, five classes of P450 enzyme inducers are recognized, which are represented by 3-methylcholanthrene, phenobarbital, pregnenolone-16a-carbonitrile (PCN), clofibric acid, and isoniazid. The first four inducers cause a marked (<10-fold) increase in the rate of transcription of one or more specific P450 enzymes. For each of these four inducers, the *trans*-acting factor that mediates the transcriptional activation of the P450 genes has been identified, as shown in Table 6-7. For the most part, these *trans*-acting factors are ligand-activated receptors that must dimerize with another protein in order to form a DNA-binding protein that can bind to discrete regions of DNA (*cis*-acting factors or response elements) and thereby activate gene transcription (Honkakoski and Negishi, 2000; Waxman, 1999).

P450 ENZYME	RECEPTOR	RECEPTOR LIGAND	CORECEPTOR	CORECEPTOR LIGAND
CYP1A	AhR	TCDD, PAH, β-NF	Arnt	None
CYP2B	CAR	Androstanol, Phenobarbital	RXR	9-cis retinoic acid
CYP3A	PXR	PCN, Rifampin	RXR	9-cis retinoic acid
CYP4A	PPARα	Peroxisome proliferators	RXR	9-cis retinoic acid

TCDD, 2,3,7,8-tetrachlorodibenzo-p-dioxin; PAH, polycyclic aromatic hydrocarbon; β-NF, β-naphthoflavone.

Androstanol may represent a physiologic ligand that blocks the constitutive DNA-binding properties of CAR.

Table 6-7 Receptors Mediating the Induction of P450 Enzymes

Treatment of rats with 3-methylcholanthrene causes a marked (> 20-fold) induction of CYP1A1 and CYP1A2. Liver microsomes from untreated rats contain low levels of CYP1A2 and virtually undetectable levels of CYP1A1. In addition to polycyclic aromatic hydrocarbons, such as 3-methylcholanthrene and benzo[a]pyrene, inducers of the CYP1A enzymes include flavones (e.g., b-naphthoflavone), polyhalogenated aromatic hydrocarbons (e.g., TCDD, 3,3',4,4',5,5'-hexachlorobiphenyl), acid condensation products of indole-3-carbinol, and certain drugs and food additives (e.g., chlorpromazine, phenothiazine, clotrimazole, ketoconazole, miconazole, isosafrole). Induction of CYP1A1 involves transcriptional activation of the *CYP1A1* gene, which, together with message stabilization, results in an increase in the levels of mRNA and newly synthesized protein.

In the absence of an inducer, transcription of the *CYP1A1* gene is suppressed by a repressor protein, which accounts for the low constitutive levels of CYP1A1 in most species. (Guinea pig and rhesus monkey appear to express CYP1A1 constitutively and hence are exceptions to this general rule). Induction of CYP1A1 involves both derepression and activation of transcription by the *Ah* receptor. Although this cytosolic receptor binds several *aromatic hydrocarbons, such as 3-methylcholanthrene and benzo[a]pyrene, the ligand with the highest binding affinity is TCDD, which is why the *Ah* receptor is also known as the dioxin receptor (Whitlock, 1993). The *Ah* receptor is normally complexed in a 1:2 ratio with heat-shock protein (hsp90), which dissociate upon binding of ligand to the *Ah* receptor, enabling the receptor to be phosphorylated by tyrosine kinase. The activated *Ah* receptor then enters the nucleus and forms a heterodimer complex with the *Ah*-receptor-nuclear translocator *Arnt*. Inside the nucleus, the *Ah* receptor-*Arnt* complex binds to regulatory sequences [known as *dioxin-responsive elements (DRE)* or *xenobiotic responsive elements (XRE)*] and enhances the transcription of the *CYP1A1* gene and other genes with an XRE or XRE-like sequence in their upstream enhancer region [namely CYP1A2, DT-diaphorase, glutathione *S*-transferase, UDP-glucuronosyltransferase (UGT1A6 and UGT1A7), and aldehyde dehydrogenase]. The XRE is only a small segment of DNA (the consensus sequence is 5'-TXGCGTG-3', where X is normally T or A), which can be located more than a thousand bases from the initiation site for transcription. The enhancer region of the *CYP1A1* gene contains multiple XREs, which accounts for the marked (<100-fold) increase in CYP1A1 mRNA and protein levels following exposure to ligands for the *Ah* receptor.

Arnt was initially thought to be a cytosolic protein that simply facilitates the translocation of the ligand-bound *Ah* receptor into the nucleus. It is now recognized as an important component of the receptor complex that binds to DNA and activates transcription of genes under the control of the *Ah* receptor. For heterodimer formation, the *Ah* receptor must be bound to ligand and possibly phosphorylated, and *Arnt* must be phosphorylated, apparently by protein kinase C. The *Ah* receptor is often compared with the steroid/thyroid/retinoid family of receptors, which also bind ligands in the cytoplasm and are translocated to the nucleus where they bind to DNA and enhance gene transcription. However, the *Ah* receptor is a novel ligand-activated transcription factor, very distinct from these other receptors. Whereas the steroid/thyroid/ retinoid receptors have "zinc-finger" DNA-binding domains and form homodimers, the *Ah* receptor forms a heterodimer with *Arnt;* both of these contain a basic helix-loop-helix (bHLH) domain near their *N*-terminus. The basic region binds DNA and the helix-loop-helix is involved in protein–protein interactions. The XRE recognized by the *Ah* receptor-*Arnt* complex contains a sequence of four base pairs (5'-GCGT-3') that is part of the recognition motif for other bHLH proteins (Whitlock, 1993).

In mice, the *Ah* receptor is encoded by a single gene, but there are four allelic variants: a low-affinity form known as *Ah*[d] (an ~104-kDa protein expressed in strains

DBA/2, AKR, and 129) and three high-affinity forms known as Ah^{b-1} (an ~95-kDa protein expressed in C57 mice), Ah^{b-2} (an ~104-kDa protein expressed in BALB/c, C3H, and A mice), and Ah^{b-3} (an ~105-kDa protein expressed in MOLF/Ei mice) (Poland et al., 1994). Mice that express the low-affinity form of the receptor (Ah^d) require higher doses (~10 times) of TCDD to induce CYP1A1. Even though they respond to high doses of TCDD, Ah^d mice are called *nonresponsive* because it is not possible to administer sufficient amounts of polycyclic aromatic hydrocarbons to cause induction of CYP1A1. Although several genetic alterations give rise to the four allelic variants of the Ah receptor, the low-affinity binding of ligands to the Ah^d receptor from nonresponsive mice is attributable to a single amino acid substitution (Ala^{375} ® Val^{375}).

In vivo, the Ah^d and Ah^b genotypes can be distinguished by phenotypic differences in the effects of 3-methylcholanthrene treatment on the duration of action of the muscle relaxant zoxazolamine. Treatment of nonresponsive (Ah^d) mice with 3-methylcholanthrene results in no change in zoxazolamine-induced paralysis time. In contrast, such treatment of responsive (Ah^b) mice causes an induction of CYP1A1, which accelerates the 6-hydroxylation of zoxazolamine and reduces paralysis time from about 1 h to several minutes.

Some of the genes regulated by the Ah receptor contain other responsive elements and their expression is controlled by other transcription factors (Nebert, 1994). To a limited extent, the induction of CYP1A1 by polycyclic aromatic hydrocarbons can also be mediated by another cytosolic receptor known as the 4S-binding protein, which has been identified as the enzyme glycine *N*-methyltransferase. The first intron of the CYP1A1 gene contains a glucocorticoid-responsive element (GRE); hence the induction of CYP1A1 by TCDD can be augmented by glucocorticoids. DTdiaphorase is inducible up to tenfold by two classes of agents: chemicals like 3-methylcholanthrene and TCDD that bind to the Ah receptor and chemicals that cause oxidative stress, such as menadione, *tert*-butylhydroquinone, and 3,5-di-*tert*-butylcatechol, which produce reactive oxygen species through redox cycling reactions. These latter effects are mediated by the antioxidant responsive elements (ARE); therefore these enzymes are inducible by so-called *monofunctional* agents that do not induce CYP1A1 (see the section on DT-diaphorase above). The flavonoid b-naphthoflavone, the polycyclic aromatic hydrocarbon benzo[a]pyrene, and the polyhalogenated aromatic hydrocarbon TCDD all induce DT-diaphorase by both mechanisms; the parent compound binds to the Ah receptor and is responsible for inducing CYP1A1 as well as DT-diaphorase via the XRE, whereas electrophilic and/or redox active metabolites of b-naphthoflavone, benzo[a]pyrene, and TCDD are responsible for inducing glutathione *S*-transferase as well as DT-diaphorase via the ARE (Radjendirane and Jaiswal, 1999). The ARE core sequence for enzyme induction (5'-G**TGAC**AAA**GC**-3') is similar to the AP-1 DNA-binding site (5'-TGACTCA-3'), which is regulated by redox status (see the earlier section on quinone reduction).

The enhancer region of *CYP1A2* also contains an XRE (or XRE-like sequences), so inducers of CYP1A1 are also inducers of CYP1A2. However, the induction of CYP1A2 differs from that of CYP1A1 in several respects: it occurs at lower doses of inducer; it often involves stabilization of mRNA or enzyme from degradation, and it requires liver-specific factors. The first of these differences (dose–response) may explain why low-level exposure of humans to CYP1A inducers results in an increase in hepatic levels of CYP1A2 but not CYP1A1. The second of these differences (namely stabilization of mRNA and/or enzyme) apparently explains why compounds that form stable complexes with CYP1A2, such as isosafrole, can induce CYP1A2 even in nonresponsive (Ah^d) mice. The third difference (the requirement for hepatic factors) explains why CYP1A2 is not expressed or inducible in extrahepatic tissues, hepatoma-derived cell lines, or isolated hepatocytes cultured under conditions that do not restore liver-specific gene expression. CYP1B1 is also regulated by the Ah receptor. In contrast to CYP1A2, CYP1B1 is primarily expressed in extrahepatic tissues, which is also true of human CYP1A1.

Liver microsomes from untreated rats contain low levels of CYP2B2 and extremely low or undetectable levels of CYP2B1, which are structurally related enzymes (97 percent identical) with very similar substrate specificities. Treatment of rats with phenobarbital causes a marked (> 20-fold) induction of cytochromes CYP2B1 and CYP2B2. In addition to barbiturates, such as phenobarbital and glutethimide, inducers of the CYP2B enzymes include drugs (e.g., phenytoin, loratadine, doxylamine, griseofulvin, chlorpromazine, phenothiazine, clotrimazole, ketoconazole, miconazole), pesticides (e.g., DDT, chlordane, dieldrin), food additives (e.g., butylated hydroxytoluene and butylated hydroxyanisole), personal care ingredients [e.g., octamethylcyclotetrasiloxane (or D4)] and certain polyhalogenated aromatic hydrocarbons [e.g., 2,2',4,4',5,5'-hexachlorobiphenyl and 1,4-bis[2]-(3,5-chloropyridyloxy)benzene or TCPOBOP]. Treatment of rats with phenobarbital also results in a two- to fourfold increase in the levels of CYP2A1, CYP2C6, and CYP3A2, as well as a 50 to 75 percent decrease in the levels of CYP2C11, which is present only in adult male rats. In addition, treatment of rats with phenobarbital generally causes an increase (50 to 300 percent) in the concentration of cytochrome b$_5$, NADPH-cytochrome P450 (c) reductase, epoxide hydrolase, aldehyde dehydrogenase, glutathione *S*-transferase and UDP-glucuronosyltransferase. Indeed treatment of rodents with phenobarbital and related inducers causes hepatocellular hyperplasia and/or hypertrophy, which is accompanied by a proliferation of the endoplasmic reticulum.

The mechanism of induction of CYP2B1 by phenobarbital has not been elucidated in as much detail as the induction of CYP1A1 by TCDD. As in the case of CYP1A1, induction of CYP2B1 involves transcriptional activation of the *CYP2B1* gene, which, together with message stabilization, results in an increase in the levels of mRNA and newly synthesized protein. As shown in Table 6-7, CYP2B1 induction by phenobarbital appears to be mediated by CAR$_b$, which must dimerize with another nuclear receptor, the retinoid X receptor (RXR), which is activated by 9-*cis*-retinoic acid. CAR$_b$ is a constitutively activated receptor, meaning it is active as a DNA-binding protein in the absence of a bound ligand. However, androstanol and androstenol have been identified as high affinity CAR$_b$ ligands, although these steroids are not CYP2B1 inducers. It would appear that androstanol and androstenol (or related steroids) bind to CAR$_b$ and *block* its inherent ability to function as a DNA-binding protein. Accordingly, induction by phenobarbital appears to involve the displacement of these androstanes from CAR$_b$. Once derepressed, CAR$_b$ can dimerize with RXR, enter the nucleus and bind to the phenobarbital-responsive element (PBRE) preceding the CYP2B1 gene and numerous other phenobarbital-responsive genes. The fact that, according to this model, phenobarbital-type inducers need only displace androstanes from CAR$_b$, which presumably does not require highly specific binding, may help to explain why CYP2B1 inducers lack any discernible structure-activity relationship.

The bacterium *B. megaterium* contains two cytochrome P450 enzymes, known as P450BM-1 and P450BM-3, that are inducible by phenobarbital and other compounds that induce rat CYP2B1 (Liang et al., 1995). The 5'-enhancer regions of these bacterial genes contain a 15-base-pair DNA sequence that, when deleted or mutated, results in P450BM-1 or P450BM-2 expression. A similar 15-base-pair DNA sequence, which is known as the *Barbie box* (after *barbiturate*), is present in the 5'-enhancer region of CYP2B1, CYP2B2, and numerous other mammalian genes that are transcriptionally activated by phenobarbital. All Barbie boxes contain a four base pair sequence (5'-AAAG-3'), making this the likely site of DNA-protein interactions. In the absence of inducer, a repressor protein, Bm3R1, binds to the Barbie box and impedes or prevents transcription of the structural gene. Binding of the inducer to this repressor causes its dissociation from the Barbie box, which results in increased transcription. However, in light of the discoveries surrounding CAR$_b$, it is now clear that the key feature of the bacterial phenobarbital induction mechanism, namely removal of the repressor protein Bm3R1 from the Barbie box, is not the mechanism of phenobarbital induction in mammals.

Treatment of rodents with PCN causes an induction of CYP3A1 and CYP3A2—two independently regulated CYP3A enzymes with very similar structures (87 percent similar) and substrate specificities. In contrast to CYP3A1, CYP3A2 is present in liver microsomes from untreated rats, although the levels of this enzyme decline markedly after puberty in female rats. Consequently, CYP3A2 is a male-specific protein in mature rats, and it is inducible in mature male but not mature female rats (whereas CYP3A1 is inducible in mature male and female rats). In addition to PCN, inducers of CYP3A enzymes include steroids (e.g., dexamethasone and spironolactone), macrolide antibiotics (e.g., troleandomycin and erythromycin estolate), and azole antifungals (e.g., clotrimazole, ketoconazole, and miconazole). Although it primarily induces the CYP2B enzymes (see above), phenobarbital is also an inducer of CYP3A2.

The induction of CYP3A1, like that of CYP1A1 and CYP2B1, involves transcriptional activation of the structural gene, which, together with message stabilization, results in an increase in the levels of CYP3A1 mRNA and newly synthesized protein. The mechanism of induction of CYP3A1 involves the binding of PCN and related inducers to an orphan receptor known as the pregnane-X receptor (PXR). The ligand-activated PXR dimerizes with RXR (which is activated by 9-*cis*-retinoic acid), and the heterodimer is translocated to the nucleus where it binds to response elements that activate the transcription of CYP3A1 and other PCN-inducible genes. The ligand-binding properties of PXR vary among mammalian species. PCN is a ligand for rodent PXR, whereas rifampin is not. The converse is true of human PXR, which explains why PCN, but not rifampin, is an effective CYP3A inducer in rodents, whereas rifampin, but not PCN, is an effective inducer of human CYP3A4.

In the case of macrolide antibiotics, such as troleandomycin and erythromycin, induction of CYP3A1 involves both transcriptional activation and stabilization of the newly synthesized enzyme against protein degradation. This latter effect involves biotransformation of the macrolide antibiotic to a metabolite that binds tightly to the heme moiety. The induction of CYP3A1 by macrolide antibiotics is often masked by their ability to function as metabolism-dependent inhibitors. The enzyme-inducing effects of clotrimazole, ketoconazole, and miconazole are similarly masked by the ability of these azole antimycotics to bind to and inhibit cytochrome P450 enzymes (including CYP3A1). Substrates and ligands stabilize CYP3A1 by inhibiting its cAMP-dependent-phosphorylation on Ser$_{393}$, which otherwise denatures the protein and targets it for degradation in the endoplasmic reticulum.

Treatment of male rats with clofibric acid causes a marked induction (up to 40-fold) of CYP4A1, CYP4A2, and CYP4A3, which are three independently regulated CYP4A enzymes with similar substrate specificities (Sundseth and Waxman, 1991). CYP4A1 is expressed in the liver, whereas CYP4A3 is expressed in the liver and kidney. CYP4A2 is expressed in the liver and kidney of male rats, but it is neither expressed nor inducible in female rats. In addition to clofibric acid, inducers of

CYP4A enzymes include perfluorodecanoic acid, phthalate ester plasticizers, 2,4-dichlorophenoxyacetic acid (2,4-D), ciprofibrate and other hypolipidemic drugs, aspirin and other NSAIDs, nicotinic acid, dehydroepiandrosterone sulfate, and leukotriene receptor antagonists (MK-0571 and RG 7512). A feature common to all these CYP4A enzyme inducers is their ability to cause proliferation of hepatic peroxisomes.

As in the case of CYP1A1, CYP2B1, and CYP3A1, the induction of CYP4A enzymes by clofibric acid involves transcriptional activation of the structural gene, which results in an increase in the levels of mRNA and newly synthesized protein. The transcription factor that activates the *CYP4A* genes is the peroxisome proliferator-activated receptor (PPARa), a member of the steroid/ thyroid/retinoid superfamily of nuclear receptors that regulates transcription of the genes for fatty acyl-CoA oxidase, bifunctional enzyme (enoyl-CoA hydratase/3-hydroxyacyl-CoA dehydrogenase), and fatty acid binding protein (Muerhoff et al., 1992; Demoz et al., 1994). Binding of a peroxisome proliferator to PPARa results in the formation of a heterodimer with RXR, which is activated by 9-*cis*-retinoic acid. The ligand-bound heterodimer of PPARa and RXR binds to a regulatory DNA sequence known as the peroxisome proliferator response element. Three PPREs have been identified in the 5'-enhancer region of the rabbit *CYP4A6* gene. Each of these elements contains a sequence known as DR1, an imperfect repeat of the nuclear receptor binding consensus sequence separated by one nucleotide (PuGGTCA N PuGGTCA). Peroxisome proliferators can bind to PPARa stereoselectively; therefore, the enantiomers of certain drugs differ in their ability to induce CYP4A and cause a proliferation of peroxisomes. Androsterone sulfate and arachidonic acid are physiologic ligands for PPARa.

Treatment of rats with isoniazid causes a two- to fivefold induction of CYP2E1. In sexually mature rats, the levels of liver microsomal CYP2E1 are slightly greater in female than in male rats. In addition to isoniazid, inducers of CYP2E1 include ethanol, acetone, pyrazole, pyridine, ketoconazole, fasting, and uncontrolled diabetes. A common feature of CYP2E1 inducers is their ability to inhibit or be biotransformed by CYP2E1 and/or their ability to increase serum ketone bodies. Like CYP3A1, CYP2E1 is induced both by transcriptional activation of the gene and stabilization of the protein against degradation (Koop and Tierney, 1990). Induction of CYP2E1 can also involve mRNA stabilization and/or increased efficiency of mRNA translation. The mechanism of CYP2E1 induction varies even among closely related inducers. For example, although diabetes and fasting both increase the levels of CYP2E1 mRNA by ~10-fold, the increase with diabetes results from mRNA stabilization, whereas the increase with fasting results from increased gene transcription. Acetone and other substrates stabilize CYP2E1 by blocking its cAMP-dependent-phosphorylation on Ser_{129}, which otherwise causes the denaturation and degradation of this enzyme. The enzyme-inducing effects of ethanol, acetone, pyrazole, pyridine, and isoniazid are often masked in vivo by the binding of these substrates to CYP2E1.

In mature rats, the levels of certain P450 enzymes are sexually differentiated; that is, they are higher in either male or female rats. Male-specific enzymes include CYP2A2, CYP2C11, CYP2C13, CYP3A2, and CYP4A2. The only known female-specific P450 enzyme is CYP2C12, although the levels of several other P450 enzymes are greater in female than male rats, including CYP2A1, CYP2C7, and CYP2E1. These gender-related differences in P450 enzyme expression are due in large part to sex differences in the pattern of secretion of growth hormone, which is pulsatile in male rats and more or less continuous in females (Waxman et al., 1991). Treatment of mature male rats with various xenobiotics perturbs the pattern of growth hormone secretion and causes a partial "feminization" of P450 enzyme expression, which includes decreased expression of CYP2C11. Sex differences in the expression of P450 enzymes occur to a limited extent in mice, but no marked sex differences in P450 expression have been observed in dogs, monkeys, or humans.

Enzymatic assays have been developed to monitor the induction of the aforementioned P450 enzymes. A series of 7-alkoxyresorufin analogs has proven very useful for monitoring the induction of rat and mouse CYP1A and CYP2B enzymes. CYP1A enzymes preferentially catalyze the *O*-dealkylation of 7-methoxyresorufin and 7-ethoxyresorufin, whereas CYP2B enzymes preferentially catalyze the *O*-dealkylation of 7-pentoxyresorufin and 7-benzyloxyresorufin. The effects of treating rats with phenobarbital on the levels of liver CYP2A1, CYP2B1/2, CYP2C11, and CYP3A1/2 can be monitored by changes in specific pathways of testosterone oxidation. For all practical purposes, the rates of testosterone 2a-, 7a-, and 16b-hydroxylation accurately reflect the levels of CYP2C11, CYP2A1, and CYP2B1/2, respectively. The 2b-, 6b-, and 15b-hydroxylation of testosterone collectively reflect the levels of CYP3A1 and/or CYP3A2. Induction of CYP2E1 can be monitored by increases in 4-nitrophenol hydroxylase, aniline 4-hydroxylase, and chlorzoxazone 6-hydroxylase activity, although none of these reactions is specifically catalyzed by CYP2E1. The 12-hydroxylation of lauric acid appears to be catalyzed specifically by CYP4A enzymes. Indeed the w-hydroxylation of fatty acids and their derivatives (such as eicosanoids) appears to be a physiologic function of these enzymes. CYP4A enzymes also catalyze the 11-hydroxylation of lauric acid, but this reaction is also catalyzed by other P450 enzymes, including the CYP2B and CYP2E enzymes. Induction of CYP4A enzymes by clofibric acid increases the ratio 12- to 11-hydroxylauric acid, whereas induction of CYP2B enzymes by phenobarbital or CYP2E1 by isoniazid has the opposite effect.

In addition to measuring certain enzyme activities, changes in the levels of specific P450 enzymes can also be monitored by immunochemical techniques, such as Western immunoblotting. When P450 induction involves increased gene transcription and/or mRNA stabilization, the increase in mRNA levels can be measured by Northern blotting. These techniques are particularly useful for detecting P450 induction by chemicals that bind tightly to the active site of cytochrome P450 enzymes and thus mask their detection by enzymatic assays. Such chemicals include macrolide antibiotics (e.g., erythromycin and troleandomycin), methylenedioxycontaining compounds (e.g., safrole and isosafrole), azole antimycotics (e.g., clotrimazole, ketoconazole, and miconazole) and musk xylene (Lehman-McKeeman et al., 1999).

Numerous phenobarbital-type inducers and peroxisome proliferators are epigenetic tumorigens (Grasso et al., 1991). Rodents treated chronically with these chemicals develop liver and/or thyroid tumors. The liver tumors seem to be a consequence of hepatocellular hyperplasia/hypertrophy and the sustained proliferation of either the endoplasmic reticulum (in the case of CYP2B inducers) or peroxisomes (in the case of CYP4A inducers). The thyroid tumors are the result of UDP-glucuronosyltransferase induction, which accelerates the glucuronidation of thyroid hormones, leading to a compensatory increase in thyroid-stimulating hormone (TSH). Sustained stimulation of the thyroid gland by TSH leads to the development of thyroid follicular tumors. These epigenetic mechanisms of chemical-induced tumor formation do not appear to operate in humans. Prolonged treatment (> 35 years) with anticonvulsants, such as phenobarbital or phenytoin, does not increase the incidence of liver or thyroid tumor formation in humans. Prolonged elevation of TSH in humans does not lead to tumor formation but causes goiter, a reversible enlargement of the thyroid gland associated with iodide deficiency and treatment with drugs that block thyroid hormone synthesis. Chemicals that cause peroxisome proliferation in rodents do not do so in humans and other primates, possibly because of low levels of PPARa in primate liver and/or the presence of other transcription factors (such as LXRa and the thyroid hormone receptor) that bind to or near the PPRE consensus site. Gene knockout mice lacking PPARa are refractory to peroxisome proliferation and peroxisome proliferator–induced changes in gene expression (including induction of CYP4A and b-oxidation enzymes). Furthermore, PPARa-null mice are resistant to hepatocarcinogenesis when fed a diet containing WY-14,643, a potent peroxisome proliferator and nongenotoxic carcinogen (Gonzalez et al., 1998).

PHASE II ENZYME REACTIONS

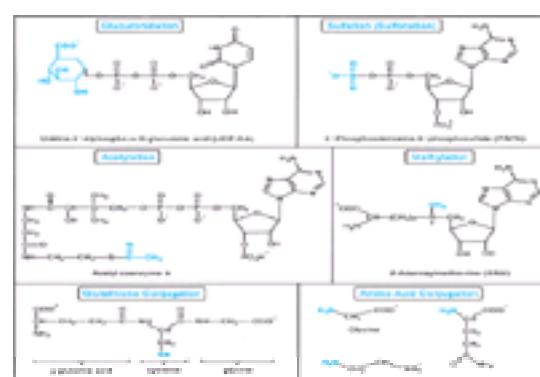
Phase II biotransformation reactions include glucuronidation, sulfonation (more commonly called sulfation), acetylation, methylation, conjugation with glutathione (mercapturic acid synthesis), and conjugation with amino acids (such as glycine, taurine, and glutamic acid) (Paulson et al., 1986). The cofactors for these reactions, which are shown in Fig. 6-45, react with functional groups that are either present on the xenobiotic or are introduced/exposed during phase I biotransformation. With the exception of methylation and acetylation, phase II biotransformation reactions result in a large increase in xenobiotic hydrophilicity, so they greatly promote the excretion of foreign chemicals. Glucuronidation, sulfation, acetylation, and methylation involve reactions with activated or "high-energy" cofactors, whereas conjugation with amino acids or glutathione involves reactions with activated xenobiotics. Most phase II biotransforming enzymes are mainly located in the cytosol; a notable exception is the UDP-glucuronosyltransferases, which are microsomal enzymes (Table 6-1). Phase II reactions generally proceed much faster than phase I reactions, such as those catalyzed by cytochrome P450. Therefore, the rate of elimination of xenobiotics whose excretion depends on biotransformation by cytochrome P450 followed by phase II conjugation is generally determined by the first reaction.


Figure 6-45. Structures of cofactors for phase II biotransformation.

The functional group that reacts with or is transferred to the xenobiotic is shown in blue.

Glucuronidation

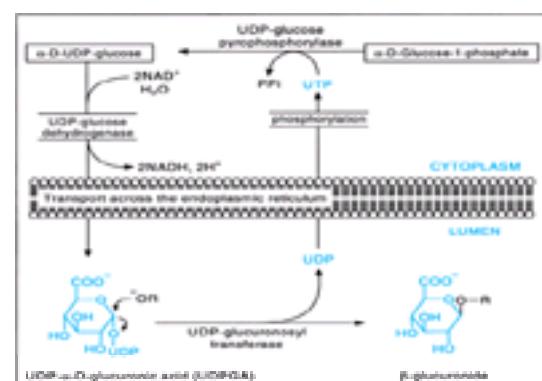
Glucuronidation is a major pathway of xenobiotic biotransformation in mammalian species except for members of the cat family (lions, lynxes, civets, and domestic cats) (Miners and Mackenzie, 1992; Mackenzie et al., 1992; Burchell and Coughtrie, 1992; Burchell, 1999; Tukey and Strassburg, 2000). Glucuronidation requires the cofactor uridine diphosphate-glucuronic acid (UDP-glucuronic acid), and the reaction is catalyzed by UDP-glucuronosyltransferases (UGTs), which are located in the endoplasmic reticulum of liver and other tissues, such as the kidney, intestine, skin, brain, spleen, and nasal mucosa (Fig. 6-46). Examples of xenobiotics that are glucuronidated are shown in Fig. 6-47. The site of glucuronidation is generally an electron-rich nucleophilic heteroatom (O, N, or S). Therefore, substrates for glucuronidation contain such functional groups as aliphatic alcohols and phenols (which form *O*-glucuronide ethers), carboxylic acids (which form *O*-glucuronide esters), primary and secondary aromatic and aliphatic amines (which form *N*-glucuronides), and free sulfhydryl groups (which form *S*-glucuronides). In humans and monkeys, more than thirty tertiary amines, including tripelennamine, cyclobenzaprine and imipramine, are substrates for *N*-glucuronidation, which leads to formation of positively charged quaternary glucuronides (Hawes, 1998). Certain xenobiotics—such as phenylbutazone, sulfinpyrazone and feprazone—contain carbon atoms that are sufficiently nucleophilic to form *C*-glucuronides. Coumarin and certain other carbonyl-containing compounds are glucuronidated to form arylenol-glucuronides. In addition to numerous xenobiotics, substrates for glucuronidation include several endogenous compounds, such as bilirubin, steroid hormones, and thyroid hormones. A listing of over 350 UDP-glucuronosyltransferase substrates is available at www.AnnualReview.org (Tukey and Strassburg, 2000).


Figure 6-46. Synthesis of UDP-glucuronic acid and inversion of configuration (a ® b) during glucuronidation of a phenolic xenobiotic (designated RO⁻).

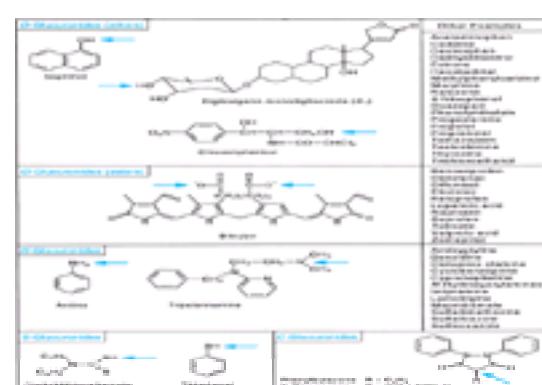
Note that these microsomal enzymes face the lumen of the endoplasmic reticulum.


Figure 6-47. Examples of xenobiotics and endogenous substrates that are glucuronidated.

The arrow indicates the site of glucuronidation.

Glucuronide conjugates of xenobiotics and endogenous compounds are polar, water-soluble conjugates that are eliminated from the body in urine or bile. Whether glucuronides are excreted from the body in bile or urine depends on the size of the aglycone (parent compound or phase I metabolite). In rat, glucuronides are preferentially excreted in urine if the molecular weight of the aglycone is less than 250, whereas glucuronides of larger molecules (aglycones with molecular weight > 350) are preferentially excreted in bile. Molecular weight cutoffs for the preferred route of excretion vary among mammalian species. The carboxylic acid moiety of glucuronic acid, which is ionized at physiologic pH, promotes excretion because (1) it increases the aqueous solubility of the xenobiotic and (2) it is recognized by the biliary and renal organic anion transport systems, which enables glucuronides to be secreted into urine and bile. The cofactor for glucuronidation is synthesized from glucose-1-phosphate, and the linkage between glucuronic acid and UDP has an a-configuration, as shown in Fig. 6-46. This configuration protects the cofactor from hydrolysis by b-glucuronidase. However, glucuronides of xenobiotics have a b-configuration. This inversion of configuration occurs because glucuronides are formed by nucleophilic attack by an electron-rich atom (usually O, N, or S) on UDP-glucuronic acid, and this attack occurs on the opposite side of the linkage between glucuronic acid and UDP, as shown in Fig. 6-46. In contrast to the UDP-glucuronic acid cofactor, xenobiotics conjugated with glucuronic acid are substrates for b-glucuronidase. Although present in the lysosomes of some mammalian tissues, considerable b-glucuronidase activity is present in the intestinal microflora. The intestinal enzyme can release the aglycone, which can be reabsorbed and enter a cycle called *enterohepatic circulation,* which delays the elimination of xenobiotics. Nitrogen-glucuronides are more slowly hydrolyzed by b-glucuronidase than *O*- or *S*-glucuronides, whereas *O*-glucuronides tend to be more stable to acid-catalyzed hydrolysis than *N*- or *S*-glucuronides. The potential for glucuronides to be hydrolyzed in the presence of acid or base complicates the analysis of conjugates in urine or feces.

The *C*-terminus of all UDP-glucuronosyltransferases contains a membrane-spanning domain that anchors the enzyme in the endoplasmic reticulum. The enzyme faces the lumen of the endoplasmic reticulum, where it is ideally placed to conjugate lipophilic xenobiotics and their metabolites generated by cytochrome P450 and other microsomal phase I enzymes. The lumenal orientation of UDP-glucuronosyltransferases poses a problem because UDP-glucuronic acid is a water-soluble cofactor synthesized in the cytoplasm. A transporter has been postulated to shuttle this cofactor into the lumen of the endoplasmic reticulum, and it may also shuttle UDP (the byproduct of glucuronidation) back into the cytoplasm for synthesis of UDP-glucuronic acid, as shown in Fig. 6-46. In vitro, the glucuronidation of xenobiotics by liver microsomes can be stimulated by detergents, which disrupt the lipid bilayer of the endoplasmic reticulum and allow UDP-glucuronosyltransferases free access to UDP-glucuronic acid. High concentrations of detergent can inhibit UDP-glucuronosyltransferases, presumably by disrupting their interaction with phospholipids, which are important for catalytic activity.

Radominska-Pandya et al. (1999) have proposed that UDP-glucuronosyltransferases form homo- and heterodimers in the endoplasmic reticulum, which are stabilized by substrate binding (which gains access to the active site by diffusion through the lipid bilayer). According to this model, UDP-glucuronic acid gains access to the active site via a proteinaceous channel formed between the two monomers. After conjugation, the product glucuronide and UDP are expelled into the cytosol by the same channel used for entry of the cofactor, after which the dimer dissociates to allow pairing of the monomers with other UDP-glucuronosyltransferases. This model obviates the need for a transporter to shuttle UDP-glucuronic acid from the cytosol to the lumen of endoplasmic reticulum. It is not known whether such dimerization, if it occurs, alters the substrate specificity of the individual UDP-glucuronosyltransferases, which would have implications for studies designed to determine the substrate specificity of recombinant enzymes, which are invariably expressed individually.

Cofactor availability can limit the rate of glucuronidation of drugs that are administered in high doses and are conjugated extensively, such as aspirin and acetaminophen. In experimental animals, the glucuronidation of xenobiotics can be impaired in vivo by factors that reduce or deplete UDP-glucuronic acid levels, such as diethyl ether, borneol, and galactosamine. The lowering of UDP-glucuronic acid levels by fasting, such as might occur during a severe toothache, is thought to predispose individuals to the hepatotoxic effects of acetaminophen, although even then hepatotoxicity only occurs with higher-than-recommended doses of this analgesic (Whitcomb and Block, 1994).

The existence of multiple forms of UDP-glucuronosyltransferase was first suggested by the observation that in rats developmental changes in glucuronidation rates were substrate-dependent, and the glucuronidation of xenobiotics could be differentially affected by treatment of rats with chemicals known to induce cytochrome P450. Based on their ontogeny and inducibility, the UDP-glucuronosyltransferase activities in rat liver microsomes were categorized into four groups. The activity of enzyme(s) in the first group peaks 1 to 5 days *before* birth, and it is inducible by 3-methylcholanthrene and other CYP1A enzyme inducers. Substrates for the group 1 enzyme(s) tend to be planar chemicals, such as 1-naphthol, 4-nitrophenol, and 4-methylumbelliferone. The activity of enzyme(s) in the second group peaks ~5 days *after* birth and is inducible by phenobarbital and other CYP2B enzyme inducers. Substrates for the group 2 enzyme(s) tend to be bulky chemicals, such as chloramphenicol, morphine, 4-hydroxybiphenyl, and monoterpenoid alcohols. The activity of enzyme(s) in the third group peaks around the time of puberty (~1 month) and is inducible by PCN and other CYP3A enzyme inducers. Substrates for the group 3 enzyme(s) include digitoxigenin monodigitoxoside (dt $_1$), a metabolite of digitoxin formed by CYP3A (see Fig. 6-43), and possibly bilirubin. The activity of enzyme(s) in the fourth group also peak around the time of puberty (~1 month) and is inducible by clofibrate and other CYP4A enzyme inducers. Substrates for the group 4 enzyme(s) include bilirubin but not dt $_1$, which distinguishes group 3 from group 4 UDP-glucuronosyltransferases.

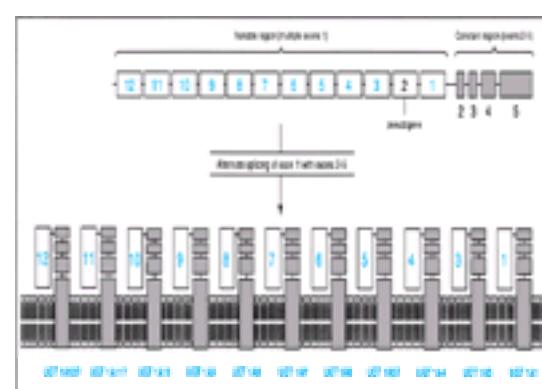
Although this classification system still has some practical value, it has become evident that the four groups of UDP-glucuronosyltransferases do not simply represent four independently regulated enzymes with different substrate specificities. This realization stems from various studies, including those conducted with Gunn rats, which are hyperbilirubinemic due to a genetic defect in bilirubin conjugation. The glucuronidation defect in Gunn rats is substrate-dependent in a manner that does not match the categorization of UDP-glucuronosyltransferases into the four aforementioned groups. For example, in Gunn rats the glucuronidation of the group 2 substrates, morphine and chloramphenicol, is not impaired, whereas the glucuronidation of 1-naphthol, dt $_1$ and bilirubin (group 1, 3, and 4 substrates) is low or undetectable. The induction of UDP-glucuronosyltransferase activity by 3-methylcholanthrene, PCN, and clofibric acid is impaired in Gunn rats, whereas the induction by phenobarbital is normal. (Although phenobarbital does not induce the conjugation of bilirubin in Gunn rats, it does so in normal Wistar rats.) Only when the UDP-glucuronosyltransferases were cloned did it become apparent why the genetic defect in Gunn rats affects three of the four groups of UDP-glucuronosyltransferases that are otherwise independently regulated as a function of age and xenobiotic treatment (Owens and Ritter, 1992). It is now apparent that the UDP-glucuronosyltransferases expressed in rat liver microsomes belong to two gene families, UGT1 and UGT2. The former gene family contains at least seven enzymes, all of which belong to the same subfamily designated UGT1A. The individual members of the rat UGT1A subfamily are UGT1A1, 1A2, 1A3, 1A5, 1A6, 1A7, and 1A8. UGT1A4 is not a member of the rat UGT1A subfamily, although additional members may yet be identified. The second UGT gene family in rats is divided into two subfamilies, UGT2A and UGT2B; the former contains a single member (UGT2A1) whereas the second contains at least six members (UGT2B1, 2B2, 2B3, 2B6, 2B8, and 2B12). Members of gene family 2 are all distinct gene products (i.e., UGT2A1 and the six UGT2B enzymes are encoded by seven separate genes). In contrast, members of family 1 are formed from a single gene with multiple copies of the first exon, each of which can be connected in cassette fashion with a common set of exons (exons 2 to 5). This arrangement is illustrated in Fig. 6-48 for the human UGT1 gene locus. In rats, the fourth copy of exon 1 is a pseudogene, hence, there is no UGT1A4 in rats. In humans, the second copy of exon 1 is a pseudogene, hence, there is no UGT1A2 in humans. (The human UGT1A gene locus is discussed later in this section.) The rat UGT1A gene locus is known to contain eight versions of the first exon, which produce seven functional UGT1A enzymes. Additional members of the rat UGT1A subfamily are thought to exist, including one that glucuronidates dt $_1$, a metabolite of digitoxin (see Fig. 6-43).


Figure 6-48. Structure of the human UGT 1 locus which encodes multiple forms of UDP-glucuronosyltransferase.

A simplified view of the UGT1A gene locus is that the multiple UGT1A enzymes are constructed by linking different substrate binding sites (encoded by multiple copies of exon 1) to a constant portion of the enzyme (encoded by exons 2 to 5). This constant region is involved in cofactor binding and membrane insertion. This method of generating multiple forms of an enzyme from a single gene locus is economical, but it is also the genetic equivalent of putting all of one's eggs in the same basket. Whereas a mutation in any one of the UGT2 enzymes affects a single enzyme, a mutation in the constant region of the UGT1 gene affects all enzymes encoded by this locus. In the Gunn rat, a mutation at codon 415 introduces a premature stop signal, so that all forms of UDP-glucuronosyltransferase encoded by the UGT1 locus are truncated and functionally inactive. The UDP-glucuronosyltransferases known to be encoded by the rat UGT1 locus include the 3-methylcholanthrene-inducible enzyme that conjugates planar molecules like 1-naphthol (UGT1A6 and UGT1A7), the phenobarbital- and clofibric acid-inducible enzyme that conjugates bilirubin (UGT1A1 and, to a lesser extent, UGT1A4), and the PCN-inducible enzyme that conjugates dt $_1$ (which will be named when the first exon for this enzyme is cloned and localized within the UGT1A gene locus). All of these UGT1 enzymes are defective in Gunn rats.

The second family of rat UDP-glucuronosyltransferases, which share less than 50 percent of amino acid sequence identity with the first family, are divided into two subfamilies (UGT2A and UGT2B), and its members are distinct gene products. The single member of the 2A subfamily, UGT2A1, is expressed specifically in olfactory epithelium where it conjugates a wide variety of substrates. The six known members of the rat UGT2B subfamily (UGT2B1, 2, 3, 6, 8, and 12) are expressed in liver and various extrahepatic tissues. Members of the UGT2B subfamily are named in the order they are cloned, regardless of the species of origin (much like the nomenclature system for most of the P450 enzymes). UGT2B enzymes have been cloned from rat (forms 1, 2, 3, 6, 8, and 12), humans (forms 4, 7, 10, 11, 15, and 17), mouse (form 5), and rabbits (forms 13, 14, and 16). A rabbit UDP-glucuronosyltransferase has been classified as UGT2C1; however, UGT2C genes in other mammalians have not been identified. In rats, at least one UGT2B enzyme (UGT2B1) is inducible by phenobarbital. The gene encoding this enzyme is not defective in Gunn rats; therefore, treatment of Gunn rats with phenobarbital induces the glucuronidation of substrates for UGT2B1. However, UGT2B1 does not conjugate bilirubin (a reaction mainly catalyzed by UGT1A1 and/or UGT1A4), which is why phenobarbital cannot induce the conjugation of bilirubin in Gunn rats. UGT2B1 is the main enzyme responsible for catalyzing the 3-*O*-glucuronidation of morphine, which is markedly increased by treatment of rats with phenobarbital. Whereas as Gunn rats are genetically defective in all UGT1A enzymes, LA rats are selectively defective in UGT2B2, which allowed this enzyme to be identified as the principal enzyme responsible for glucuronidating androsterone and triiodothyronine (T $_3$) in rats (Burchell, 1999). The multiple forms of human UDP-glucuronosyltransferase are also products of either a single UGT1A gene locus (see Fig. 6-48) or multiple UGT2 genes. The human UGT1A locus contains 12 potential copies of the first exon, although only nine transcripts have been identified (UGT1A1, 1A3, 1A4, 1A5, 1A6, 1A7, 1A8, 1A9, and 1A10), all of which are transcribed in vivo into functional enzymes with the possible exception of UGT1A5 (Tukey and Strassburg, 2000). The UGT2 genes expressed in humans include UGT2A1 (which is expressed only in olfactory tissue in an analogous manner to the corresponding rat enzyme), and UGT2B4, 2B7, 2B10, 2B11, 2B15, and 2B17. The tissue distribution and substrate specificity of the human UGT1 and UGT2 enzymes have been reviewed by Tukey and Strassburg (2000). Suffice it to say that these enzymes are expressed in a wide variety of tissues, and some enzymes—including UGT1A7, 1A8, 1A10, 2A1, and 2B17—are expressed only in extrahepatic tissues, which has implications for the common practice of using human liver microsomes to investigate the role of glucuronidation in drug metabolism. Numerous UGT1 and UGT2 enzymes are expressed throughout the gastrointestinal tract, where they contribute significantly to the first-pass elimination of numerous xenobiotics. Several UGT2B enzymes are expressed in steroid-sensitive tissues, such as prostate and mammary gland, where they presumably terminate the effects of steroid hormones.

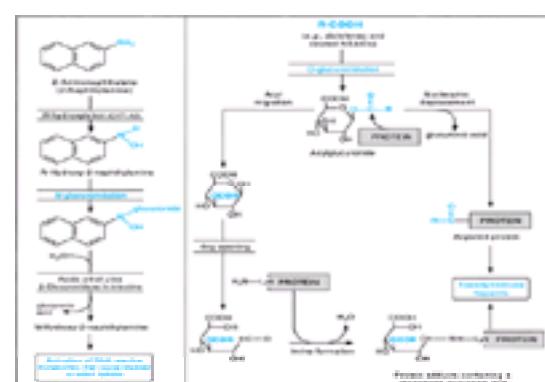
Probe drugs have been identified for some but not all of the human UDP-glucuronosyltransferases, including UGT1A1 (bilirubin), UGT1A4 (imipramine), UGT1A6 (1-naphthol and possibly acetaminophen), UGT1A8 (propofol), and UGT2B7 (morphine) (Burchell, 1997). The glucuronidation of morphine by UGT2B7 involves conjugation of the phenolic 3-hydroxyl and the alcoholic 6-hydroxyl group in a 7:1 ratio. The 6-*O*-glucuronide is 600 times more potent an analgesic than the parent

drug, whereas the 3-O-glucuronide is devoid of analgesic activity. UGT2B7 is present in the brain, where it might facilitate the analgesic effect of morphine through formation of the 6-O-glucuronide, which presumably does not readily cross the blood-brain barrier and may be retained in the brain longer than morphine (Tukey and Strassburg, 2000).

In humans, Crigler-Najjar syndrome and Gilbert's disease are congenital defects in bilirubin conjugation analogous to that seen in Gunn rats. The major bilirubin-conjugating enzyme in humans is UGT1A1. Genetic polymorphisms in exons 2-5, which affect all enzymes encoded by the UGT1A locus, and polymorphisms in exon 1, which specifically affect UGT1A1, have been identified in patients with Crigler-Najjar syndrome and Gilbert's disease. More than thirty genetic polymorphisms are associated with these diseases (Tukey and Strassburg, 2000). Some polymorphisms are associated with type I Crigler-Najjar syndrome, a severe form of the disease characterized by a complete loss of bilirubin-conjugating activity and marked hyperbilirubinemia, whereas others are associated with the less severe type II Crigler-Najjar syndrome or Gilbert's disease. The milder forms of hyperbilirubinemia respond to phenobarbital, which stimulates bilirubin conjugation presumably by inducing UGT1A1. Type I Crigler-Najjar syndrome is associated with impaired glucuronidation of propofol, 17a-ethinylestradiol and various phenolic substrates for UGT1A enzymes.

There is some evidence for genetic polymorphisms in some of the human UGT2 enzymes. For example, oxazepam is glucuronidated by UGT2B7, which preferentially glucuronidates S-oxazepam over its R-enantiomer. Ten percent of the population appear to be poor glucuronidators of S-oxazepam, which may or may not reflect genetic polymorphisms of the UGT2B7 gene. Such polymorphisms appear to be the underlying cause of alterations in hyodeoxycholate glucuronidation in gastric mucosa (Tukey and Strassburg, 2000). Human UGT1A6 glucuronidates acetaminophen, and the glucuronidation of acetaminophen in humans is enhanced by cigarette smoking and dietary cabbage and brussels sprouts, which suggests that human UGT1A6 is inducible by polycyclic aromatic hydrocarbons and derivatives of indole 3-carbinol (Bock et al., 1994). However, direct evidence for induction of human UGT1A6 is lacking, even though rat UGT1A6 is highly inducible by polycyclic aromatic hydrocarbons and other CYP1A inducers. (It should be noted that the UGT1A enzymes in rat and human are named according to the location of the first exon relative to the shared exons within the UGT1A gene locus. Consequently, the identically named UGT1A enzymes in rats and humans need not necessarily glucuronidate the same substrates nor be under similar regulatory control.) Nevertheless, ligands for the Ah receptor, such as those present in cigarette smoke, induce CYP1A2, which would be expected to enhance the hepatotoxicity of acetaminophen. Increased acetaminophen glucuronidation may explain why cigarette smoking does not enhance the hepatotoxicity of acetaminophen. Conversely, decreased glucuronidation may explain why some individuals with Gilbert's syndrome are predisposed to the hepatotoxic effects of acetaminophen (De Morais et al., 1992). Low rates of glucuronidation also predispose humans to the adverse gastrointestinal effects of irinotecan, a derivative of camptothecin (Gupta et al., 1994). Low rates of glucuronidation predispose newborns to jaundice and to the toxic effects of chloramphenicol; the latter was once used prophylactically to prevent opportunistic infections in newborns until it was found to cause severe cyanosis and even death (gray baby syndrome).

Glucuronidation generally detoxifies xenobiotics and potentially toxic endobiotics, such as bilirubin, for which reason glucuronidation is generally considered a beneficial process. However, steroid hormones glucuronidated on the D-ring (but not the A-ring) cause cholestasis, and induction of UDP-glucuronosyltransferase activity has been implicated as an epigenetic mechanism of thyroid tumor formation in rodents (Curran and DeGroot, 1991; McClain, 1989). Inducers of UDP-glucuronosyltransferases cause a decrease in serum thyroid hormone levels, which triggers a compensatory increase in thyroid-stimulating hormone (TSH). During sustained exposure to the enzyme-inducing agent, prolonged stimulation of the thyroid gland by TSH (> 6 months) results in the development of thyroid follicular cell neoplasia. Glucuronidation followed by biliary excretion is a major pathway of thyroxine biotransformation in rodents whereas deiodination is the major pathway (up to 85 percent) of thyroxine metabolism in humans. In contrast to the situation in rodents, prolonged stimulation of the thyroid gland by TSH in humans will result in malignant tumors only in exceptional circumstances and possibly only in conjunction with some thyroid abnormality. Therefore, chemicals that cause thyroid tumors in rats or mice by inducing UDP-glucuronosyltransferase activity are unlikely to cause such tumors in humans. In support of this conclusion, extensive epidemiologic data in epileptic patients suggest that phenobarbital and other anticonvulsants do not function as thyroid (or liver) tumor promoters in humans.

In some cases, glucuronidation represents an important event in the toxicity of xenobiotics. For example, the aromatic amines that cause bladder cancer, such as 2-aminonaphthalene and 4-aminobiphenyl, undergo N-hydroxylation in the liver followed by N-glucuronidation of the resultant N-hydroxyaromatic amine. The N-glucuronides, which accumulate in the urine of the bladder, are unstable in acidic pH and thus are hydrolyzed to the corresponding unstable, tumorigenic N-hydroxyaromatic amine, as shown in Fig. 6-49. A similar mechanism may be involved in colon tumor formation by aromatic amines, although in this case hydrolysis of the N-glucuronide is probably catalyzed by b-glucuronidase in intestinal microflora. Some acylglucuronides are reactive intermediates that bind covalently to protein by mechanisms that may or may not result in cleavage of the glucuronic acid moiety, as shown in Fig. 6-49. Several drugs—including the NSAIDs diclofenac, diflunisal, etodolac, ketoprofen, suprofen, and tolmetin—contain a carboxylic acid moiety that is glucuronidated to form a reactive acylglucuronide. Neoantigens formed by binding of acylglucuronides to protein might be the cause of rare cases of NSAID-induced immune hepatitis. Binding of acylglucuronides to protein can involve isomerization reactions that lead to retention of a rearranged glucuronide moiety (Fig. 6-49). Formation of a common neoantigen (i.e., one that contains a rearranged glucuronic acid moiety) might explain the allergic cross-reactivities (cross-sensitization) observed among different NSAIDs (Spahn-Langguth and Benet, 1992; Kretz-Rommel and Boesterli, 1994).


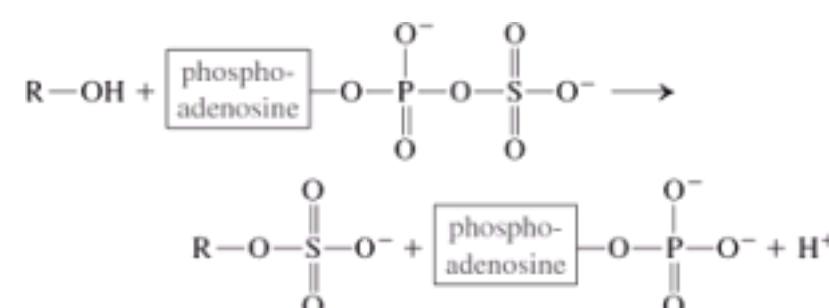


Figure 6-49. Role of glucuronidation in the activation of xenobiotics to toxic metabolites.

Sulfation

Many of the xenobiotics and endogenous substrates that undergo O-glucuronidation also undergo sulfate conjugation, as illustrated in Fig. 6-28 for acetaminophen (Mulder, 1981; Paulson et al., 1986). Sulfate conjugation generally produces a highly water-soluble sulfuric acid ester. The reaction is catalyzed by sulfotransferases, a large multigene family of soluble (cytosolic) enzymes found primarily in the liver, kidney, intestinal tract, lung, platelets, and brain. The cofactor for the reaction is 3'-phosphoadenosine-5'-phosphosulfate (PAPS), the structure of which is shown in Fig. 6-45. The sulfate conjugation of aliphatic alcohols and phenols, R—OH, proceeds as follows:

Sulfate conjugation involves the transfer of sulfonate not sulfate (i.e., SO_3^- not SO_4^-) from PAPS to the xenobiotic. (The commonly used terms *sulfation* and *sulfate conjugation* are used here, even though *sulfonation* and *sulfonate conjugation* are more appropriate descriptors.) Sulfation is not limited to phenols and aliphatic alcohols (which are often the products of phase I biotransformation), although these represent the largest groups of substrates for sulfotransferases. Certain aromatic amines, such as aniline and 2-aminonaphthalene, can undergo sulfate conjugation to the corresponding sulfamates. The N-oxide group in minoxidil and the N-hydroxy group in N-hydroxy-2-aminonaphthalene and N-hydroxy-2-acetylaminofluorene can also be sulfated. In all cases, the conjugation reaction involves nucleophilic attack of oxygen or nitrogen on the electrophilic sulfur atom in PAPS with cleavage of the phosphosulfate bond. Table 6-8 lists some examples of xenobiotics and

endogenous compounds that are sulfated without prior biotransformation by phase I enzymes. An even greater number of xenobiotics are sulfated after a hydroxyl group is exposed or introduced during phase I biotransformation.

FUNCTIONAL GROUP	EXAMPLE
Primary alcohol	Chloramphenicol, ethanol, hydroxymethyl polycyclic aromatic hydrocarbons, polyethylene glycols
Secondary alcohol	Bile acids, 2-butanol, cholesterol, dehydroepiandrosterone, doxaminol
Phenol	Acetaminophen, eutron, ethinylestradiol, naphthol, pentachlorophenol, phenol, picenadol, salicylamide, trimetrexate
Catechol	Dopamine, ellagic acid, α-methyl-DOPA
N-oxide	Minoxidil
Aliphatic amine	2-Amino-3,8-dimethylimidazo[4,5-f]-quinoxaline (MeIQx)*
	2-Amino-3-methylimidazo-[4,5-f]-quinoline (IQ)*
	2-Cyanoethyl-N-hydroxythioacetamide, desipramine
Aromatic amine	2-Aminonaphthalene, aniline
Aromatic hydroxylamine	N-hydroxy-2-aminonaphthalene
Aromatic hydroxyamide	N-hydroxy-2-acetylaminofluorene

*Amino acid pyrolysis products.

Table 6-8 Examples of Xenobiotics and Endogenous Compounds That Undergo Sulfate Conjugation

Carboxylic acids can be conjugated with glucuronic acid but not with sulfate. However, a number of carboxylic acids, such as benzoic acid, naphthoic acid, naphthylacetic acid, salicylic acid, and naproxen, are competitive inhibitors of sulfotransferases (Rao and Duffel, 1991). Pentachlorophenol and 2,6-dichloro-4-nitrophenol are potent sulfotransferase inhibitors because they bind to the enzyme but cannot initiate a nucleophilic attack on PAPS due to the presence of electron-withdrawing substituents in the *ortho-* and *para*-positions on the aromatic ring.

Sulfate conjugates of xenobiotics are excreted mainly in urine. Those excreted in bile may be hydrolyzed by aryl sulfatases present in gut microflora, which contributes to the enterohepatic circulation of certain xenobiotics. Sulfatases are also present in the endoplasmic reticulum and lysosomes, where they primarily hydrolyze sulfates of endogenous compounds presumably in a manner analogous to that described for microsomal b-glucuronidase (Dwivedi et al., 1987) (see comments on egasyn under "Carboxylesterases"). Some sulfate conjugates are substrates for further biotransformation. For example, dehydroepiandrosterone3-sulfate is 16a-hydroxylated by CYP3A7, the major P450 enzyme expressed in human fetal liver, whereas androstane-3,17-diol-3,17-disulfate is 15b-hydroxylated by CYP2C12, a female-specific P450 enzyme in rats. Sulfation facilitates the deiodination of thyroxine and triiodothyronine and can determine the rate of elimination of thyroid hormones in some species.

The sulfate donor PAPS is synthesized from inorganic sulfate (SO_4^{2-}) and ATP in a two step reaction: The first reaction is catalyzed by ATP sulfurylase, which converts ATP and SO_4^{2-} to adenosine-5'-phosphosulfate (APS) and pyrophosphate. The second reaction is catalyzed by APS kinase, which transfers a phosphate group from ATP to the 3'-position of APS. The major source of sulfate required for the synthesis of PAPS appears to be derived from cysteine through a complex oxidation sequence. Because the concentration of free cysteine is limited, the cellular concentrations of PAPS (~75 µM) are considerably lower than those of UDP-glucuronic acid (~350 µM) and glutathione (~10 mM).

The relatively low concentration of PAPS limits the capacity for xenobiotic sulfation. In general, sulfation is a high-affinity but low-capacity pathway of xenobiotic conjugation, whereas glucuronidation is a low-affinity but high-capacity pathway. Acetaminophen is one of several xenobiotics that are substrates for both sulfotransferases and UDP-glucuronosyltransferases (see Fig. 6-28). The relative amount of sulfate and glucuronide conjugates of acetaminophen is dependent on dose. At low doses, acetaminophen sulfate is the main conjugate formed due to the high affinity of sulfotransferases. As the dose increases, the proportion of acetaminophen conjugated with sulfate decreases, whereas the proportion conjugated with glucuronic acid increases. In some cases, even the absolute amount of xenobiotic conjugated with sulfate can decrease at high doses apparently because of substrate inhibition of sulfotransferase.

Multiple sulfotransferases have been identified in all mammalian species examined. An international workshop approved the abbreviation SULT for sulfotransferase (although ST remains a common abbreviation) and developed a nomenclature system based on amino acid sequences (and, to some extent, function), but the names of the individual forms have not been universally agreed upon. For example, some groups use SULT1A1 to name one of the human phenol sulfotransferases whereas others use it to name the corresponding rat enzyme. The nomenclature system used here is that summarized by Nagata and Yamazoe (2000), which is similar to the nomenclature system developed for cytochrome P450. The sulfotransferases are arranged into gene families that share less than 40 percent amino acid sequence identity. The five gene families identified to date (SULT1–SULT5) are subdivided into subfamilies that are 40 to 65 percent identical. For example, SULT1 is divided into five subfamilies designated SULT1A–SULT1E. Two sulfotransferases that share more than 65 percent similarity are considered individual members of the same subfamily. For example, SULT1A2, SULT1A3, and SULT1A5 are three individual members of the human SULT1A subfamily. The individual sulfotransferases are named in the order they are sequenced without regard to the species of origin. Although five SULT gene families have been identified, these have not been identified in all mammalian species. Furthermore, SULT1 and SULT2 are the only gene families subdivided into subfamilies [five in the case of SULT1 (SULT1A–1E); two in the case of SULT2 (SULT2A and SULT2B)]. Most of the sulfotransferases cloned to date belong to one of two families, SULT1 and SULT2. These two families are functionally different; the SULT1 enzymes catalyze the sulfation of phenols, whereas the SULT2 enzymes catalyze the sulfation of alcohols. A sulfotransferase that catalyzes the sulfonation of amines (to form sulfamates) has been cloned from rabbit, and this enzyme belongs to the SULT3 gene family. The properties of the sulfotransferases encoded by the SULT4 and SULT5 gene families are not known.

Eleven cytosolic sulfotransferases have been cloned from rat, and they belong either to the SULT1 or SULT2 gene families. The individual rat enzymes are SULT1A1, 1B1, 1C1, 1C6, 1C7, 1D2, 1E2, 1E6, 2A1, 2A2, and 2A5 (Nagata and Yamazoe, 2000). The enzymes were previously categorized into five classes based on their catalytic activity. These five functional classes were *arylsulfotransferase,* which sulfates numerous phenolic xenobiotics; *alcohol sulfotransferase,* which sulfates primary and secondary alcohols including nonaromatic hydroxysteroids (for which reason these enzymes are also known as hydroxysteroid sulfotransferases); *estrogen sulfotransferase,* which sulfates estrone and other aromatic hydroxysteroids; *tyrosine ester sulfotransferase,* which sulfates tyrosine methyl ester and 2-cyanoethyl-*N*-hydroxythioacetamide, and *bile salt sulfotransferase,* which sulfates conjugated and unconjugated bile acids. The *arylsulfotransferase* and *estrogen sulfotransferase* are composed largely of SULT1 enzymes, which catalyze the sulfation of phenolic xenobiotics, catechols, and aromatic steroids. The *alcohol sulfotransferase* and *bile salt sulfotransferase* are composed largely of SULT2 enzymes, which catalyze the sulfation of a variety of primary and secondary alcohols, bile acids and hydroxysteroids (such as dehydroepiandrosterone or DHEA). The individual sulfotransferases have broad and overlapping substrate specificities. Consequently, sulfation reactions that are specific for a single sulfotransferase enzyme are the exception rather than the rule.

In rats, sulfotransferase activity varies considerably with the sex and age. In mature rats, phenol sulfotransferase activity (SULT1A activity) is higher in males, whereas alcohol sulfotransferase and bile salt sulfotransferase activities (SULT2 activities) are higher in females. Sex differences in the developmental expression of individual sulfotransferase are the result of a complex interplay between gonadal, thyroidal, and pituitary hormones, which similarly determine sex differences in P450 enzyme expression. However, compared with P450 enzymes, the sulfotransferases are refractory or only marginally responsive to the enzyme-inducing effects of 3-methylcholanthrene and phenobarbital, although one or more individual SULT2 enzymes are inducible by PCN. In general, sulfotransferase activity is low in pigs but high in cats. The high sulfotransferase activity in cats offsets their low capacity to conjugate xenobiotics with glucuronic acid.

Nine genes encoding cytosolic sulfotransferases have been identified in humans, and they belong either to the SULT1 or SULT2 gene families. The individual human enzymes are SULT1A2, 1A3, 1A5, 1B2, 1C2, 1C3, 1E4, 2A3, and 2B1 (Nagata and Yamazoe, 2000). A tenth human sulfotransferase has been identified by the Human Chromosome Project Group. The properties of this sulfotransferase, which is a member of the SULT5 gene family, have yet to be determined. Several of the human SULT genes have multiple initiation sites for transcription, which produces different mRNA transcripts. Consequently, in some cases, different versions of the same human SULT gene have been cloned several times. For example, there are three alternative first exons (exons 1a, 1b, and 1c) in the human SULT1A5 gene (none of which contains a coding region), and five SULT1A5 cDNAs have been cloned from various human tissues, each with a unique 5'-region (Nagata and Yamazoe, 2000).

Human liver cytosol contains two phenol sulfotransferase activities (PST) that can be distinguished by their thermal stability; hence, they are known as TS-PST (*thermally stable*) and TL-PST (*thermally labile*) (Weinshilboum, 1992; Weinshilboum et al., 1997). It is now known that TS-PST actually reflects the activity of two sulfotransferases, namely SULT1A2 and SULT1A3, whereas TL-PST reflects the activity of SULT1A5 (hence, the three members of the SULT1A gene subfamily in human are represented functionally by TS-PST and TL-PST activity). SULT1A2 and SULT1A3 function as homo- and heterodimers, and are co-regulated. Although

these two individual sulfotransferases are not catalytically identical, they are sufficiently similar to consider them as the single activity traditionally known as TS-PST.

Because of differences in their substrate specificity, TS-PST and TL-PST are also known as phenol-PST and monoamine-PST, respectively. TL-PST preferentially catalyzes the sulfation of dopamine, epinephrine, and levadopa, whereas TS-PST preferentially catalyzes the sulfation of simple phenols, such as phenol, 4-nitrophenol, minoxidil, and acetaminophen. TS-PST also catalyzes the *N*-sulfation of 2-aminonaphthalene. TS-PST (sensitive) and TL-PST (insensitive) can also be distinguished by differences in their sensitivity to the inhibitory effects of 2,6-dichloro-4-nitrophenol.

The expression of TS-PST in human liver is largely determined by genetic factors, which also determine the corresponding sulfotransferase activity in blood platelets. Inherited variation in platelet TS-PST largely reflects genetic polymorphisms in SULT1A3. An allelic variant of SULT1A3 known as SULT1A3*2 (Arg$_{213}$ ® His$_{213}$) is associated with low TS-PST activity and decreased thermal stability. This particular genetic polymorphism is common in both Caucasians and Nigerians (with an allele frequency of 0.31 and 0.37, respectively), and is correlated with interindividual variation in the sulfation of acetaminophen. Low TS-PST predisposes individuals to diet-induced migraine headaches, possibly due to impaired sulfation of unidentified phenolic compounds in the diet that cause such headaches.

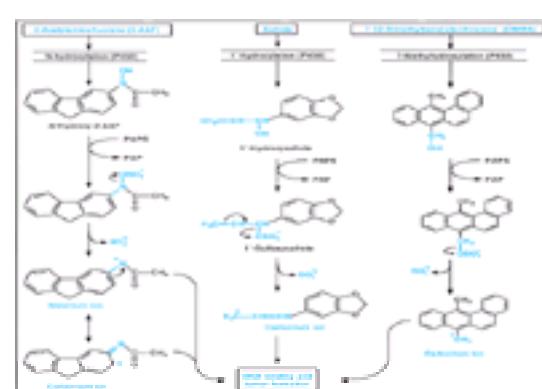
Human SULT1B2, like the corresponding enzyme in other species, catalyzes the sulfation of thyroid hormones. Genetic polymorphisms in this gene have not been identified, although SULT1B2 levels in human liver cytosol vary widely. SULT1B2 is also expressed in human colon, small intestine and blood leukocytes. Humans have two SULT1C enzymes (SULT1C2 and SULT1C3). Their function has not been determined, although the corresponding rat enzyme (SULT1C1) catalyzes the sulfation of *N*-hydroxy-2-acetylaminofluorene (see Fig. 6-50). High levels of SULT1C2 and 1C3 are expressed in fetal liver and kidney. Hepatic levels decline in adulthood, but significant levels of SULT1C2 and 1C3 are present in adult kidney, stomach and thyroid. Human SULT1E4 has been identified has a high affinity estrogen sulfotransferase. SULT1A3 also catalyzes the sulfation of estrogen, such as 17b-estradiol, but it does so with a much lower affinity than does SULT1E4. The sulfation of 17a-ethinylestradiol in human hepatocytes is inducible by rifampin (Li et al., 1999), which raises the possibility that SULT1E4 is an inducible enzyme. In addition to human liver, SULT1E4 is expressed in placenta, breast, and uterine tissue.


Figure 6-50. Role of sulfation in the generation of tumorigenic metabolites (nitrenium or carbonium ions) of 2-acetylaminofluorene, safrole, and 7,12-dimethylbenz[a]anthracene (DMBA).

SULT2A3 is the human alcohol sulfotransferase long known as DHEA-ST (for its ability to sulfate dehydroepiandrosterone). In addition to DHEA, substrates for SULT2A3 include steroid hormones, bile acids and cholesterol. Furthermore, SULT2A3 converts several procarcinogens to electrophilic metabolites, including hydroxymethyl polycyclic aromatic hydrocarbons, *N*-hydroxy-2-acetylaminofluorene and 1'-hydroxysafrole, as shown in Fig. 6-50. The thermal stability of SULT2A3 is intermediate between that of the two phenol sulfotransferases (TS-PST and TL-PST), and the enzyme is resistant to the inhibitory effects of 2,6-dichloro-4-nitrophenol. SULT2A3 is not expressed in blood platelets, but the activity of this enzyme has been measured in human liver cytosol. SULT2A3 is bimodally distributed, possibly due to a genetic polymorphism, with a high activity group composed of ~25 percent of the population. Several genetic polymorphisms of the SULT2A3 have been identified, but the underlying basis for the high activity group remains to be determined.

Human SULT2B1 is also a DHEA-sulfotransferase. It is expressed in placenta, prostate, and trachea. The SULT2B1 gene can be transcribed from one of two exons, both of which contain coding sequences, hence, two forms of SULT2B1 (known as 2B1a and 2B1b) with different *N*-terminal amino acid sequences can be transcribed by alternate splicing of a single gene. This situation is analogous to the alternative splicing of multiple exons 1 in the UGT1 gene family (see Fig. 6-48).

In general, sulfation is an effective means of decreasing the pharmacologic and toxicologic activity of xenobiotics. There are cases, however, in which sulfation increases the toxicity of foreign chemicals because certain sulfate conjugates are chemically unstable and degrade to form potent electrophilic species. As shown in Fig. 6-50, sulfation plays an important role in the activation of aromatic amines, methyl-substituted polycyclic aromatic hydrocarbons, and safrole to tumorigenic metabolites. To exert its tumorigenic effect in rodents, safrole must be hydroxylated by cytochrome P450 to 1'-hydroxysafrole, which is then sulfated to the electrophilic and tumor-initiating metabolite, 1'-sulfooxysafrole (Boberg et al., 1983). 1'-Hydroxysafrole is a more potent hepatotumorigen than safrole. Two lines of evidence support a major role for sulfation in the hepatotumorigenic effect of 1'-hydroxysafrole. First, the hepatotumorigenic effect of 1'-hydroxysafrole can be inhibited by treating mice with the sulfotransferase inhibitor, pentachlorophenol. Second, the hepatotumorigenic effect of 1'-hydroxysafrole is markedly reduced in brachymorphic mice, which have a diminished capacity to sulfate xenobiotics because of a genetic defect in PAPS synthesis. Brachymorphic mice are undersized because the defect in PAPS synthesis prevents the normal sulfation of glycosaminoglycans and proteoglycans such as heparin and chondroitin, which are important components of cartilage. These particular sulfation reactions are catalyzed by membrane-bound sulfotransferase, which are thought not to play a role in xenobiotic sulfation.

Methylation

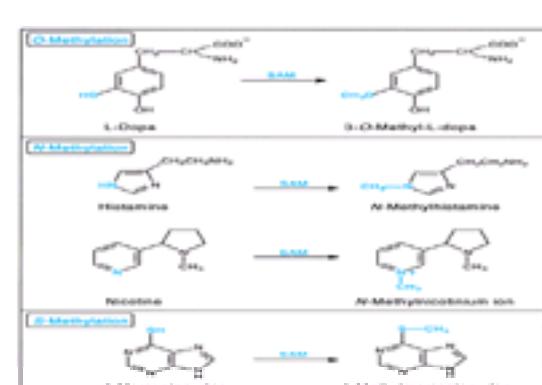
Methylation is a common but generally minor pathway of xenobiotic biotransformation. Methylation differs from most other phase II reactions because it generally decreases the water-solubility of xenobiotics and masks functional groups that might otherwise be conjugated by other phase II enzymes. One exception to this rule is the *N*-methylation of pyridine-containing xenobiotics, such as nicotine, which produces quaternary ammonium ions that are water-soluble and readily excreted. Another exception is the *S*-methylation of thioethers to form positively charged sulfonium ions, a reaction catalyzed by thioether methyltransferase (TEMT), which has only been identified in mice (Weinshilboum et al., 1999). The cofactor for methylation is *S*-adenosylmethionine (SAM), the structure of which is shown in Fig. 6-45. The methyl group bound to the sulfonium ion in SAM has the characteristics of a carbonium ion and is transferred to xenobiotics and endogenous substrates by nucleophilic attack from an electron-rich heteroatom (*O*, *N*, or *S*). Consequently, the functional groups involved in methylation reactions are phenols, catechols, aliphatic and aromatic amines, *N*-heterocyclics, and sulfhydryl-containing compounds. The conversion of benzo[a]pyrene to 6-methylbenzo[a]pyrene is a rare example of *C*-methylation. Another reaction that appears to involve *C*-methylation, the conversion of cocaine to ethylcocaine, is actually a transesterification reaction, as shown in Fig. 6-2. Metals can also be methylated. Inorganic mercury and arsenic can both be dimethylated, and inorganic selenium can be trimethylated. The selenium atom in ebselen is methylated following the ring opening of this anti-inflammatory drug. Some examples of xenobiotics and endogenous substrates that undergo *C*-, *N*-, or *S*-methylation are shown in Fig. 6-51. During these methylation reactions, SAM is converted to *S*-adenosylhomocysteine.


Figure 6-51. Examples of compounds that undergo O-, N-, *or* S-*methylation.*

The *O*-methylation of phenols and catechols is catalyzed by two different enzymes known as phenol *O*-methyltransferase (POMT) and catechol- *O*-methyltransferase (COMT) (Weinshilboum, 1989, 1992b). POMT is a microsomal enzyme that methylates phenols but not catechols, and COMT is both a cytosolic and microsomal enzyme with the converse substrate specificity. COMT plays a greater role in the biotransformation of catechols than POMT plays in the biotransformation of phenols. COMT was originally described as a cytosolic, Mg^{2+}-requiring, monomeric enzyme (Mr 25,000). However, in rats and humans, COMT is encoded by a single gene with two different transcription initiation sites. Transcription at one site produces a cytosolic form of COMT, whereas transcription from the other site produces a membrane-bound form by adding a 50–amino acid segment that targets COMT to the endoplasmic reticulum (Weinshilboum et al., 1999). The cytosolic form of COMT is present in virtually all tissues, including erythrocytes, but the highest concentrations are found in liver and kidney. The membrane-bound form is more highly expressed in brain.

Substrates for COMT include several catecholamine neurotransmitters, such as epinephrine, norepinephrine, and dopamine, and catechol drugs, such as the anti-Parkinson's disease agent L-dopa (3,4-dihydroxyphenylalanine) and the antihypertensive drug methyldopa (a-methyl-3,4-dihydroxyphenylalanine). Catechol estrogens, which are formed by 2- or 4-hydroxylation of the steroid A-ring, are substrates for COMT, as are drugs that are converted to catechols either by two consecutive hydroxylation reactions (as in the case of phenobarbital and diclofenac), by ring opening of a methylenedioxy group (as in the case of stiripentol and 3,4-methylenedioxymethamphetamine), or by hydrolysis of vicinal esters (as in the case of ibopamine). Formation of catechol estrogens, particularly 4-hydroxyestradiol, has been suggested to play an important role in estrogen-induced tumor formation in hamster kidney, rat pituitary, and mouse uterus (Zhu and Liehr, 1993). These tissues contain high levels of epinephrine or dopamine, which inhibit the *O*-methylation of 4-hydroxyestradiol by COMT. Nontarget tissues do not contain high levels of catecholamines, which suggests that 4-hydroxyestradiol induces tumor formation in those tissues that fail to methylate and detoxify this catechol estrogen. These observations in animals are especially intriguing in view of subsequent clinical evidence that low COMT activity appears to be a risk modifier for breast cancer (Weinshilboum et al., 1999).

In humans, COMT is encoded by a single gene with alleles for a low activity form (COMT^L) and high activity form (COMT^H) (Weinshilboum, 1989, 1992b; Weinshilboum at al., 1999). This polymorphism results from a single G ® A transition that results in an amino acid substitution (Val ® Thr) at position 108 in cytosolic COMT and position 158 in microsomal COMT (Weinshilboum et al., 1999). The presence of methionine at position 108 in the cytosolic enzyme not only decreases the catalytic activity of COMT, but it decreases the thermal stability of the enzyme, which has long been used to differentiate COMT ^{L} (thermolabile) from COMT^H (thermostable). In Caucasians, these allelic variants are expressed with equal frequency, so that 25 percent of the population is homozygous for either the low or high activity enzyme, and 50 percent is heterozygous and have intermediate COMT activity. COMT activity is generally higher in Asians and African Americans due to a higher frequency of the COMT^H allele (~0.75 for Asians and African Americans vs. ~0.5 for Caucasians) (McLeod et al., 1994). The genetically determined levels of COMT in erythrocytes correlates with individual differences in the proportion of L-dopa converted to 3- *O*-methyldopa and the proportion of methyldopa converted to its 3-*O*-methyl metabolite. *O*-Methylation is normally a minor pathway of L-dopa biotransformation, but 3- *O*-methyldopa is the major metabolite when L-dopa is administered with a dopa decarboxylase inhibitor, such as carbidopa or benserazide, which is common clinical practice. High COMT activity, resulting in extensive *O*-methylation of L-dopa to 3-*O*-methyldopa, has been associated with poor therapeutic management of Parkinson's disease and an increased incidence of drug-induced toxicity (dyskinesia). However, there is no evidence that the genetic polymorphism in COMT represents a risk modifier for the development of Parkinson's disease or related disorders, such as schizophrenia (Weinshilboum et al., 1999).

Several *N*-methyltransferases have been described in humans and other mammals, including phenylethanolamine *N*-methyltransferase (PNMT), which catalyzes the *N*-methylation of the neurotransmitter norepinephrine to form epinephrine; histamine *N*-methyltransferase (HNMT), which specifically methylates the imidazole ring of histamine and closely related compounds (Fig. 6-51), and nicotinamide *N*-methyltransferase (NNMT), which methylates compounds containing a pyridine ring, such as nicotinamide and nicotine, or an indole ring, such as tryptophan and serotonin (Weinshilboum, 1989, 1992b; Weinshilboum et al., 1999). PNMT is expressed in the adrenal medulla and in certain regions of the brain, and is not thought to play a significant role in the biotransformation of xenobiotics. However, HNMT and NNMT are expressed in liver, intestine and/or kidney, where they play a role in xenobiotic biotransformation.

Histamine *N*-methyltransferase is a cytosolic enzyme (Mr 33,000). Its activity (which can be measured in erythrocytes) varies sixfold among individuals due to a genetic polymorphism (C ® T) that results in a point mutation at amino acid residue 105 (Thr ® Ile). The latter allele (Ile $_{105}$) is quite common (10 percent frequency) and encodes a variant of HNMT with decreased catalytic activity and thermal stability.

Nicotinamide *N*-methyltransferase activity in human liver, like HNMT activity in erythrocytes, varies considerably from one individual to the next, but it is not known to what extent genetic polymorphisms account for this variation. NNMT is a monomeric, cytosolic enzyme (Mr ~30,000) that appears to a member of a family of methyltransferases that includes PNMT and TEMT (the thioether *S*-methyltransferase present in mouse lung). NNMT catalyzes the *N*-methylation of nicotinamide and structurally related pyridine compounds (including pyridine itself) to form positively charged pyridinium ions. Nicotinic acid (niacin), a commonly used lipid-lowering agent, is converted to nicotinamide in vivo, which is then methylated by NNMT (or it is incorporated into nicotinamide adenine dinucleotide, NAD). In contrast to many other methyltransferases, NNMT is not expressed in erythrocytes.

The system that is used to classify human *N*-methyltransferases may not be appropriate for other species. In guinea pigs, for example, nicotine and histamine are both methylated by a common *N*-methyltransferase. Guinea pigs have an unusually high capacity to methylate histamine and xenobiotics. The major route of nicotine biotransformation in the guinea pig is methylation, although *R*-(+)-nicotine is preferentially methylated over its *S*-(–)-enantiomer (Cundy et al., 1985). Guinea pigs also methylate the imidazole ring of cimetidine.

S-Methylation is an important pathway in the biotransformation of sulfhydryl-containing xenobiotics, such as the antihypertensive drug captopril, the antirheumatic agent D-penicillamine, the antineoplastic and immunosuppressive drugs 6-mercaptopurine, 6-thioguanine and azathioprine, metabolites of the alcohol deterrent disulfiram, and the deacetylated metabolite of the antidiuretic, spironolactone. In humans, *S*-methylation is catalyzed by two enzymes, thiopurine methyltransferase (TPMT) and thiol methyltransferase (TMT). A third enzyme, thioether *S*-methyltransferase (TEMT) has been identified in mice (Weinshilboum et al., 1999).

TPMT is a cytoplasmic enzyme that preferentially methylates aromatic and heterocyclic compounds such as the thiopurine drugs 6-mercaptopurine, 6-thioguanine and azathioprine. TMT is a microsomal enzyme that preferentially methylates aliphatic sulfhydryl compounds such as captopril, D-penicillamine, and disulfiram derivatives. Both enzymes are present in erythrocytes at levels that reflect the expression of TPMT and TMT in liver and other tissues. Although TPMT and TMT are independently regulated, their expression in erythrocytes is largely determined by genetic factors. TPMT is encoded by a single gene with alleles for a low activity form (TPMT^L) and for a high activity form (TPMT^H). The gene frequency of TPMT^L and TPMT^H are 6 and 94 percent, respectively, which produces a trimodal distribution of TPMT activity with low, intermediate and high activity expressed in 0.3, 11.1, and 88.6 percent of the population, respectively. At least eight separate genetic polymorphisms are associated with low TPMT activity. In Caucasians, the allele that is most commonly associated with the TPMT ^{L} phenotype is TPMT*3, which differs from the wild-type enzyme (TPMT*1) at both residue 154 (Ala ® Thr) and 240 (Tyr ® Cys) (Weinshilboum et al., 1999).

Cancer patients with low TPMT activity are at increased risk for thiopurine-induced myelotoxicity, in contrast to the potential need for higher-than-normal doses to achieve therapeutic levels of thiopurines in patients with TPMT high activity (Weinshilboum, 1989, 1992b). The thiopurine drugs metabolized by TPMT have a relatively narrow therapeutic index, and are used to treat life-threatening illnesses such as acute lymphoblastic leukemia or organ-transplant patients. Phenotyping for the TPMT genetic polymorphism represents one of the first examples in which testing for a genetic variant has entered standard clinical practice (Weinshilboum et al., 1999).

TPMT can be inhibited by benzoic acid derivatives, which also complicates therapy with drugs that metabolized by TPMT. Patients with inflammatory bowel disorders such as Crohn's disease are often treated with thiopurine drugs, which are metabolized by TPMT, and with sulfasalazine or olsalazine, which are potent TPMT inhibitors. The combination of these drugs can lead to thiopurine-induced myelosuppression.

A genetic polymorphism for TMT also has been described, but its pharmacologic and toxicologic significance remain to be determined. The molecular basis for the polymorphism has not been determined, but studies have shown that 98 percent of the fivefold individual variation in erythrocyte TMT activity is due to inheritance, with an allele for high TMT activity having a frequency of 0.12. TMT is relatively specific for aliphatic sulfhydryl compounds such as 2-mercaethanol, captopril, D-penicillamine and *N*-acetylcysteine. TMT is present in liver microsomes and erythrocyte membranes. TMT is not inhibited by benzoic acid derivatives, but it is

inhibited by the cytochrome P450 inhibitor SKF 525A ([Weinshilboum et al., 1999](#)). The hydrogen sulfide produced by anaerobic bacteria in the intestinal tract is converted by S-methyltransferases to methane thiol and then to dimethylsulfide. Another source of substrates for S-methyltransferase are the thioethers of glutathione conjugates. Glutathione conjugates are hydrolyzed to cysteine conjugates, which can either be acetylated to form mercapturic acids or cleaved by beta lyase. This beta lyase pathway converts the cysteine conjugate to pyruvate, ammonia and a sulfhydryl-containing xenobiotic, which is a potential substrate for S-methylation.

Acetylation

N-Acetylation is a major route of biotransformation for xenobiotics containing an aromatic amine (R–NH$_2$) or a hydrazine group (R –NH –NH$_2$), which are converted to aromatic amides (R –NH –COCH$_3$) and hydrazides (R –NH –NH –COCH$_3$), respectively ([Evans, 1992](#)). Xenobiotics containing primary aliphatic amines are rarely substrates for N-acetylation, a notable exception being cysteine conjugates, which are formed from glutathione conjugates and converted to mercapturic acids by N-acetylation in the kidney (see "[Glutathione Conjugation](#)," below). Like methylation, N-acetylation masks an amine with a nonionizable group, so that many N-acetylated metabolites are less water soluble than the parent compound. Nevertheless, N-acetylation of certain xenobiotics, such as isoniazid, facilitates their urinary excretion.

The N-acetylation of xenobiotics is catalyzed by N-acetyltransferases and requires the cofactor acetyl-coenzyme A (acetyl-CoA), the structure of which is shown in [Fig. 6-45](#). The reaction occurs in two sequential steps according to a *ping-pong Bi-Bi* mechanism (Hein, 1988). In the first step, the acetyl group from acetyl-CoA is transferred to an active site cysteine residue within an N-acetyltransferase with release of coenzyme A (E–SH + CoA–S –COCH$_3$ ® E-S –COCH$_3$ + CoA –SH). In the second step, the acetyl group is transferred from the acylated enzyme to the amino group of the substrate with regeneration of the enzyme. For strongly basic amines, the rate of N-acetylation is determined by the first step (acetylation of the enzyme), whereas the rate of N-acetylation of weakly basic amines is determined by the second step (transfer of the acetyl group from the acylated enzyme to the acceptor amine). In certain cases (discussed below), N-acetyltransferases can catalyze the O-acetylation of xenobiotics.

N-Acetyltransferases are cytosolic enzymes found in liver and many other tissues of most mammalian species, with the notable exception of the dog and fox, which are unable to acetylate xenobiotics. In contrast to other xenobiotic-biotransforming enzymes, the number of N-acetyltransferases is limited ([Vatsis et al., 1995](#)). Humans, rabbits, and hamsters express only two N-acetyltransferases, known as NAT1 and NAT2, whereas mice express three distinct forms of the enzymes, namely NAT1, NAT2, and NAT3. *NAT* is the official gene symbol for arylamine N-acetyltransferase [EC 2.3.1.5], which reflects the fact that aromatic amines, not aliphatic amines, are the preferred substrates for these enzymes. Individual N-acetyltransferases and their allelic variants have been named in the order of their description in the literature, which makes for a somewhat confusing nomenclature system ([Vatsis et al., 1995](#)). For example, in humans, the wild-type *NAT1* gene is designated *NAT1*4* (note the use of italics). Although *NAT1*3* is also a human gene (an allelic variant), *NAT1*1* and *NAT1*2* are rabbit genes. Similarly, *NAT2*4* is the human wild-type *NAT2* gene, whereas *NAT2*1* is a chicken gene, *NAT2*2* is a rabbit gene, and *NAT2*3* is a rabbit variant (a deleted gene). The official website for maintaining and updating NAT nomenclature is [http://www. louisville.edu/medschool/pharmacology/NAT.html](http://www.louisville.edu/medschool/pharmacology/NAT.html).

In each species examined, NAT1 and NAT2 are closely related proteins (79 to 95 percent identical in amino acid sequence) with an active site cysteine residue (Cys$_{68}$) in the N-terminal region ([Grant et al., 1992](#); [Vatsis et al., 1995](#)). Although they are encoded by intronless genes on the same chromosome, NAT1 and NAT2 are independently regulated proteins: NAT1 is expressed in most tissues of the body—including liver, urinary bladder, colon, mammary gland, lung, kidney, small intestine and pineal gland—whereas NAT2 is mainly expressed in liver and intestine. However, most (but not all) of the tissues that express NAT1 also appear to express low levels of NAT2, at least at the level of mRNA ([Rychter et al., 1999](#)).

NAT1 and NAT2 also have different but overlapping substrate specificities, although no substrate is exclusively N-acetylated by one enzyme or the other. Substrates preferentially N-acetylated by human NAT1 include *para*-aminobenzoic acid (PABA), *para*-aminosalicylic acid, sulfamethoxazole, and sulfanilamide, while substrates preferentially N-acetylated by human NAT2 include isoniazid, hydralazine, procainamide, dapsone, aminoglutethimide, and sulfamethazine. Some xenobiotics, such as the carcinogenic aromatic amine, 2-aminofluorene, are N-acetylated equally well by NAT1 and NAT2.

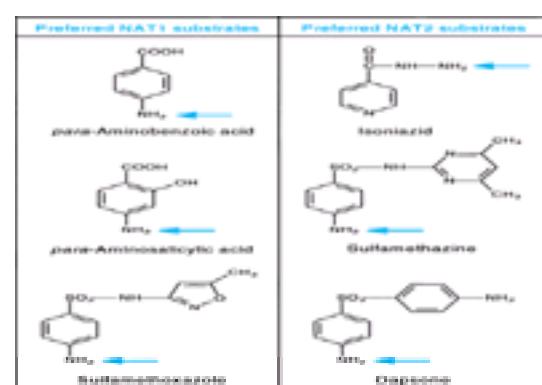
Several drugs are N-acetylated following their biotransformation by phase I enzymes. For example, caffeine is $N3$-demethylated by CYP1A2 to paraxanthine ([Fig. 6-40](#)), which is then N-demethylated to 1-methylxanthine and N-acetylated to 5-acetylamino-6-formylamino-3-methyluracil (AFMU) by NAT2. Other drugs converted to metabolites that are N-acetylated by NAT2 include sulfasalazine, nitrazepam, and clonazepam. Examples of drugs that are N-acetylated by NAT1 and NAT2 are shown in [Fig. 6-52](#). It should be noted, however, that there are species differences in the substrate specificity of N-acetyltransferases. For example, *para*-aminobenzoic acid is preferentially N-acetylated by NAT1 in humans and rabbits but by NAT2 in mice and hamsters.


Figure 6-52. Examples of substrates for the human **N-**acetyltransferases, NAT1, and the highly polymorphic NAT2.*

Genetic polymorphisms for N-acetylation have been documented in humans, hamsters, rabbits, and mice ([Evans, 1992](#); [Grant et al., 1992](#); [Vatsis et al., 1995](#); Hivonen, 1999; Heim et al., 2000). A series of clinical observations in the 1950s established the existence of *slow* and *fast acetylators* of the antitubercular drug isoniazid. The incidence of the slow acetylator phenotype is high in Middle Eastern populations (e.g., ~70 percent in Egyptians, Saudi Arabians, and Moroccans), intermediate in Caucasian populations (~50 percent in Americans, Australians, and Europeans), and low in Asian populations (e.g., <25 percent of Chinese, Japanese, and Koreans).

The slow acetylator phenotype is caused by various mutations in the *NAT2* gene that either decrease NAT2 activity or enzyme stability (at least 26 allelic variants of human *NAT2* have been documented). For example, a point mutation (T ® C) in nucleotide 341 (which causes the amino acid substitution Ile$_{114}$ ® Thr$_{114}$) decreases V_{max} for N-acetylation without altering the K_m for substrate binding or the stability of the enzyme. This mutation (which is the basis for the *NAT2*5* allele) is the most common cause of the slow acetylator phenotype in Caucasians but is rarely observed in Asians. (Note: There are six known *NAT2*5* alleles, designated *NAT2*5A* through *NAT*5F*. The allele containing just the Ile$_{114}$ ® Thr$_{114}$ substitution is *NAT2*5D*. The others contain this and at least one other nucleotide and/or amino acid substitution.) The *NAT2*7* allele is more prevalent in Asians than Caucasians, and involves a point mutation (G ® A) in nucleotide 857 (which causes the amino acid substitution Gly$_{286}$ ® Glu$_{286}$), which decreases the stability, rather than the activity, of NAT2. Within the slow NAT2 acetylator phenotype there is considerable variation in rates of xenobiotic N-acetylation. This is because different mutations in the *NAT2* gene have different effects on NAT2 activity and/or enzyme stability, and because the N-acetylation of "NAT2-substrates" by NAT1 becomes significant in slow acetylators.

NAT1 and NAT2 used to be referred to as *monomorphic* and *polymorphic N*-acetyltransferases because only the latter enzyme was thought to be genetically polymorphic. However, at least 22 allelic variants have now been documented for the human NAT1 gene (almost as many as for the NAT2 gene), although these variants are less prevalent than the NAT2 allelic variants, hence, there is less genetically determined variation in the metabolism of "NAT1 substrates." Nevertheless, there is evidence that phenotypic differences in the N-acetylation of *para*-aminosalicylic acid are distributed bimodally, consistent with the existence of low and high activity forms of NAT1. Furthermore, an extremely slow acetylator of *para*-aminosalicylic acid has been identified with mutations in both *NAT1* alleles; one that decreases NAT1 activity and stability and one that encodes a truncated and catalytically inactive form of the enzyme. The incidence and pharmacologic/toxicologic significance of genetic polymorphisms in *NAT1* that produce phenotypically discernible alterations in NAT1 activity remain to be determined.

Genetic polymorphisms in *NAT2* have a number of pharmacologic and toxicologic consequences for drugs that are *N*-acetylated by this enzyme. The pharmacologic effects of the antihypertensive drug hydralazine are more pronounced in slow NAT2 acetylators. Slow NAT2 acetylators are predisposed to several drug toxicities, including nerve damage (peripheral neuropathy) from isoniazid and dapsone, systemic lupus erythematosus from hydralazine and procainamide, and the toxic effects of coadministration of the anticonvulsant phenytoin with isoniazid. Slow NAT2 acetylators that are deficient in glucose-6-phosphate dehydrogenase are particularly prone to hemolysis from certain sulfonamides. HIV-infected individuals of the slow acetylator phenotype suffer more often from adverse drug events and, among patients with Stevens-Johnson syndrome, the overwhelming majority are slow acetylators. Fast NAT2 acetylators are predisposed to the myelotoxic effects of amonafide because *N*-acetylation retards the clearance of this antineoplastic drug.

Some epidemiologic studies suggest that rapid NAT2 acetylators are at increased risk for the development of isoniazid-induced liver toxicity, although several other studies contradict these findings and provide convincing evidence that slow NAT2 acetylation is a risk modifier for isoniazid-induced hepatotoxicity. Following its acetylation by NAT2, isoniazid can be hydrolyzed to isonicotinic acid and acetylhydrazine ($CH_3CO–NHNH_2$). This latter metabolite can be *N*-hydroxylated by FMO or cytochrome P450 to a reactive intermediate, as shown in [Fig. 6-33*A*]. The generation of a reactive metabolite from acetylhydrazine would seem to provide a mechanistic basis for enhanced isoniazid hepatotoxicity in fast acetylators. However, acetylhydrazine can be further acetylated to diacetylhydrazine ($CH_3CO–NHNH–COCH_3$), and this detoxication reaction is also catalyzed by NAT2. Therefore, acetylhydrazine is both produced and detoxified by NAT2, hence slow acetylation, not fast acetylation, becomes the risk modifier for isoniazid-induced hepatotoxicity, just as it is for isoniazid-induced peripheral neuropathy. Rifampin and alcohol have been reported to enhance the hepatotoxicity of isoniazid. These drug interactions are probably the result of increased *N*-hydroxylation of acetylhydrazine due to cytochrome-P450 induction rather than to an alteration in NAT2 activity.

Isoniazid is an anti-tubercular drug, and its inactivation by NAT2 is interesting from the perspective that several organisms, including *Mycobacterium tuberculosis,* express a NAT2-like enzyme, which has implications for isoniazid-resistance in tuberculosis.

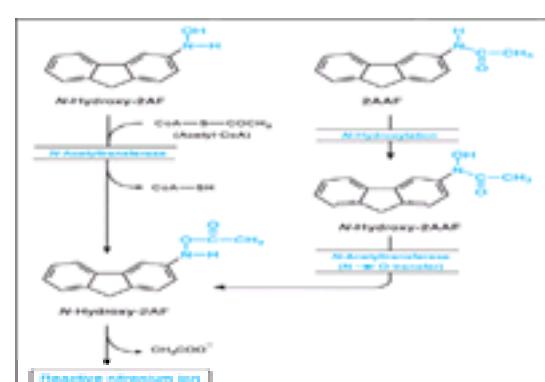
Aromatic amines can be both activated and deactivated by *N*-acetyltransferases ([Kato and Yamazoe, 1994b]; [Hirvonen, 1999]; [Hein et al., 2000]). The *N*-acetyltransferases detoxify aromatic amines by converting them to the corresponding amides because aromatic amides are less likely than aromatic amines to be activated to DNA-reactive metabolites by cytochrome P450, PHS, and UDP-glucuronosyltransferase. However, *N*-acetyltransferases can activate aromatic amines if they are first *N*-hydroxylated by cytochrome P450 because *N*-acetyltransferases can also function as *O*-acetyltransferases and convert *N*-hydroxyaromatic amines (hydroxylamines) to acetoxy esters. As shown in [Fig. 6-9], the acetoxy esters of *N*-hydroxyaromatic amines, like the corresponding sulfate esters ([Fig. 6-50]), can break down to form highly reactive nitrenium and carbonium ions that bind to DNA. *N*-Acetyltransferases catalyze the *O*-acetylation of *N*-hydroxyaromatic amines by two distinct mechanisms. The first reaction, which is exemplified by the conversion of *N*-hydroxyaminofluorene to *N*-acetoxyaminofluorene, requires acetyl-CoA and proceeds by the same mechanism previously described for *N*-acetylation. The second reaction is exemplified by the conversion of 2-acetylaminofluorene to *N*-acetoxyaminofluorene, which does not require acetyl-CoA but involves an intramolecular transfer of the *N*-acetyl group from nitrogen to oxygen. These reactions are shown in [Fig. 6-53].


Figure 6-53. Role of N-*acetyltransferase in the* O-*acetylation of* N-*hydroxy-2-aminofluorene* (N-*hydroxy-2AF) and the intramolecular rearrangement of* N-*hydroxy-2-acetylaminofluorene* (N-*hydroxy-2-AAF).

Genetic polymorphisms in *NAT2* have been reported to influence susceptibility to aromatic amine-induced bladder and colon cancer ([Evans, 1992]; [Kadlubar, 1994]; [Hirvonen, 1999]; [Hein et al., 2000]). Bladder cancer is thought to be caused by bicyclic aromatic amines (benzidine, 2-aminonaphthalene, and 4-aminobiphenyl), whereas colon cancer is thought to be caused by heterocyclic aromatic amines, such as the products of amino acid pyrolysis (e.g., 2-amino-6-methylimidazo[4,5-*b*]pyridine or PhIP, and others listed in [Table 6-6]). Epidemiologic studies suggest that slow NAT2 acetylators are more likely than fast NAT2 acetylators to develop bladder cancer from cigarette smoking and from occupational exposure to bicyclic aromatic amines. The possibility that slow NAT2 acetylators are at increased risk for aromatic amine-induced cancer is supported by the finding that dogs, which are poor acetylators, are highly prone to aromatic amine-induced bladder cancer. By comparison, fast NAT2 acetylators appear to be at increased risk for colon cancer from heterocyclic aromatic amines.

The influence of acetylator phenotype on susceptibility to aromatic amine-induced cancer can be rationalized on the ability of *N*-acetyltransferases to activate and detoxify aromatic amines and by differences in the substrate specificity and tissues distribution of NAT1 and NAT2 (recall that NAT1 is expressed in virtually all tissues, whereas NAT2 is expressed mainly in the liver and intestinal tract). Both NAT1 and NAT2 catalyze the *C*-acetylation (activation) of *N*-hydroxy bicyclic aromatic amines, whereas the *O*-acetylation of *N*-hydroxy heterocyclic aromatic amines is preferentially catalyzed by NAT2. Bicyclic aromatic amines can also be *N*-acetylated (detoxified) by NAT1 and NAT2, but heterocyclic aromatic amines are poor substrates for both enzymes. Therefore, the fast acetylator phenotype protects against aromatic amine-induced bladder cancer because NAT2 (as well as NAT1) catalyzes the *N*-acetylation (detoxication) of bicyclic aromatic amines in the liver. In slow acetylators, a greater proportion of the bicyclic aromatic amines are activated through *N*-hydroxylation by CYP1A2. These *N*-hydroxylated aromatic amines can be activated by *O*-acetylation, which can be catalyzed in the bladder itself by NAT1. Recent evidence suggests that a high level of NAT1 in the bladder is a risk modifier for aromatic amine-induced bladder cancer. In addition, the fast acetylator phenotype potentiates the colon cancer-inducing effects of heterocyclic aromatic amines. These aromatic amines are poor substrates for NAT1 and NAT2, so that high levels of NAT2 in the liver do little to prevent their *N*-hydroxylation by CYP1A2. The *N*-hydroxylated metabolites of heterocyclic aromatic amines can be activated by *O*-acetylation, which can be catalyzed in the colon itself by NAT2. The presence of NAT2 (and NAT1) in the colons of fast acetylators probably explains why this phenotype is a risk modifier for the development of colon cancer.

Whether fast acetylators are protected from or predisposed to the cancer-causing effects of aromatic amines depends on the nature of the aromatic amine (bicyclic vs. heterocyclic) and on other important risk modifiers. For example, CYP1A2 plays an important role in the *N*-hydroxylation of both bicyclic and heterocyclic amines, and high CYP1A2 activity has been shown to be a risk modifier for aromatic amine-induced bladder and colon cancer. A single nucleotide polymorphism in intron 1 of CYP1A2 is associated with high inducibility, and this allelic variant is a risk modifier for bladder cancer in smokers or in people who are slow NAT2 acetylators ([Brockmöller et al., 1998]). It remains to be determined whether the activation of aromatic amines by *N*-glucuronidation and the activation of *N*-hydroxy aromatic amines by sulfation have a similar impact on the incidence of bladder and colon cancer. These and other risk modifiers may explain why some epidemiologic studies, contrary to expectation, have shown that slow NAT2 acetylators are at increased risk for aromatic amine-induced bladder cancer, as was demonstrated recently for benzidine manufacturers in China ([Hayes et al., 1993]).

The *N*-acetylation of aromatic amines (a detoxication reaction) and the *O*-acetylation of *N*-hydroxy aromatic amines (an activation reaction) can be reversed by a microsomal enzyme called arylacetamide deacetylase ([Probst et al., 1994]). This enzyme is similar to but distinct from the microsomal carboxylesterases that hydrolyze esters and amides. Whether arylacetamide deacetylase alters the overall balance between detoxication and activation of aromatic amines remains to be determined.

Overall, it would appear that low NAT2 activity increases the risk of bladder, breast, liver, and lung cancers and decreases the risk of colon cancer, whereas low NAT1 activity increases the risk of bladder and colon cancers and decreases the risk of lung cancer ([Hirvonen, 1999]). The individual risks associated with particular NAT1 and/or NAT2 acetylator genotypes are small, but they increase when considered in conjunction with other susceptibility genes and/or exposure to carcinogenic aromatic and heterocyclic amines. Because of the relatively high frequency of allelic variants of *NAT1* and *NAT2*, the attributable risk of cancer in the population may

be high (Hein et al., 2000).

Amino Acid Conjugation

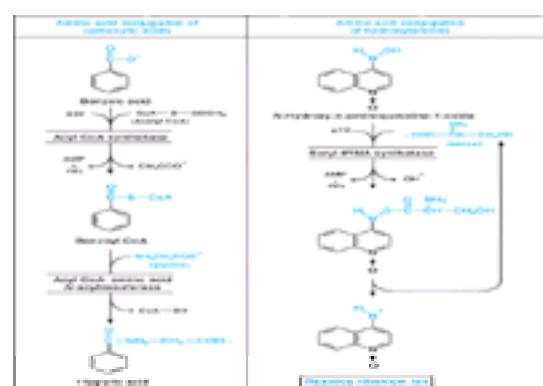
There are two principal pathways by which xenobiotics are conjugated with amino acids, as illustrated in Fig. 6-54. The first involves conjugation of xenobiotics containing a carboxylic acid group with the amino group of amino acids such as glycine, glutamine, and taurine (see Fig. 6-45). This pathway involves activation of the xenobiotic by conjugation with CoA, which produces an acyl-CoA thioether that reacts with the *amino group* of an amino acid to form an amide linkage. The second pathway involves conjugation of xenobiotics containing an aromatic hydroxylamine (*N*-hydroxy aromatic amine) with the *carboxylic acid group* of such amino acids as serine and proline. This pathway involves activation of an amino acid by aminoacyl-tRNA-synthetase, which reacts with an aromatic hydroxylamine to form a reactive *N*-ester (Kato and Yamazoe, 1994b).


Figure 6-54. Conjugation of xenobiotics with amino acids.

The conjugation of benzoic acid with glycine to form hippuric acid was discovered in 1842, making it the first biotransformation reaction discovered (Paulson et al., 1985). The first step in this conjugation reaction involves activation of benzoic acid to an acyl-CoA thioester. This reaction requires ATP and is catalyzed by acyl-CoA synthetase (ATP-dependent acid:CoA ligase). The second step is catalyzed by acyl-CoA:amino acid *N*-acyltransferase, which transfers the acyl moiety of the xenobiotic to the amino group of the acceptor amino acid. The reaction proceeds by a *ping-pong Bi-Bi* mechanism, and involves transfer of the xenobiotic to a cysteine residue in the enzyme with release of coenzyme A, followed by transfer of the xenobiotic to the acceptor amino acid with regeneration of the enzyme. The second step in amino acid conjugation is analogous to amide formation during the acetylation of aromatic amines by *N*-acetyltransferase. Substrates for amino acid conjugation are restricted to certain aliphatic, aromatic, heteroaromatic, cinnamic, and arylacetic acids.

The ability of xenobiotics to undergo amino acid conjugation depends on steric hindrance around the carboxylic acid group, and by substituents on the aromatic ring or aliphatic side chain. In rats, ferrets, and monkeys, the major pathway of phenylacetic acid biotransformation is amino acid conjugation. However, due to steric hindrance, diphenylacetic acid cannot be conjugated with an amino acid, so the major pathway of diphenylacetic acid biotransformation in these same three species is acylglucuronidation. Bile acids are endogenous substrates for glycine and taurine conjugation. However, the activation of bile acids to an acyl-CoA thioester is catalyzed by a microsomal enzyme, cholyl-CoA synthetase, and conjugation with glycine or taurine is catalyzed by a single cytosolic enzyme, bile acid-CoA:amino acid *N*-acyltransferase (Falany et al., 1994). In contrast, the activation of xenobiotics occurs mainly in mitochondria, which appear to contain multiple acyl-CoA synthetases. The second step in the conjugation of xenobiotics with amino acid is catalyzed by cytosolic and/or mitochondrial forms of *N*-acyltransferase. Two different types of *N*-acyltransferases have been purified from mammalian hepatic mitochondria. One prefers benzoyl-CoA as substrate, whereas the other prefers arylacetyl-CoA. Another important difference between the amino acid conjugates of xenobiotics and bile acids is their route of elimination: Bile acids are secreted into bile whereas amino acid conjugates of xenobiotics are eliminated primarily in urine. The addition of an endogenous amino acid to xenobiotics may facilitate this elimination by increasing their ability to interact with the tubular organic anion transport system in the kidney.

In addition to glycine, glutamine, and taurine, acceptor amino acids for xenobiotic conjugation include ornithine, arginine, histidine, serine, aspartic acid, and several dipeptides, such as glycylglycine, glycyltaurine, and glycylvaline. The acceptor amino acid used for conjugation is both species and xenobiotic-dependent. For benzoic, heterocyclic, and cinnamic acids, the acceptor amino acid is glycine, except in birds and reptiles, which use ornithine. Arylacetic acids are also conjugated with glycine except in primates, which use glutamine. In mammals, taurine is generally an alternative acceptor to glycine. Taurine conjugation is well developed in nonmammalian species and carnivores. Whereas most species conjugate bile acids with both glycine and taurine, cats and dogs conjugated bile acids only with taurine. Conjugation of carboxylic acid-containing xenobiotics is an alternative to glucuronidation. Conjugation with amino acids is a detoxication reaction, whereas the glucuronidation of carboxylic acid-containing xenobiotic produces potentially toxic acylglucuronides (see Fig. 6-49). Amino acid conjugation of ibuprofen and related *profens* (2-substituted propionic acid NSAIDs) is significant for two reasons: it limits the formation of potentially toxic acylglucuronides, and it leads to chiral inversion (the interconversion of *R*- and *S*-enantiomers) (Shirley et al., 1994). This latter reaction requires conversion of the profen to its acyl-CoA thioester, which undergoes chiral inversion by 2-arylpropionyl-CoA epimerase (this involves the intermediacy of a symmetrical, conjugated enolate anion). Chiral inversion explains why the *R*- and *S*-enantiomers of several profen NSAIDs have comparable anti-inflammatory effects in vivo, even though the *S*-enantiomers are considerably more potent than their antipodes as inhibitors of cyclooxygenase (the target of NSAID therapy).

In contrast to amino acid conjugation of carboxylic acid-containing xenobiotics, which is a detoxication reaction, amino acid conjugation of *N*-hydroxy aromatic amines (hydroxylamines) is an activation reaction because it produces *N*-esters that can degrade to form electrophilic nitrenium and carbonium ions (Anders, 1985; Kato and Yamazoe, 1994b). Conjugation of hydroxylamines with amino acids is catalyzed by cytosolic aminoacyl-tRNA synthetases and requires ATP (see Fig. 6-54). Hydroxylamines activated by aminoacyl-tRNA synthetases include *N*-hydroxy-4-aminoquinoline 1-oxide, which is conjugated with serine, and *N*-hydroxy-Trp-P-2, which is conjugated with proline. [*N*-hydroxy-Trp-P-2 is the *N*-hydroxylated metabolite of Trp-P-2, a pyrolysis product of tryptophan (see Table 6-6)]. It is now apparent that the hydroxyl-amines formed by the cytochrome P450–dependent *N*-hydroxylation of aromatic amines can potentially be activated by numerous reactions, including *N*-glucuronidation by UDP-glucuronosyltransferase (Fig. 6-49), *O*-acetylation by *N*-acetyltransferase (Fig. 6-9), *O*-sulfation by sulfotransferase (Fig. 6-50), and conjugation with amino acids by seryl- or prolyl-tRNA synthetase (Fig. 6-54).

Glutathione Conjugation

The preceding section described the conjugation of xenobiotics with certain amino acids, including some simple dipeptides, such as glycyltaurine. This section describes the conjugation of xenobiotics with the tripeptide glutathione, which is comprised of glycine, cysteine, and glutamic acid (the latter being linked to cysteine via the g-carboxyl group, not the usual a-carboxyl group, as shown in Fig. 6-45). Conjugation of xenobiotics with glutathione is fundamentally different from their conjugation with other amino acids and dipeptides (Sies and Ketterer, 1988; Mantle et al., 1987). Substrates for glutathione conjugation include an enormous array of electrophilic xenobiotics, or xenobiotics that can be biotransformed to electrophiles. In contrast to the amides formed by conjugation of xenobiotics to other amino acids, glutathione conjugates are thioethers, which form by nucleophilic attack of glutathione thiolate anion (GS⁻) with an electrophilic carbon atom in the xenobiotic. Glutathione can also conjugate xenobiotics containing electrophilic heteroatoms (*O*, *N*, and *S*).

The synthesis of glutathione involves formation of the peptide bond between cysteine and glutamic acid, followed by peptide bond formation with glycine. The first reaction is catalyzed by g-glutamylcysteine synthetase; the second by glutathione synthetase. At each step, ATP is hydrolyzed to ADP and inorganic phosphate. The first reaction is inhibited by buthionine-*S*-sulfoximine, which can be used in vivo to decrease glutathione levels in experimental animals. The conjugation of xenobiotics with glutathione is catalyzed by a family of glutathione *S*-transferases. These enzymes are present in most tissues, with high concentrations in the liver, intestine, kidney, testis, adrenal, and lung, where they are localized in the cytoplasm (> 95 percent) and endoplasmic reticulum (<5 percent).

Substrates for glutathione *S*-transferase share three common features: they are hydrophobic, they contain an electrophilic atom, and they react nonenzymatically with glutathione at some measurable rate. The mechanism by which glutathione *S*-transferase increases the rate of glutathione conjugation involves deprotonation of GSH to GS⁻ by an active site tyrosinate (Tyr-O⁻), which functions as a general base catalyst (Atkins et al., 1993; Dirr et al., 1994). The concentration of glutathione in liver is extremely high (~10 mM); hence, the nonenzymatic conjugation of certain xenobiotics with glutathione can be significant. However, some xenobiotics are conjugated with glutathione stereoselectively, indicating that the reaction is largely catalyzed by glutathione *S*-transferase. Like glutathione, the glutathione

S-transferases are themselves abundant cellular components, accounting for up to 10 percent of the total cellular protein. These enzymes bind, store, and/or transport a number of compounds that are not substrates for glutathione conjugation. The cytoplasmic protein formerly known as ligandin, which binds heme, bilirubin, steroids, azo-dyes and polycyclic aromatic hydrocarbons, is glutathione *S*-transferase.

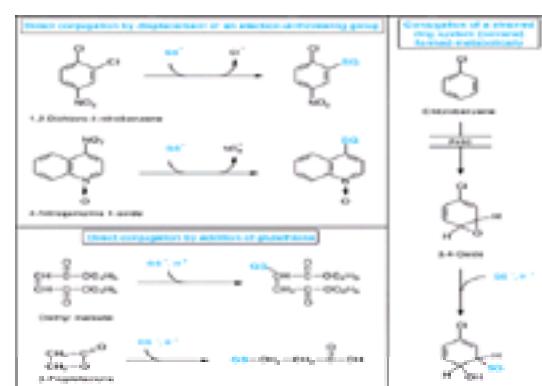
As shown in Fig. 6-55, substrates for glutathione conjugation can be divided into two groups: those that are sufficiently electrophilic to be conjugated directly, and those that must first be biotransformed to an electrophilic metabolite prior to conjugation. The second group of substrates for glutathione conjugation includes reactive intermediates produced during phase I or phase II biotransformation, and include oxiranes (arene oxides and alkene epoxides), nitrenium ions, carbonium ions, and free radicals. The conjugation reactions themselves can be divided into two types: *displacement reactions,* in which glutathione displaces an electron-withdrawing group, and *addition reactions,* in which glutathione is added to an activated double bond or strained ring system.


Figure 6-55. Examples of glutathione conjugation of xenobiotics with an electrophilic carbon.

GS⁻ represents the anionic form of glutathione.

The displacement of an electron-withdrawing group by glutathione typically occurs when the substrate contains halide, sulfate, sulfonate, phosphate, or a nitro group (i.e., good *leaving groups*) attached to an allylic or benzylic carbon atom. Displacement of an electron-withdrawing group from aromatic xenobiotics is decreased by the presence of other substituents that donate electrons to the aromatic ring ($-NH_2$, $-OH$, $-OR$, and $-R$). Conversely, such displacement reactions are increased by the presence of other electron-withdrawing groups ($-F$, $-Cl$, $-Br$, $-I$, $-NO_2$, $-CN$, $-CHO$, and $-COOR$). This explains why 1,2-dichloro-4-nitrobenzene and 1-chloro-2,4-dinitrobenzene, each of which contains three electron-withdrawing groups, are commonly used as substrates for measuring glutathione *S*-transferase activity in vitro. Glutathione *S*-transferase can catalyze the *O*-demethylation of dimethylvinphos and other methylated organophosphorus compounds. The reaction is analogous to the interaction between methyliodide and glutathione, which produces methylglutathione and iodide ion ($GS^- + CH_3I \circledR GS–CH_3 + I^-$). In this case, iodide is the leaving group. In the case of dimethylvinphos, the entire organophosphate molecule (minus the methyl group) functions as the leaving group.

The addition of glutathione to a carbon–carbon double bond is also facilitated by the presence of a nearby electron-withdrawing group, hence, substrates for this reaction typically contain a double bond attached to $-CN$, $-CHO$, $-COOR$, or $-COR$. The double bond in diethyl maleate is attached to two electron-withdrawing groups and readily undergoes a Michael addition reaction with glutathione, as shown in Fig. 6-55. Diethyl maleate reacts so well with glutathione that it is often used in vivo to decrease glutathione levels in experimental animals. The loop diuretic ethacrynic acid contains an a/b-unsaturated ketone that readily reacts with glutathione and other sulfhydryls by Michael addition. The conversion of acetaminophen to a glutathione conjugate involves addition of glutathione to an activated double bond, which is formed during the cytochrome P450–dependent dehydrogenation of acetaminophen to *N*-acetylbenzoquinoneimine, as shown in Fig. 6-28.

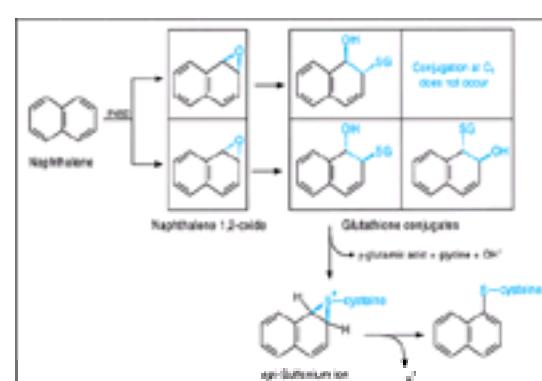
Arene oxides and alkene epoxides, which are often formed by cytochrome P450–dependent oxidation of aromatic hydrocarbons and alkenes, are examples of strained ring systems that open during the addition of glutathione (Fig. 6-55). In many cases, conjugation of arene oxides with glutathione proceeds stereoselectively, as shown in Fig. 6-56 for the 1,2-oxides of naphthalene. The glutathione conjugates of arene oxides may undergo rearrangement reactions, which restore aromaticity and possibly lead to migration of the conjugate to the adjacent carbon atom (through formation of an episulfonium ion), as shown in Fig. 6-56. Conjugation of quinones and quinoneimines with glutathione also restores aromaticity, as shown in Fig. 6-28 for *N*-acetylbenzoquinoneimine, the reactive metabolite of acetaminophen. Compared with glucuronidation and sulfation, conjugation with glutathione is a minor pathway of acetaminophen biotransformation, even though liver contains high levels of both glutathione and glutathione *S*-transferases. The relatively low rate of glutathione conjugation reflects the slow rate of formation of *N*-acetylbenzoquinoneimine, which is catalyzed by cytochrome P450 (Fig. 6-28).


Figure 6-56. Stereoselective conjugation of naphthalene 1,2-oxide and rearrangement of 2-naphthyl to 1-naphthyl conjugates.

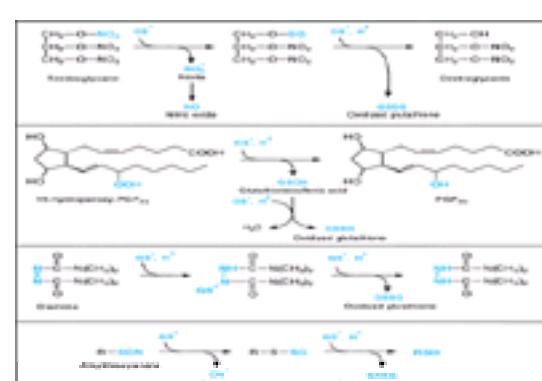
Glutathione can also conjugate xenobiotics with an electrophilic heteroatom (*O*, *N*, and *S*), as shown in Fig. 6-57. In each of the examples shown in Fig. 6-57, the initial conjugate formed between glutathione and the heteroatom is cleaved by a second molecule of glutathione to form oxidized glutathione (GSSG). The initial reactions shown in Fig. 6-57 are catalyzed by glutathione *S*-transferase, whereas the second reaction (which leads to GSSG formation) generally occurs nonenzymatically. Analogous reactions leading to the reduction and cleavage of disulfides have been described previously (see Fig. 6-11). Some of the reactions shown in Fig. 6-57, such as the reduction of hydroperoxides to alcohols, can also be catalyzed by glutathione peroxidase, which is a selenium-dependent enzyme. (For their role in the reduction of hydroperoxides, the glutathione *S*-transferases are sometimes called nonselenium-requiring glutathione peroxidases.) Cleavage of the nitrate esters of nitroglycerin releases nitrite, which can be converted to the potent vasodilator, nitric oxide. The ability of sulfhydryl-generating agents to partially prevent or reverse tolerance to nitroglycerin suggests that glutathione-dependent denitration may play a role in nitroglycerin-induced vasodilation.


Figure 6-57. Examples of glutathione conjugation of electrophilic heteroatoms.

Glutathione S-transferases catalyze two important isomerization reactions, namely the conversion of the endoperoxide, PGH_2, to the prostaglandins PGD_2 and PGE_2, and the conversion of D^5 steroids to D^4 steroids, such as the formation of androstenedione from androst-5-ene-3,17-dione. Another physiologic function of glutathione S-transferase is the synthesis of leukotriene C_4, which is catalyzed by a microsomal form of the enzyme.

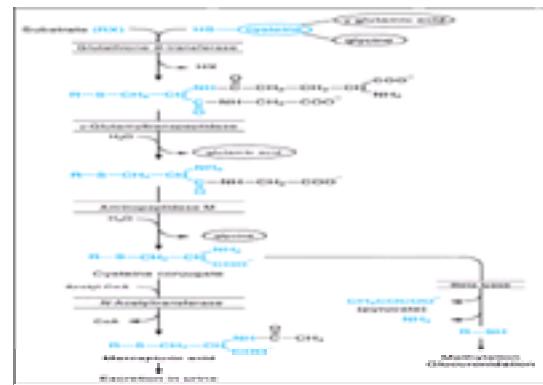
Glutathione conjugates formed in the liver can be excreted intact in bile, or they can be converted to mercapturic acids in the kidney and excreted in urine. As shown in Fig. 6-58, the conversion of glutathione conjugates to mercapturic acids involves the sequential cleavage of glutamic acid and glycine from the glutathione moiety, followed by N-acetylation of the resulting cysteine conjugate. The first two steps in mercapturic acid synthesis are catalyzed by g-glutamyltranspeptidase and aminopeptidase M. The glutathione conjugate, leukotriene C_4, is similarly hydrolyzed by g-glutamyltranspeptidase to form leukotriene D_4, which is hydrolyzed by aminopeptidase M to form leukotriene E_4. Glutathione S-transferases are dimers composed of identical subunits (Mr 23 to 29 kDa), although some forms are heterodimers. Each subunit contains 200 to 240 amino acids and one catalytic site. Numerous subunits have been cloned and sequenced, which forms the basis of a nomenclature system for naming the glutathione S-transferases (Mannervick et al., 1992; Hayes and Pulford, 1995; Whalen and Boyer, 1998). Each enzyme is assigned a two-digit number to designate its subunit composition. For example, the homodimers of subunits 1 and 2 are designated 1-1 and 2-2, respectively, whereas the heterodimer is designated 1-2. The soluble glutathione S-transferases were initially arranged into four classes designated A, M, P, and T (which refer to alpha, mu, pi, and theta or a, μ, p, and q). More recently, three additional classes have been identified, namely K (kappa), S (sigma), and Z (zeta) (Hayes and Pulford, 1995; Whalen and Boyer, 1998; Strange et al., 2000). None of these seven gene classes corresponds to the microsomal glutathione S-transferase, which appears to have evolved independently. By definition, the subunits in the different classes share less than 40 percent amino acid identity. Generally, the subunits within a class are ~70 percent identical and can form heterodimers, whereas the subunits in different classes are only ~30 percent identical, which appears to prevent dimerization of two subunits from different classes.


Figure 6-58. Glutathione conjugation and mercapturic acid biosynthesis.

Humans express four subunits belonging to the alpha class of glutathione S-transferases, designated hGSTA1 to hGSTA4. Rats express at lease five, and possibly as many as eight, GSTA subunits. The first five alpha subunits are known as rGSTA1 to rGSTA5, which are also known as Ya $_1$, Ya$_2$, Yc$_1$, Yk (or Ya), and Yc$_2$. Rat GSTA1 and GSTA2 are also known as ligandin. Members of the alpha class of glutathione S-transferases have basic isoelectric points. They are the major glutathione S-transferases in liver and kidney.

Humans express six subunits belonging to the mu class of glutathione S-transferases, designated hGSTM1a, –M1b, –M2, –M3, –M4, and –M5. The first two subunits are allelic variants that differ by a single amino acid; hGSTM1a is a "basic variant" with lysine at residue 173, whereas hGSTM1b is an "acidic variant" with asparagine at the corresponding site. Rats express six subunits, designated rGSTM1 to rGSTM6. Rat M1, M2, M3, and M4 are also known as Yb $_1$, Yb$_2$, Yb$_3$, and Yb$_4$. Members of the mu class of glutathione S-transferases have neutral isoelectric points. Human GSTM2 and M3 are expressed in muscle and brain, respectively.

Humans express two subunits belonging to the pi class of glutathione S-transferases (hGSTP1a and hGSTP1b), whereas rats express only one subunit (rGSTP1). The two human pi enzymes are allelic variants that differ by a single amino acid (Ile $_{105}$ in hGSTP1a, and Val$_{105}$ in hGSTP1b). However, hGSTP1b is seven times more active that hGST1a in conjugating diol epoxides of polycyclic aromatic hydrocarbons (Strange et al., 2000). Members of the pi class of glutathione S-transferases have acidic isoelectric points. They are expressed in the placenta, lung, gut, and other extrahepatic tissues. In rats, GSTP1 is one of several preoplastic antigens that are overexpressed in chemical-induced tumors.

Humans appear to express two subunits belonging to the theta class of glutathione S-transferases (hGSTT1 and hGSTT2), whereas rats appear to express three subunits (rGSTT1 to rGSTT3). A single kappa and single zeta subunit are expressed in humans, but not rats, and are subunits for hGSTK1 and hGSTZ1, respectively. In contrast, a single sigma subunit is expressed in rats, but not humans, and is the subunit for rGSTS1. Alternative names for all glutathione S-transferase subunits are summarized in Hayes and Pulford (1995), along with information on their substrate specificity and tissue distribution. The microsomal glutathione S-transferases are distinct from the soluble enzymes. Two microsomal glutathione S-transferases have been identified: one is a trimeric enzyme that conjugates xenobiotics with glutathione, the other is a distinct enzyme that conjugates leukotriene A $_4$ (a lipid epoxide derived of arachidonic acid) with glutathione to form leukotriene C$_4$. This latter enzyme is known as leukotriene C $_4$ synthase.

The conjugation of certain xenobiotics with glutathione is catalyzed by all classes of glutathione S-transferase. For example, the alpha, mu, and pi classes of human glutathione S-transferase all catalyze the conjugation of 1-chloro-2,4-dinitrobenzene. Other reactions are fairly specific for one class of enzymes (Hayes and Pulford, 1995). For example, the alpha glutathione S-transferases preferentially isomerize D^5 steroids to D^4 steroids and reduce linoleate and cumene hydroperoxide to their corresponding alcohols. The mu glutathione S-transferases preferentially conjugate certain arene oxides and alkene epoxides, such as styrene-7,8-epoxide. The pi glutathione S-transferases preferentially conjugate ethacrynic acid. However, individual members within a class of glutathione S-transferases can differ markedly in their substrate specificity. In mice, for example, the alpha glutathione S-transferases comprised of Yc subunits (mGSTA3-3) can rapidly conjugate aflatoxin B $_1$ 8,9-epoxide, whereas those comprised of Ya subunits (GSTA1-1) are virtually incapable of catalyzing this reaction (Eaton and Gallagher, 1994).

In rodents, individual members of the alpha and mu class of glutathione S-transferases are inducible (generally 2- to 3-fold) by 3-methylcholanthrene, phenobarbital, corticosteroids, oltipraz and various antioxidants (such as ethoxyquin and butylated hydroxyanisole). Several glutathione S-transferase substrates (i.e., Michael acceptors) are glutathione S-transferase inducers, as are certain nonsubstrates, such as hydrogen peroxide and other reactive oxygen species (Rushmore et al., 1991; Daniel, 1993; Nguyen et al., 1994; Hayes and Pulford, 1995). Induction is usually associated with increased levels of mRNA due to transcriptional activation of the gene encoding a subunit of glutathione S-transferase. Not all subunits are induced to the same extent. Treatment of rats with xenobiotics generally increases the hepatic concentration of rGSTA2 and M1 subunits to a greater extent than the rGSTA1 and A3 subunits, which in turn are induced more than rGSTA4 and M2. The rat GSTA5 and P1, which are constitutively expressed at low levels in adult rat liver, are dramatically induced by ethoxyquin and coumarin, respectively.

The enhancer regions of the genes encoding some of the rodent glutathione S-transferases (such as rGSTA2-2) have been shown to contain a xenobiotic (dioxin)-responsive element (XRE), a putative phenobarbital-responsive element, a glucocorticoid-responsive element (GRE), and an antioxidant responsive element (ARE, which is also known as the electrophile-responsive element, or EpRE). Accordingly, in rodents, certain glutathione S-transferase subunits, such as rGSTA1 (Ya$_1$) and rGSTA1 (Ya$_2$), are regulated by both *monofunctional* and *bifunctional* agents, as described previously for DT-diaphorase (see "Quinone Reduction" and "Induction of Cytochrome P450," above). Induction of glutathione S-transferases by the monofunctional agent sulforaphane is thought to be responsible, at least in part, for the anticancer effects of broccoli (Zhang et al., 1992). It remains to be determined whether factors that regulate the expression of glutathione S-transferases in rodents have similar effects in humans, but some differences have been noted. For example, the 5' promoter region of alpha glutathione S-transferase in humans (hGSTA1) lacks the ARE and XRE consensus sequences through which the corresponding rat enzyme is induced. However, such sequences appear to be present in

the promoter region of human GSTM4 and GSTP1 genes (Hayes and Pulford, 1995; Whalen and Boyer, 1998). [A functional ARE is also present in the promoter region of human DT-diaphorase (NQO1)]. Therefore, certain subunits of glutathione *S*-transferases are inducible by a variety of mechanisms in rats, and other subunits appear to be inducible by similar mechanisms in humans. Species differences in glutathione *S*-transferase regulation may also stem from differences in xenobiotic biotransformation, especially differences in the formation of electrophiles, Michael acceptors and/or the production of oxidative stress. For example, coumarin is thought be an inducer of GSTP1 in rats because it is converted in rat liver to reactive metabolites, namely coumarin 2,3-epoxide and *ortho*-hydroxyphenylacetaldehyde (see Fig. 6-38). In contrast, the major route of coumarin biotransformation in humans is by 7-hydroxylation, which would not be expected to be associated with glutathione *S*-transferase induction.

Conjugation with glutathione represents an important detoxication reaction because electrophiles are potentially toxic species that can bind to critical nucleophiles, such as proteins and nucleic acids, and cause cellular damage and genetic mutations. All of the enzymes involved in xenobiotic biotransformation have the potential to generate reactive intermediates, most of which are detoxified to some extent by conjugation with glutathione. Glutathione is also a cofactor for glutathione peroxidase, which plays an important role in protecting cells against lipid peroxidation. Resistance to toxic compounds is often associated with an over-expression of glutathione *S*-transferase. Examples include the resistance of insects to DDT (see Fig. 6-18), of corn to atrazine, and of cancer cells to chemotherapeutic agents.

Glutathione *S*-transferase is the major determinant of certain species differences in chemical-induced toxicity. For example, low doses of aflatoxin B$_1$ cause liver toxicity and tumor formation in rats but not mice, even though rats and mice convert aflatoxin B$_1$ to the highly reactive 8,9-epoxide at similar rates (this reaction is shown in Fig. 6-27). This species difference arises because mice express high levels of an alpha class glutathione *S*-transferase (mGSTA3-3 or Yc) enabling them to conjugate aflatoxin B$_1$ 8,9-epoxide with glutathione up to fifty times faster than rats (or humans, which are also considered a susceptible species) (Eaton and Gallagher, 1994). Mice become sensitive to the adverse effects of aflatoxin B$_1$ following treatment with agents that decrease glutathione levels, such as diethyl maleate (which depletes glutathione) or buthionine- *S*-sulfoximine (which inhibits glutathione synthesis). Conversely, treatment of rats with inducers of glutathione *S*-transferase (rGSTA5-5 or Yc$_2$), such as ethoxyquin, BHA, oltipraz, and phenobarbital, protects them from the hepatotoxic/tumorigenic action of aflatoxin B$_1$ (Hayes et al., 1994).

The conjugation of aflatoxin B$_1$ 8,9-epoxide with glutathione provides an interesting example of the stereospecificity with which certain glutathione conjugation reactions can occur. Cytochrome P450 converts aflatoxin B$_1$ to a mixture of *exo*- and *endo*-8,9-epoxides (only a generic 8,9-epoxide is shown in Fig. 6-27; meaning the figure does not indicate whether the oxygen atom is above or below the plane of the ring system). Both enantiomeric epoxides are formed by liver microsomes from mice, rats and humans, but only the *exo*-epoxide binds extensively to DNA (where it binds to the N^7 position of guanine). Mouse alpha-GST (mGSTA3-3) rapidly conjugates the *exo*-epoxide, which accounts for the resistance of this species to aflatoxin-induced hepatotoxicity and tumorigenicity (as described above). Rat and human alpha-glutathione *S*-transferases do not rapidly conjugate either the *exo*- or the *endo*- epoxide (with the exception of the inducible rat glutathione *S*-transferase [A5-5], which is not constitutively expressed in rats to any great extent). However, human mu-GSTs (hGSTM1a-1a and hGSTM2-2) can conjugate aflatoxin B$_1$ 8,9-epoxide, but they preferentially conjugate the relatively innocuous *endo*-isomer (Wang et al., 2000).

Species differences in the detoxication of aflatoxin B$_1$ 8,9-epoxide suggest that individual differences in glutathione *S*-transferase may determine susceptibility to the toxic effects of certain chemicals. In support of this interpretation, a genetic polymorphism for hGSTM1 has been identified, and individuals who are homozygous for the null allele (i.e., those with low glutathione *S*-transferase activity due to complete deletion of the GSTM1 gene) appear to be at increased risk for cigarette smoking–induced lung cancer and bladder cancer (Hayes and Pulford, 1995; Whalen and Boyer, 1998; Strange et al., 2000). Depending on the ethnic group, 22 to 100 percent of the population are homozygous for the GSTM1 null genotype, which results in a complete lack of GSTM1 activity in all tissues. Similarly, theta GST activity is absent from 11 to 58 percent of the population (depending on ethnicity) due to deletion of the GSTT1 gene, which appears to increase susceptibility to development of astrocytoma, meningioma and myelodysplasia. When examined for their individual effect, these null genotypes generally have a small effect on susceptibility, with an odds ratio of 2 or less. However, the odds ratio can increase dramatically when these null glutathione *S*-transferase genotypes are examined in conjunction with other genotypes or with environmental factors (such as exposure to carcinogens). For example, when the GSTM1 null genotype is combined with cigarette smoking and a particular CYP1A1 allele, the odds ratio can increase to 8.9 (in one study) or 21.9 (in another study). Polymorphisms that result in amino substitutions have been reported for most human glutathione *S*-transferase genes; some of which alter glutathione *S*-transferase function. Some of these polymorphisms may also be risk modifiers for certain diseases in an analogous manner to the GSTM1 and GSTT1 null genotypes.

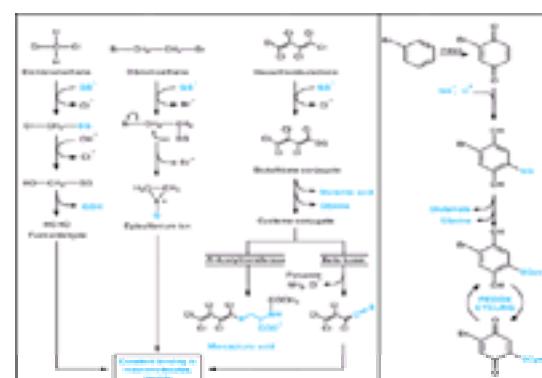
In some cases, conjugation with glutathione enhances the toxicity of a xenobiotic (Monks et al., 1990; Dekant and Vamvakas, 1993). Four mechanisms of glutathione-dependent activation of xenobiotics have been identified, as shown in Fig. 6-59. These mechanisms are (1) formation of glutathione conjugates of haloalkanes, organic thiocyanates, and nitrosoguanides that release a toxic metabolite; (2) formation of glutathione conjugates of vicinal dihaloalkanes that are inherently toxic because they can form electrophilic sulfur mustards; (3) formation of glutathione conjugates of halogenated alkenes that are degraded to toxic metabolites by b-lyase in the kidney; and (4) formation of glutathione conjugates of quinones, quinoneimines, and isothiocyanates that are degraded to toxic metabolites by g-glutamyltranspeptidase and endopeptidase M in the kidney.


Figure 6-59. Role of glutathione conjugation in the activation of xenobiotics to toxic metabolites.

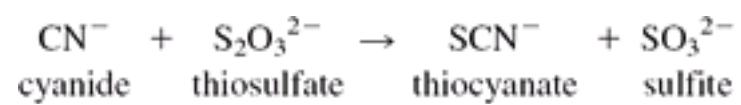
The first mechanism is illustrated by dichloromethane, which is conjugated with glutathione to form chloromethyl-glutathione, which then breaks down to formaldehyde. Both formaldehyde and the glutathione conjugate are reactive metabolites, and either or both may be responsible for dichloromethane-induced tumorigenesis in sensitive species. The rate of conjugation of dichloromethane with glutathione is considerably faster in mice, which are susceptible to dichloromethane-induced tumorigenesis, than in rats or hamsters, which are resistant species.

The second mechanism accounts for the toxicity of dichloroethane and dibromoethane. These vicinal dihaloalkanes are converted to glutathione conjugates that can rearrange to form mutagenic and nephrotoxic episulfonium ions (sulfur half-mustards) (Fig. 6-59). Dichloroethane and dibromoethane can also be oxidized by cytochrome P450 to chloroacetaldehyde and bromoacetaldehyde (by reactions analogous to those shown in Fig. 6-44). Either pathway can potentially account for the toxic and tumorigenic effects of these dihaloalkanes. However, the toxicity and DNA-binding of dihaloalkanes are increased by factors that decrease their oxidation by cytochrome P450 and increase their conjugation with glutathione.


The third mechanism accounts for the nephrotoxicity of several halogenated alkenes. Several halogenated alkenes, such as hexachlorobutadiene, cause damage to the kidney tubules in rats, which leads to carcinoma of the proximal tubules. These nephrotoxic halogenated alkenes are conjugated with glutathione and transported to the kidney for processing to mercapturic acids. The cysteine conjugates, which form by removal of glutamic acid and glycine, are substrates for *N*-acetyltransferase, which completes the synthesis of mercapturic acids, and b-lyase, which removes pyruvate and ammonia from the cysteine conjugate to produce thionylacyl halides and thioketenes. The early damage to renal mitochondria caused by halogenated alkenes is prob-ably because cysteine-conjugate b-lyase is a mitochondrial enzyme.

The fourth mechanism accounts for the nephrotoxicity of bromobenzene, which causes damage to the proximal tubules in rats. Bromobenzene is oxidized by cytochrome P450 in the liver to bromohydroquinone, which is conjugated with glutathione and transported to the kidney (Fig. 6-59). The glutathione conjugate is converted to the cysteine derivative by g-glutamyltranspeptidase and aminopeptidase M. Substitution of bromohydroquinones with cysteine lowers their redox

potential and thereby facilitates their oxidation to toxic quinones. The cysteine conjugates of bromohydroquinone are thought to undergo redox cycling and cause kidney damage through the generation of reactive oxygen species. 4-Aminophenol is thought to cause kidney damage by a similar mechanism, except a benzoquinoneimine is involved in conjugation with glutathione and subsequent damage to proximal tubules of the kidney. Treatment of rats with the glutathione depletor, buthionine- S-sulfoximine, protects them against the nephrotoxic effects of 4-aminophenol, which implicates glutathione conjugation in the activation of this compound.

Rhodanese

Rhodanese is a mitochondrial enzyme that converts cyanide to the far less toxic metabolite, thiocyanate. The reaction involves transfer of sulfur from thiosulfate (or another sulfur donor) as follows:

$$\underset{\text{cyanide}}{CN^-} \quad + \quad \underset{\text{thiosulfate}}{S_2O_3^{2-}} \quad \rightarrow \quad \underset{\text{thiocyanate}}{SCN^-} \quad + \quad \underset{\text{sulfite}}{SO_3^{2-}}$$

The sulfite produced by this reaction can be converted to sulfate by the molybdozyme, sulfite oxidase. Cyanide can also be "detoxified" by binding to methemoglobin (the oxidized or ferric form of hemoglobin). 4-Dimethylaminophenol is used to induce methemoglobinemia as an antidote to cyanide poisoning because methemoglobin competes with cytochrome oxidase for the cyanide ion. However, 4-dimethylaminophenol is nephrotoxic to rats, presumably by a mechanism similar to that described above for the structural analog, 4-aminophenol (see preceding section and section on " Peroxidase-Dependent Cooxidation").

Phosphorylation—The Dog That Did Not Bark

All phase II conjugation reactions ultimately require ATP, either to activate the xenobiotic for conjugation with glutathione or amino acids or to synthesize high-energy cofactors such as UDP-glucuronic acid and PAPS. The process is inefficient in that several ATP molecules (or their equivalent) are used to synthesize each cofactor molecule. The question arises: Why is ATP not used directly by phase II enzymes? In other words, why are xenobiotics never phosphorylated, which would require less ATP and would achieve the goal of converting xenobiotics to water-soluble conjugates? It is difficult to be certain why this does not occur, but three reasons suggest themselves. First, if xenobiotics could be phosphorylated, high intracellular levels of a xenobiotic might consume so much ATP as to jeopardize cell viability, whereas UDP-glucuronic acid and PAPS can be depleted without killing cells. Second, phosphorylation of endogenous substrates, such as glucose, is a mechanism for trapping endogenous substrates in a cell. This works because the plasmamembrane of all cells is a barrier to the passage of polar compounds by virtue of its hydrophobic properties (lipid bilayer) and its lack of transporters that pump phosphorylated compounds out of the cell. A lipid bilayer is also a physical barrier to other water-soluble conjugates, such as glucuronides and sulfates, but these are transported out of the cell by various transporters. Third, phosphorylation of both small molecules (such as inositol) and proteins (such as membrane-bound receptors and various transcription factors) plays an important role in intracellular and intranuclear signaling. It is possible that some xenobiotics, if they were phosphorylated, might interfere with these regulatory systems and thereby disrupt cellular homeostasis. Whatever the reason, there appears to be strong evolutionary pressure against the conjugation of xenobiotics with phosphoric acid.

CHAPTER 7

TOXICOKINETICS

Michele A. Medinsky and John L. Valentine

INTRODUCTION

The study of the kinetics of chemicals was originally initiated for drugs and consequently was termed *pharmacokinetics.* However, toxicology is not limited to the study of adverse drug effects but entails an investigation of the deleterious effects of all chemicals. Therefore, the study of the kinetics of xenobiotics is more properly called *toxicokinetics.* Toxicokinetics refers to the modeling and mathematical description of the time course of disposition (absorption, distribution, biotransformation, and excretion) of xenobiotics in the whole organism. The classic way to describe the kinetics of drugs is to represent the body as consisting of one or two compartments even if those compartments have no apparent physiologic or anatomic reality. An alternate approach, physiologically based toxicokinetics, represents the body as a series of mass balance equations that describe each organ or tissue on the basis of physiologic considerations. It should be emphasized that there is no inherent contradiction between the classic and physiologically based approaches. Classic pharmacokinetics, as will be shown, requires certain assumptions that the physiologically based models do not require. Under ideal conditions, physiologic models can predict tissue concentrations, whereas classic models cannot. However, the values of the appropriate parameters are often unknown or inexact, hampering meaningful physiologically based toxicokinetic modeling.

CLASSIC TOXICOKINETICS

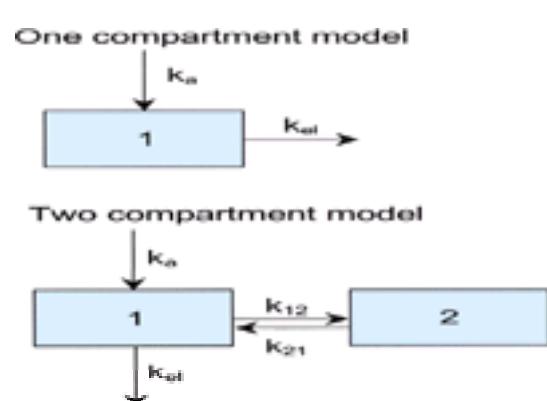
Often, it is difficult to obtain relevant biological tissues in order to ascertain a chemical or chemical concentration in the body and then relate that chemical concentration to a toxicologic response. The least invasive and simplest method to gather information on absorption, distribution, metabolism, and elimination of a compound is by sampling blood or plasma over time. If one assumes that the concentration of a compound in blood or plasma is in equilibrium with concentrations in tissues, then changes in plasma chemical concentrations reflect changes in tissue chemical concentrations, and relatively simple pharmacokinetic models can adequately describe the behavior of that chemical in the body. Compartmental pharmacokinetic models consist of a central compartment representing plasma and tissues that rapidly equilibrate with chemical, connected to one or more peripheral compartments that represent tissues that more slowly equilibrate with chemical (Fig. 7-1). Chemical is administered into the central compartment and distributes between central and peripheral compartments. Chemical elimination occurs from the central compartment, which is assumed to contain rapidly perfused tissues capable of eliminating chemical (e.g., kidneys and liver). Advantages of compartmental pharmacokinetic models are that they require no information on tissue physiology or anatomic structure. These models are valuable in predicting the plasma chemical concentrations at different doses, in establishing the time course of chemical in plasma and tissues and the extent of chemical accumulation with multiple doses, and in determining effective dose and dose regimens in toxicity studies (Gibaldi and Perrier, 1982).


Figure 7-1. Compartmental pharmacokinetic models where k_a is the first-order extravascular absorption rate constant into the central compartment (1), k_{ei} is the first-order elimination rate constant from the central compartment (1), and k_{12} and k_{21} are the first-order rate constants for distribution of chemical into and out of the peripheral compartment (2) in a two-compartment model.

One-Compartment Model

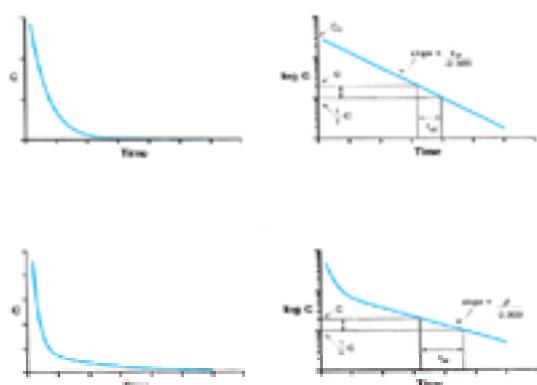
The simplest toxicokinetic analysis entails measurement of the plasma concentrations of a xenobiotic at several time points after the administration of a bolus intravenous injection. If the data obtained yield a straight line when they are plotted as the logarithms of plasma concentrations versus time, the kinetics of the xenobiotic can be described with a one-compartment model (Fig. 7-2). Compounds whose toxicokinetics can be described with a one-compartment model rapidly equilibrate, or mix uniformly, between blood and the various tissues relative to the rate of elimination. The one-compartment model depicts the body as a homogeneous unit. This does not mean that the concentration of a compound is the same throughout the body, but it does assume that the changes that occur in the plasma concentration reflect proportional changes in tissue chemical concentrations (Rowland and Tozer, 1980).


Figure 7-2. Concentration versus time curves of chemicals exhibiting behavior of a one-compartment pharmacokinetic model (top) *and a two-compartment pharmacokinetic model (bottom) on a linear scale* (left) *and a semilogarithmic scale* (right).

Elimination rate constants, k_{ei} and b are determined from the slope of the log-linear concentration versus time curve. Half-life ($T_{1/2}$) is the time required for blood or plasma chemical concentration to decrease by one-half. C_{ζ} is the concentration of the chemical at t = 0 determined by extrapolating the log-linear concentration time curve to the Y-axis (t = 0).

In the simplest case, a curve of this type can be described by the expression

$$C = C_0 \times e^{-k_{el} \times t}$$

where *C* is the blood or plasma chemical concentration over time t, C_0 is the initial blood concentration at time $t = 0$, and k_{ei} is the first-order elimination rate constant with dimensions of reciprocal time (e.g., t^{-1}).

Two-Compartment Model

After the rapid intravenous administration of some chemicals, the semilogarithmic plot of plasma concentration versus time does not yield a straight line but a curve that implies more than one dispositional phase. In these instances, the chemical requires a longer time for its concentration in tissues to reach equilibrium with the concentration in plasma, and a multicompartmental analysis of the results is necessary (Fig. 7-2). A multiexponential mathematical equation then best characterizes the elimination of the xenobiotic from the plasma.

Generally, a curve of this type can be resolved into two monoexponential terms (a two-compartment model) and is described by

$$C = A \times e^{-\alpha \times t} + B \times e^{-\beta \times t}$$

where *A* and *B* are proportionality constants and a and b are the first-order distribution and elimination rate constants, respectively (Fig. 7-2). During the distribution (a) phase, concentrations of the chemical in the plasma decrease more rapidly than they do in the postdistributional elimination (b) phase. The distribution phase may last for only a few minutes or for hours or days. Whether the distribution phase becomes apparent depends on the time when the first plasma samples are obtained, and on the relative difference in the rates of distribution and elimination. If the rate of distribution is considerably rapid relative to elimination, the timing of blood sampling becomes critical in the ability to distinguish a distribution phase. The equivalent of k_{ei} in a one-compartment model is b in a two-compartment model.

Occasionally, the plasma concentration profile of many compounds cannot be described satisfactorily by an equation with two exponential terms—for example, if the chemical has an exceptionally slow distribution into and redistribution out of a deep peripheral compartment or tissue. Sometimes three or four exponential terms are needed to fit a curve to the plot of log *C* versus time. Such compounds are viewed as displaying characteristics of three- or four-compartment open models. The principles for dealing with such models are the same as those used for the two-compartment open model, but the mathematics are more complex and beyond the scope of this discussion.

Elimination

Elimination includes biotransformation, exhalation, and excretion. The elimination of a chemical from the body whose disposition is described by a one-compartment model usually occurs through a first-order process; that is, the rate of elimination at any time is proportional to the amount of the chemical in the body at that time. First-order reactions occur at chemical concentrations that are not sufficiently high to saturate elimination processes.

The equation for a monoexponential model, $C = C_0 \times e^{-k_{el} \times t}$, can be transformed to a logarithmic equation that has the general form of a straight line, *y = mx + b*:

$$\log C = -(k_{el}/2.303) \times t + \log C_0$$

where log C_0 represents the y-intercept or initial concentration, and–(k_{ei}/2.303) represents the slope of the line. The first-order elimination rate constant (k_{ei}) can be determined from the slope of the log *C* versus time plot (*i.e.,* $k_{ei} = -2.303 \times slope$). The first-order elimination rate constants k_e and b have units of reciprocal time (*e.g.*, min^{-1} and h^{-1}) and are independent of dose.

Mathematically, the fraction of dose remaining in the body over time (C/C_0) is calculated using the elimination rate constant by rearranging the equation for the monoexponential function and taking the antilog to yield

$$C/C_0 = \text{Anti log} \; [(-k_{ei}/2.303) \times t]$$

Thus, if the elimination rate constant is, for example, 0.3 h $^{-1}$, the percentage of the dose remaining in the body ($C/C_0 \times 100$) and the percentage of the dose eliminated from the body after 1 h, i.e., $1 - (C/C_0 \times 100)$, are 74 and 26 percent, respectively, regardless of the dose administered (Table 7-1). The percentage of the total dose eliminated at one hour is said to be independent of dose.

DOSE, mg	CHEMICAL REMAINING, mg	CHEMICAL ELIMINATED, mg	CHEMICAL ELIMINATED, % of dose
10	7.4	2.6	26
30	22	8	26
90	67	23	26
250	185	65	26

Table 7-1 Elimination of Four Different Doses of a Chemical at 1 Hour After Administration as Described by a One-Compartment Open Model and

Apparent Volume of Distribution

In a one-compartment model, all chemical is assumed to distribute into plasma and tissues instantaneously. The apparent volume of distribution (V_d) is a proportionality constant that relates the total amount of chemical in the body to the concentration of a xenobiotic in plasma, and is typically described in units of liters or liters per kilogram of body weight (Kato et al., 1987). V_d is the apparent space into which an amount of chemical is distributed in the body to result in a given plasma concentration. For example, envision the body as a tank containing an unknown volume (L) of well mixed water. If a known amount (mg) of dye is placed into the water, the volume of that water can be calculated indirectly by determining the dye concentration (mg/L) that resulted after the dye has equilibrated in the tank simply by dividing the amount of dye added to the tank by the resultant concentration of the dye in water. Synonymously, the apparent volume of distribution of a chemical in the body is determined after intravenous bolus administration, and is mathematically defined as the quotient of the amount of chemical in the body and its plasma concentration. V_d is calculated as

$$C/C_0 = \text{Anti log} \left[(-k_{el}/2.303) \times t \right]$$

where $Dose_{iv}$ is the intravenous dose or known amount of chemical in body at time zero; b is the elimination rate constant; and $AUC_0^¥$ is the area under the chemical concentration versus time curve from time zero to infinity. The product, b × $AUC_0^¥$, is the concentration of xenobiotic in plasma.

For a one-compartment model, V_c can be simplified by the equation $V_d = Dose_{iv}/C_0$, where C_0 is the concentration of chemical in plasma at time zero. C_0 is determined by extrapolating the plasma disappearance curve after intravenous injection to the zero time point (Fig. 7-2). V_d is correctly called the *apparent volume of distribution* because it has no direct physiologic meaning and usually does not refer to a real biological volume. The magnitude of the V_c term is chemical-specific and represents the extent of distribution of chemical out of plasma and into other body tissues (Table 7-2). Thus, for chemicals that readily distribute into extravascular tissues, V_d often exceeds actual body spaces. A chemical with high affinity for tissues will also have a large volume of distribution. In fact, binding to tissues may be so avid that the V_c of a chemical is much larger than the actual body volume. Alternatively, a chemical that predominantly remains in the plasma will have a low V_c that approximates the volume of plasma (Wang et al., 1994). Once the V_d for a chemical is known, it can be used to estimate the amount of chemical remaining in the body at any time if the plasma concentration at that time is also known by the relationship $X_c = V_d \times C_P$, where X_c is the amount of chemical in the body and C_P is the plasma chemical concentration.

CHEMICAL	V_d (L/kg)	BODY COMPARTMENT
Chloroquine	200	
Desmethylimipramine	40	
Tetracycline	1.3	
	0.6	Total body water
Digitoxin	0.5	
	0.27	Extracellular body water
Salicylic acid	0.15	
	0.045	Plasma

Table 7-2 Volume of Distribution (V_d) for Several Chemicals Compared with Volumes of Body Fluid Compartments

Clearance

Chemicals are cleared from the body by various routes, for example, via excretion by the kidneys or intestines, biotransformation by the liver, or exhalation by the lungs. Clearance is an important toxicokinetic concept that describes the rate of chemical elimination from the body (Shargel and Yu, 1993). Clearance is described in terms of volume of fluid containing chemical that is cleared per unit of time. Thus, clearance has the units of flow (milliliters per minute). A clearance of 100 mL/min means that 100 mL of blood or plasma containing xenobiotic is completely cleared in each minute that passes. The overall efficiency of the removal of a chemical from the body can be characterized by clearance. High values of clearance indicate efficient and generally rapid removal, whereas low clearance values indicate slow and less efficient removal of a xenobiotic from the body. *Total body clearance* is defined as the sum of clearances by individual eliminating organs:

$$Cl = Cl_r + Cl_h + Cl_i \ldots$$

where Cl_r depicts renal, Cl_h hepatic, and Cl_i intestinal clearance. Clearance of xenobiotics from the blood by a particular organ cannot be higher than blood flow to that organ. For example, for a xenobiotic that is eliminated by hepatic biotransformation, hepatic clearance cannot exceed the hepatic blood flow rate even if the maximum rate of metabolism in the liver is more rapid than the rate of hepatic blood flow, because the rate of overall hepatic clearance is limited by the delivery of the xenobiotic to the metabolic enzymes in the liver via the blood. After intravenous, bolus administration, total body clearance is defined as

$$Cl = Dose_{iv}/AUC_0^¥$$

Clearance can also be calculated if the volume of distribution and elimination rate constants are known, and can be defined as $Cl = V_d \times k_e$ for a one-compartment model and $Cl = V_c \times b$ for a two-compartment model. Clearance is an exceedingly important concept.

Half-Life

Another important and frequently used parameter that characterizes the time course of xenobiotics in an organism is the half-life of elimination ($T_{1/2}$). Half-life is the time required for the blood or plasma chemical concentration to decrease by one-half, and is dependent upon both volume of distribution and clearance. $T_{1/2}$ can be calculated if V_d and Cl are known:

$$T_{1/2} = (0.693 \times V_d)/Cl$$

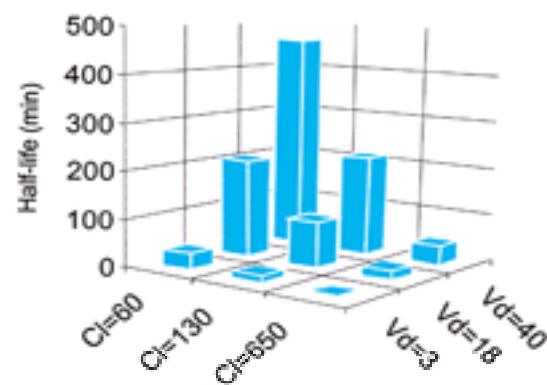
The above relationship among $T_{1/2}$, V_d and Cl demonstrates that care should be taken in analyses of data when relying upon $T_{1/2}$ as the sole determinant parameter in toxicokinetic studies, since $T_{1/2}$ is influenced by both the volume of distribution for a chemical and the rate by which the chemical is cleared from the blood. For a fixed V_d, $T_{1/2}$ decreases as Cl increases, because chemical is being removed from this fixed volume faster as clearance increases (Fig. 7-3). Conversely, as the V_c increases, $T_{1/2}$ increases for a fixed Cl since the volume of fluid that must be cleared of chemical increases but the rate of clearance does not.


Figure 7-3. The dependence of $T_{1/2}$ *on* V_d *and* Cl.

Renal C_l values of 60, 130, and 650 mL/min represent partial reabsorption, glomerular filtration, and tubular secretion, respectively. Values for V_d of 3, 18, and 40 L represent approximate volumes of plasma water, extracellular fluid and total body water, respectively, for an average-sized person.

Because of the relationship $T_{1/2} = 0.693 \times k_{ei}$, the half-life of a compound can be calculated after k_{ei} (or b) has been determined from the slope of the line that designates the elimination phase on the log C versus time plot. The $T_{1/2}$ can also be determined by means of visual inspection of the log C versus time plot, as shown in Fig. 7-2. For compounds eliminated by first-order kinetics, the time required for the plasma concentration to decrease by one-half is constant. Therefore, xenobiotics eliminated from the body by first-order processes are theoretically never completely eliminated. However, during seven half-lives, 99.2 percent of a chemical is eliminated, and for practical purposes this can be viewed as complete elimination. The half-life of a chemical obeying first-order elimination kinetics is independent of the dose, and does not change with increasing dose.

Saturation Toxicokinetics

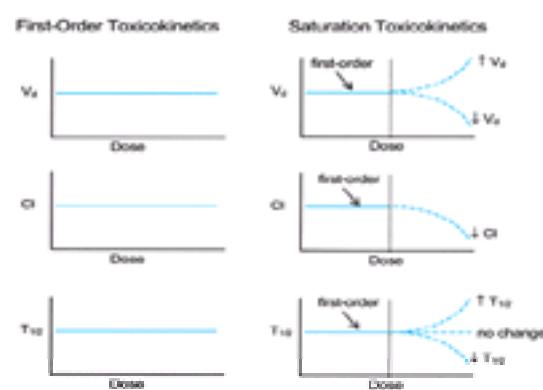
As already mentioned, the distribution and elimination of most chemicals occurs by first-order processes. However, as the dose of a compound increases, its volume of distribution or its rate of elimination may change, as shown in Fig. 7-4. This is usually referred to as saturation kinetics. Biotransformation, active transport processes, and protein binding have finite capacities and can be saturated. When the concentration of a chemical in the body is higher than the K_M (chemical concentration at one-half V_{max}, the maximum metabolic capacity), the rate of elimination is no longer proportional to the dose. The transition from first-order to saturation kinetics is important in toxicology because it can lead to prolonged residency time of a compound in the body or increased concentration at the target site of action, which can result in increased toxicity.


Figure 7-4. V_d, Cl *and* $T_{1/2}$ *following first-order toxicokinetics* (left panels) *and changes following saturable toxicokinetics* (right panels).

Vertical dashed lines represent point of departure from first-order to saturation toxicokinetics. Pharmacokinetic parameters for chemicals that follow first-order toxicokinetics are independent of dose. When protein binding or elimination mechanisms are saturated with increasing dose, pharmacokinetic parameter estimates become dose-dependent. V_d may increase, for example, when plasma protein binding is saturated, allowing more free chemical to distribute into peripheral tissue spaces. Conversely, V_d may decrease with increasing dose if tissue protein binding saturates. Then chemical may redistribute more freely back into plasma. When chemical concentrations exceed the capacity for biotransformation by metabolic enzymes, overall clearance of the chemical decreases. These changes may or may not have effects on $T_{1/2}$ depending upon the magnitude and direction of changes in both V_d and Cl.

Some of the criteria that indicate nonlinear toxicokinetics include the following: (1) The decline in the levels of the chemical in the body is not exponential, (2) $AUC_0^¥$ is not proportional to the dose, (3) V_d, Cl, k_{ei} (or b) or $T_{1/2}$ change with increasing dose, (4) the composition of excretory products changes quantitatively or qualitatively with the dose, (5) competitive inhibition by other chemicals that are biotransformed or actively transported by the same enzyme system occurs, and (6) dose-response curves show a nonproportional change in response with an increasing dose, starting at the dose level at which saturation effects become evident.

The elimination of some chemicals from the body is readily saturated. These compounds follow zero-order kinetics. Ethanol is an example of a chemical whose elimination follows zero-order kinetics, with its biotransformation being the rate-limiting step in its elimination (York, 1982). The elimination of ethanol is dependent upon the amount of dose remaining to be eliminated rather than the fraction of dose to be eliminated. As shown in Table 7-3, a constant amount, rather than a constant proportion of ethanol is biotransformed per unit of time regardless of the amount of ethanol present in the body. Important characteristics of zero-order processes are as follows: (1) An arithmetic plot of plasma concentration versus time yields a straight line, (2) the rate or amount of chemical eliminated at any time is constant and is independent of the amount of chemical in the body, and (3) a true $T_{1/2}$ or k_{ei} does not exist, but differs depending upon ethanol dose.

TIME, h	ETHANOL REMAINING, mL	ETHANOL ELIMINATED, mL	ETHANOL ELIMINATED, % of that remaining
0	50	0	0
1	40	10	20
2	30	10	25
3	20	10	33
4	10	10	50
5	0	10	100

Table 7-3 Elimination Over Time of a Chemical That Follows Zero-Order Toxicokinetics

By comparison, under first-order elimination kinetics, the elimination rate constant, apparent volume of distribution, clearance and half-life are expected not to change

with increasing dose. The important characteristics of first-order elimination are as follows: (1) The rate at which a chemical is eliminated at any time is directly proportional to the amount of that chemical in the body at that time. (2) A semilogarithmic plot of plasma concentration versus time yields a single straight line. (3) The elimination rate constant (k_{e_i} or b), apparent volume of distribution (V_c), clearance (Cl) and half-life ($T_{1/2}$) are independent of dose. (4) The concentration of the chemical in plasma and other tissues decreases similarly by some constant fraction per unit of time, the elimination rate constant (k_{e_i} or b).

Bioavailability

For most chemicals in toxicology, exposure occurs by extravascular routes (e.g., inhalation, dermal or oral), and absorption into the systemic circulation is incomplete. The extent of absorption of a xenobiotic can be experimentally determined by comparing the plasma AUC_0^Ψ after intravenous and extravascular dosing. The resulting index quantitates the fraction of dosed absorbed systemically and is called *bioavailability* (F). Bioavailability can be determined by using different doses, provided that the compound does not display dose-dependent or saturable kinetics. Pharmacokinetic data following intravenous administration is used as the reference from which to compare extravascular absorption because all chemical is delivered (or 100 percent bioavailable) to the systemic circulation. For example, bioavailability following an oral exposure can be determined as follows:

$$F = (AUC_{pc}/Dose_{po}) \times (Dose_{iv}/AUC_{iv})$$

where AUC_{pc}, AUC_{iv}, $Dose_{pc}$, and $Dose_{iv}$ are the respective area under the plasma concentration versus time curves and doses for oral and intravenous administration. Bioavailabilities for various chemicals range in values between 0 and 1. Complete absorption of chemical is demonstrated when $F = 1$. When $F < 1$, incomplete absorption of chemical is indicated. Bioavailability is an important concept in toxicokinetics. As was discussed earlier, the most critical factor influencing toxicity is not necessarily the dose but rather the concentration of a xenobiotic at the site of action. Xenobiotics are delivered to most organs by the systemic circulation. Therefore, the fraction of a chemical that reaches the systemic circulation is of critical importance in determining toxicity. Several factors can greatly alter this systemic availability, including (1) limited absorption after oral dosing, (2) intestinal first-pass effect, (3) hepatic first-pass effect, and (4) mode of formulation, which affects, for example, dissolution rate or incorporation into micelles (for lipid-soluble compounds).

In summary, for many chemicals, blood or plasma chemical concentration versus time data can be adequately described by a one- or two-compartment, classical pharmacokinetic model when basic assumptions are made (e.g., instantaneous mixing of compartments and first-order kinetics). In some instances, more sophisticated models with increased numbers of compartments will be needed to describe blood or plasma toxicokinetic data; for example if the chemical preferentially distributes into deep peripheral tissues. Modeling and knowledge of toxicokinetic data can be used in deciding on what dose or doses of chemical to use in the planning of toxicology studies (e.g., if specific blood concentrations are desired), in evaluating dose regimens (e.g., intravascular versus extravascular, bolus injection versus infusion or single dosing versus repeated doses), in choosing appropriate sampling times, and in aiding in the evaluation of toxicology data (e.g., what blood or plasma concentrations were achieved to produce a specific response, effects of repeated dosing on accumulation of chemical in the body, etc.).

Computer Software

Several computer software programs are available for compartmental modeling of pharmacokinetic data (e.g., WinNonlin, PKAnalyst, Summit and SAS, among others). Many are menu-driven and operate on Microsoft Windows or Macintosh systems. In general, concentration and time data are entered into a spreadsheet format. The operator then chooses a user-defined model or a specified model from a built-in library to fit curves to concentration versus time data. Convergence of the model occurs through an iterative process to satisfy specific statistical requirements; for example minimizing the sum of square residuals between simulated and observed data. Program outputs include pharmacokinetic parameter estimations and descriptive statistical estimations. A number of software programs also offer graphic output of both test data and model simulations. In summary, a wide variety of options and costs are available that can fit the user's needs.

PHYSIOLOGIC TOXICOKINETICS

The primary difference between *physiologic* compartmental models and *classic* compartmental models lies in the basis underlying the rate constants that describe the transport of chemicals into and out of the compartments (Andersen, 1991). In classic kinetics, the rate constants are defined by the data; thus, these models are often referred to as *data-based.* In physiologic models, the rate constants represent known or hypothesized biological processes, and these models are commonly referred to as *physiologically based.* The concept of incorporating biological realism into the analysis of drug or xenobiotic distribution and elimination is not new. For example, one of the first physiologic models was proposed by Teorell (1937). This model contained all the important determinants in chemical disposition that are considered valid today. Unfortunately, the computational tools required to solve the underlying equations were not available at that time. With advances in computer science, the software and hardware needed to implement physiological models are now well within the reach of toxicologists.

The advantages of physiologically based models compared with classic pharmacokinetics are that (1) these models can provide the time course of distribution of xenobiotics to any organ or tissue, (2) they allow estimation of the effects of changing physiologic parameters on tissue concentrations, (3) the same model can predict the toxicokinetics of chemicals across species by allometric scaling, and (4) complex dosing regimes and saturable processes such as metabolism and binding are easily accommodated (Gargas and Andersen, 1988). The disadvantages are that (1) more information is needed to implement these models compared with classic models, (2) the mathematics can be difficult for many toxicologists to handle, and (3) values for parameters are often ill defined in various species, strains, and disease states. Nevertheless, physiologically based toxicokinetic models are conceptually sound and are potentially useful tools for gaining insight into the kinetics of xenobiotics beyond what classic toxicokinetics can provide.

Basic Model Structure

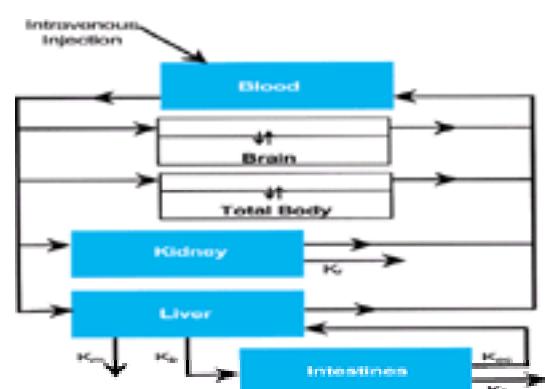
Physiologic models often look like a number of classic one-compartment models that are linked together. The actual model *structure,* or *how* the compartments are linked together, depends on both the chemical and the organism being studied. For example, a physiologic model describing the disposition of a chemical in fish would require a description of the gills (Nichols et al., 1994), whereas a model for the same chemical in mammals would require a lung (Ramsey and Andersen, 1984). Model structures can also vary with the chemicals being studied. For example a model for a nonvolatile, water-soluble chemical, which might be administered by intravenous injection (Fig. 7-5), has a structure different from that of a model for a volatile organic chemical for which inhalation is the likely route of exposure (Fig. 7-6). The route of administration is not the only difference between these two models: For example, the first model has a compartment for the intestines because biliary excretion, fecal elimination, and enterohepatic circulation are presumed important in the disposition of this chemical. The second model has a compartment for fat since fat is an important storage organ for organics. However, the models are not *completely* different. Both contain a liver compartment because the hepatic metabolism of each chemical is an important element of its disposition. It is important to realize that there is no generic physiological model. Models are simplifications of reality and ideally should contain elements believed to be important in describing a chemical's disposition.


Figure 7-5. Physiologic model for a hypothetical xenobiotic that is soluble in water, has a low vapor pressure (not volatile), and has a relatively large molecular weight (MW > 100).

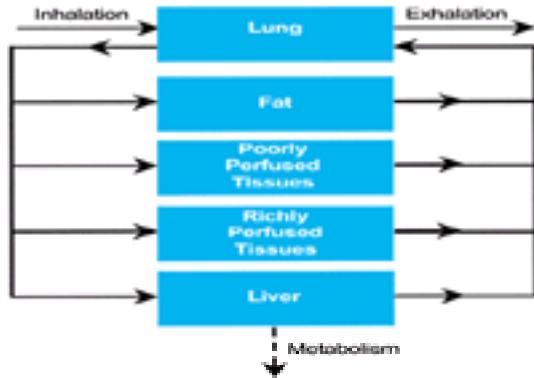
This hypothetical chemical is eliminated through metabolism in the liver (K_m), biliary excretion (K_b), renal excretion (K_l) into the urine, and fecal excretion (K_l). The chemical can also undergo enterohepatic circulation (K_{ec}). Perfusion-limited compartments are noted in white and diffusion-limited compartments are noted in blue.


Figure 7-6. Physiological model for a typical volatile organic chemical.

Chemicals for which this model would be appropriate have low molecular weights (*MW* <100), are soluble in organic solvents, and have significant vapor pressures (volatile). Transport of chemical throughout the body by blood is depicted by the black arrows. Elimination of chemical as depicted by the model includes metabolism (*dashed arrow*) and exhalation (*black arrow*). All compartments are perfusion limited.

In view of the fact that physiologic modeling requires more effort than does classic compartmental modeling, what accounts for the increase in the popularity of the kinetic approach among toxicologists? The answer lies in the potential predictive power of physiologic models. Toxicologists are constantly faced with the issue of extrapolation—from laboratory animals to humans, from high to low doses, from intermittent to continuous exposure, and from single chemicals to mixtures. Because the kinetic constants in physiologic models represent measurable biological or chemical processes, the resultant physiologic models have the potential for extrapolation from observed data to predicted situations.

One of the best illustrations of the predictive power of physiologic models is their ability to extrapolate kinetic behavior from laboratory animals to humans. For example, physiologic models developed for styrene and benzene correctly simulate the concentration of each chemical in the blood of rodents and humans (Ramsey and Andersen, 1984; Travis et al., 1990). *Simulations* are the outcomes or results (such as a chemical's concentration in blood or tissue) of numerically integrating model equations over a simulated time period, using a set of initial conditions (such as intravenous dose) and parameter values (such as organ weights). Both styrene and benzene are volatile organic chemicals; thus, the model structures for the kinetics of both chemicals in rodents and humans is identical to that shown in Fig. 7-6. However, the parameter values for rodents and humans are different. Humans have larger body weights than rodents, and thus weights of organs such as the liver are larger. Because humans are larger, they also breathe more air per unit of time than do rodents, and a human heart pumps a larger volume of blood per unit of time than does that of a rodent, although the rodent's heart beats more times in the same period. The parameters that describe the chemical behavior of styrene and benzene, such as solubility in tissues, are similar in the rodents and human models. This is often the case because the composition of tissues in different species is similar.

For both styrene and benzene there are experimental data for both humans and rodents and the model simulations can be compared with the actual data to see how well the model has performed (Ramsey and Andersen, 1984; Andersen et al., 1984; Travis et al., 1990). The conclusion is that the same model structure is capable of describing the chemicals' kinetics in two different species. Because the parameters underlying the model structure represent measurable biological and chemical determinants, the appropriate values for those parameters can be chosen for each species, forming the basis for successful interspecies extrapolation.

For both styrene and benzene, even though the same model structure is used for both rodents and humans, both the simulated and the observed kinetics of both chemicals differs between rats and humans. The terminal half-life of both organics is longer in the human compared with the rat. This longer half-life for humans is due to the fact that clearance rates for smaller species are faster than those for larger ones. Even though the larger species breathes more air or pumps more blood per unit of time than does the smaller species, blood flows and ventilation rates *per unit of body mass* are greater for the smaller species. The smaller species has more breaths per minute or heartbeats per minute than does the larger one, even though each breath or stroke volume is smaller. These faster flows per unit mass bring more xenobiotic to organs responsible for elimination. Thus, a smaller species can eliminate a xenobiotic faster than a larger one can. Because the parameters in physiologic models represent real, measurable values such as blood flows and ventilation rates, the same model structure can resolve such disparate kinetic behaviors among species.

Compartments

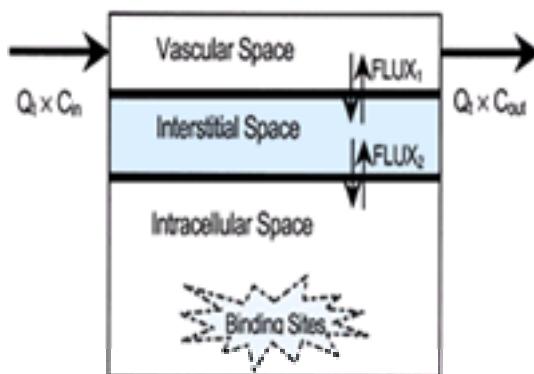
The basic unit of the physiologic model is the lumped compartment, which is often depicted as a box (Fig. 7-7). A *compartment* is a single region of the body with a *uniform* xenobiotic concentration (Rowland, 1984; Rowland, 1985). A compartment may be a particular functional or anatomic portion of an organ, a single blood vessel with surrounding tissue, an entire discrete organ such as the liver or kidney, or a widely distributed tissue type such as fat or skin. Compartments consist of three individual well-mixed phases, or *subcompartments,* that correspond to specific physiologic portions of the organ or tissue. These subcompartments are (1) the *vascular* space through which the compartment is perfused with blood, (2) the *interstitial* space that forms the matrix for the cells, and (3) the *intracellular* space consisting of the cells in the tissue (Gerlowski and Jain, 1983).


Figure 7-7. Schematic representation of a lumped compartment in a physiologic model.

The blood capillary and cell membranes separating the vascular, interstitial, and intracellular subcompartments are depicted in black. The vascular and interstitial subcompartments are often combined into a single extracellular subcompartment. Q_i is blood flow, $C_{ir.}$ is chemical concentration into the compartment and C_{out} is chemical concentration out of the compartment.

As shown in Fig. 7-7, the xenobiotic enters the vascular subcompartment at a certain rate in mass per unit of time (e.g., milligrams per hour). The rate of entry is a product of the blood flow rate to the tissue (Q_i, in liters per hour) and the concentration of the xenobiotic in the blood entering the tissue (C_{in}, in milligrams per liter). Within the compartment, the xenobiotic moves from the vascular space to the interstitial space at a certain net rate ($Flux_1$) and moves from the interstitial space to the intracellular space at different net rate ($Flux_2$). Some xenobiotics can bind to cell components; thus, within a compartment there may be both free and bound xenobiotics. The xenobiotic leaves the vascular space at a certain venous concentration (C_{out}). C_{out} is equal to the concentration of the xenobiotic in the vascular

space.

Parameters

The most common types of parameters, or information required, in physiologic models are *anatomic, physiologic, thermodynamic,* and *transport.*

Anatomic Anatomic parameters are used to physically describe the various compartments. The *size* of each of the compartments in the physiologic model must be known. The size is generally specified as a volume (milliliters or liters) because a unit density is assumed even though weights are most frequently obtained experimentally. If a compartment contains subcompartments such as those in Fig. 7-7, those volumes also must be known. Volumes of compartments often can be obtained from the literature or from specific toxicokinetic experiments. For example, kidney, liver, brain, and lung can be weighed. Obtaining precise data for volumes of compartments representing widely distributed tissues such as fat or muscle is more difficult. If necessary, these tissues can be removed by dissection and weighed. Among the numerous sources of general information on organ and tissue volumes, Brown et al. (1997) is a good starting point.

Physiologic Physiologic parameters encompass a wide variety of processes in biological systems. The most commonly used physiologic parameters are blood flow, ventilation, and elimination. The blood flow rate (Q_i, in volume per unit time, such as mL/min or L/h) to individual compartments must be known. Additionally, information on the total blood flow rate or *cardiac output* (Q_c) is necessary. If inhalation is the route for exposure to the xenobiotic or is a route of elimination, the alveolar ventilation rate (Q_p) also must be known. Blood flow rates and ventilation rates can be taken from the literature or can be obtained experimentally. Renal clearance rates and parameters to describe rates of biotransformation, or metabolism, are a subset of physiologic parameters and are required if these processes are important in describing the elimination of a xenobiotic. For example, if a xenobiotic is known to be metabolized via a saturable process both V_{max} (the maximum rate of metabolism) and K_M (the concentration of xenobiotic at one-half V_{max}) must be obtained so that elimination of the xenobiotic by metabolism can be described in the model.

Thermodynamic Thermodynamic parameters relate the *total* concentration of a xenobiotic in a tissue (*C*) to the concentration of *free* xenobiotic in that tissue (C_i). Two important assumptions are that (1) total and free concentrations are in equilibrium with each other and (2) only free xenobiotic can enter and leave the tissue (Lutz et al., 1980). Most often, total concentration is measured experimentally; however, it is the free concentration that is available for binding, metabolism, or removal from the tissue by blood. Various mathematical expressions describe the relationship between these two entities. In the simplest situation, the xenobiotic is a freely diffusible water-soluble chemical that does not bind to any molecules. In this case, the free concentration of the xenobiotic is exactly equal to the total concentration of the xenobiotic: total = free, or $C = C_i$. The affinity of many xenobiotics for tissues of different composition varies. The extent to which a xenobiotic partitions into a tissue is directly dependent on the composition of the tissue and independent of the concentration of the xenobiotic. Thus, the relationship between free and total concentration becomes one of proportionality: total = free × partition coefficient, or $C = C_i \times P$. In this case, *P* is called a *partition* or *distribution* coefficient. Knowledge of the value of *P* permits an indirect calculation of the free concentration of xenobiotic or C_i. $C_i = C/P$.

Table 7-4 compares the partition coefficients for a number of toxic volatile organic chemicals. The larger values for the fat/blood partition coefficients compared with those for other tissues suggests that these chemicals distribute into fat to a greater extent than they distribute into other tissues. This has been observed experimentally. Fat and fatty tissue such as bone marrow contain higher concentrations of benzene than do tissues such as liver and blood. Similarly, styrene concentrations in fatty tissue are higher than styrene concentrations in other tissues.

CHEMICAL	BLOOD/AIR	MUSCLE/BLOOD	FAT/BLOOD
Isoprene	3	0.67	24
Benzene	18	0.61	28
Styrene	40	1	50
Methanol	1350	3	11

Table 7-4 Partition Coefficients for Four Volatile Organic Chemicals

A more complex relationship between the free concentration and the total concentration of a chemical in tissues is also possible. For example, the chemical may bind to saturable binding sites on tissue components. In these cases, nonlinear functions relating the free concentration in the tissue to the total concentration are necessary. Examples in which more complex binding has been used are physiologic models for dioxin and *tertiary*-amyl butyl ether (Andersen et al., 1993; Collins et al., 1999).

Transport The passage of a xenobiotic across a biological membrane is complex and may occur by passive diffusion, carrier-mediated transport, facilitated transport, or a combination of processes (Himmelstein and Lutz, 1979). The simplest of these processes—passive diffusion—is a first-order process described by Fick's law of diffusion. Diffusion of xenobiotics can occur across the blood capillary membrane (*Flux₁* in Fig. 7-7) or across the cell membrane (*Flux₂* in Fig. 7-7). *Flux* refers to the rate of transfer of a xenobiotic across a boundary. For simple diffusion, the net flux (milligrams per hour) from one side of a membrane to the other is described as Flux = permeability coefficient × driving force, or

$$Flux = [PA] \times (C_1 - C_2) = [PA] \times C_1 - [PA] \times C_2$$

The permeability coefficient [*PA*] is often called the *permeability-area cross-product* for the membrane (in units of liters per hour) and is a product of the cell membrane permeability constant (*P*, in micrometers per hour) for the xenobiotic and the total membrane area (*A*, in square micrometers). The cell membrane permeability constant takes into account the rate of diffusion of the specific xenobiotic and the thickness of the cell membrane. C_1 and C_2 are the *free* concentrations of xenobiotic on each side of the membrane. For any given xenobiotic, thin membranes, large surface areas, and large concentration differences enhance diffusion.

There are two *limiting conditions* for the transport of a xenobiotic across membranes: *perfusion-limited* and *diffusion-limited.* An understanding of the assumptions underlying the limiting conditions is critical because the assumptions change the way in which the differential equations are written to describe the compartment.

Perfusion-Limited Compartments

A perfusion-limited compartment is also referred to as *blood flow–limited,* or simply *flow-limited.* A flow-limited compartment can be developed if the cell membrane permeability coefficient [*PA*] for a particular xenobiotic is much greater than the blood flow rate to the tissue (Q_t) or [*PA*]$>> Q_t$. In this case, the rate of xenobiotic uptake by tissue subcompartments is limited by the rate at which the blood containing a xenobiotic arrives at the tissue, not by the rate at which the xenobiotic crosses the cell membranes. In most tissues, the rate of entry of a xenobiotic into the interstitial space from the vascular space is not limited by the rate of xenobiotic transport across vascular cell membranes and is therefore perfusion rate limited. In the generalized tissue compartment in Fig. 7-7, this means that transport of the xenobiotic through the loosely knit blood capillary walls of most tissues is rapid compared with delivery of the xenobiotic to the tissue by the blood. As a result, the vascular blood is in equilibrium with the interstitial subcompartment and the two subcompartments are usually lumped together as a single compartment that is often called the *extracellular space.* An important exception to this vascular-interstitial equilibrium relationship is the brain, where the tightly knit blood capillary walls form a barrier between the vascular space and the interstitial space.

As indicated in Fig. 7-7, the cell membrane separates the extracellular compartment from the intracellular compartment. The cell membrane is the most important diffusional barrier in a tissue. Nonetheless, for molecules that are very small (molecular weight<100) or lipophilic, cellular permeability generally does not limit the rate

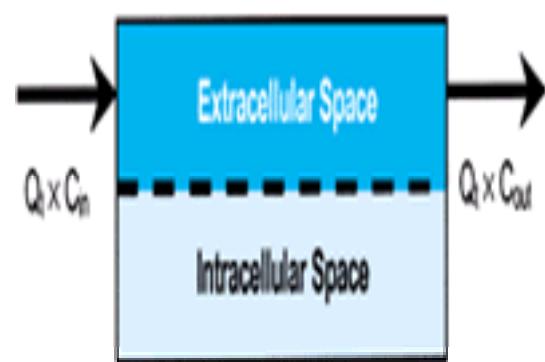
at which a molecule moves across cell membranes. For these molecules, flux across the cell membrane is fast compared with the tissue perfusion rate ([*PA*] >> *Qt*), and the molecules rapidly distribute through the subcompartments. In this case, the intracellular compartment is in equilibrium with the extracellular compartment, and these tissue subcompartments are usually lumped as a single compartment. This flow-limited tissue compartment is shown in Fig. 7-8. Movement into and out of the entire tissue compartment can be described by a single equation:


Figure 7-8. Schematic representation of a compartment that is blood-flow–limited.

Rapid exchange between the extracellular space (*blue*) and intracellular space (*light blue*) maintains the equilibrium between them as symbolized by the dashed line. Q_t is blood flow, C_{in} is chemical concentration into the compartment and C_{out} is chemical concentration out of the compartment.

$$V_t \times dC/dt = Q_t \times (C_{in} - C_{out})$$

where V_t is the volume of the tissue compartment, C is the concentration of free xenobiotic in the compartment ($V_t \times C$ equals the amount of xenobiotic in the compartment), $V_t \times dC/dt$ is the change in the amount of xenobiotic in the compartment with time expressed as mass per unit of time, Q_t is blood flow to the tissue, C_{in} is xenobiotic concentration entering the compartment, and C_{out} is xenobiotic concentration leaving the compartment. Equations of this type are called mass balance *differential* equations. Differential refers to the term d*x*/dt. Mass balance refers to the requirement that input into one equation must be balanced by outflow from another equation in the physiologic model.

In the perfusion-limited case, C_{out}, or the venous concentration of xenobiotic leaving the tissue, is equal to the free concentration of xenobiotic in the tissue, C_t. As was noted above, C_t (or C_{out}) can be related to the total concentration of xenobiotic in the tissue through a simple linear partition coefficient, $C_{out} = C_t = C/P$. In this case, the differential equation describing the rate of change in the amount of a xenobiotic in a tissue becomes

$$V_t \, dC/dt = Q_t \times (C_{in} - C/P)$$

The physiologic model shown in Fig. 7-6, which was developed for volatile organic chemicals such as styrene and benzene, is a good example of a model in which all the compartments are described as flow-limited. Distribution of xenobiotic in all the compartments is described by using equations of the type noted above. In a flow-limited compartment, the assumption is that the concentrations of a xenobiotic in all parts of the tissue are in equilibrium. For this reason, the compartments are generally drawn as simple boxes (Fig. 7-6) or boxes with dashed lines that symbolize the equilibrium between the intracellular and extracellular subcompartments (Fig. 7-8). Additionally, with a flow-limited model, estimates of flux are not required to develop the mass balance differential equation for the compartment. Given the information required to estimate flux, this is a simplifying assumption that significantly reduces the number of parameters required in the physiologic model.

Diffusion-Limited Compartments

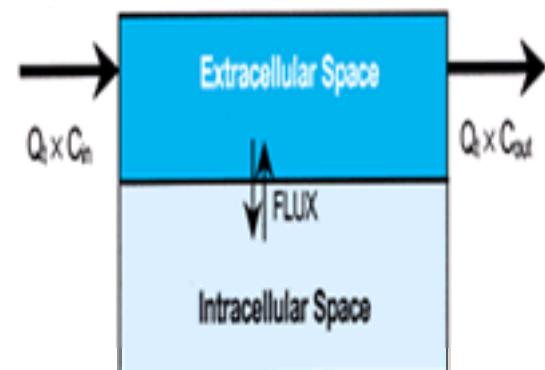
When uptake into a compartment is governed by cell membrane permeability and total membrane area, the model is said to be *diffusion-limited,* or *membrane-limited*. Diffusion-limited transport occurs when the flux, or the transport of a xenobiotic across cell membranes, is slow compared with blood flow to the tissue. In this case, the permeability-area cross-product [*PA*] is small compared with blood flow, Q_t, or *PA*<< Q_t. The distribution of large polar molecules into tissue cells is likely to be limited by the rate at which the molecules pass through cell membranes. In contrast, entry into the interstitial space of the tissue through the leaky capillaries of the vascular space is usually flow-limited even for large molecules. Figure 7-9 shows the structure of such a compartment. The xenobiotic concentrations in the interstitial and vascular spaces are in equilibrium and make up the extracellular subcompartment where uptake from the incoming blood is flow-limited. The rate of xenobiotic uptake across the cell membrane (into the intracellular space from the extracellular space) is limited by cell membrane permeability and is thus diffusion-limited. Two mass balance differential equations are necessary to describe this compartment:


Figure 7-9. Schematic representation of a compartment that is membrane-limited.

Perfusion of blood into and out of the extracellular compartment is depicted by thick arrows. Transmembrane transport (flux) from the extracellular to the intracellular subcompartment is depicted by thin double arrows. Q_t is blood flow, C_{in} is chemical concentration into the compartment and C_{out} is chemical concentration out of the compartment.

Extracellular space: $V_{t1} \times dC_1/dt = Q_t \times (C_{in} - C_{out}) - [PA] \times C_1 + [PA] \times C_2$

Intracellular space: $V_{t2} \times dC_2/dt = [PA] \times C_1 - [PA] \times C_2$

Q_t is blood flow, and C is *free* xenobiotic concentration in entering blood (in), exiting blood (out), extracellular space (1), or intracellular space (2). Both equations contain terms for flux, or transfer across the cell membrane, $[PA] \times (C_1 - C_2)$. The physiologic model in Fig. 7-5 is composed of two diffusion-limited compartments each of which contain two subcompartments—extracellular and intracellular space—and several perfusion-limited compartments.

Specialized Compartments

Lung The inclusion of a lung compartment in a physiologic model is an important consideration because inhalation is a common route of exposure to many toxic chemicals. Additionally, the lung compartment serves as an instructive example of the assumptions and simplifications that can be incorporated into physiologic

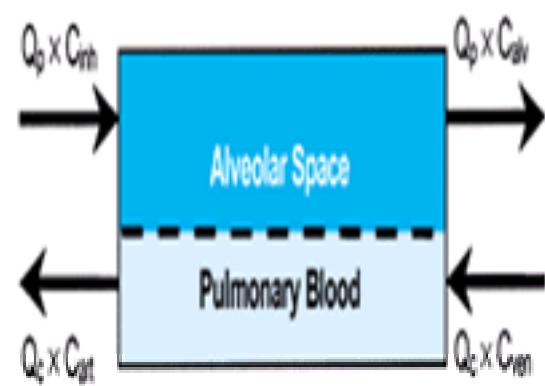
models while maintaining the overall objective of describing processes and compartments in biologically relevant terms. For example, although lung physiology and anatomy are complex, Haggard (1924) developed a simple approximation that sufficiently describes the uptake of many volatile xenobiotics by the lungs. A diagram of this simplified lung compartment is shown in Fig. 7-10. The assumptions inherent in this compartment description are as follows: (1) ventilation is continuous, not cyclic; (2) conducting airways (nasal passages, larynx, trachea, bronchi, and bronchioles) function as inert tubes, carrying the vapor to the pulmonary or gas exchange region; (3) diffusion of vapor across the lung cell and capillary walls is rapid compared with blood flow through the lung; (4) all xenobiotic disappearing from the inspired air appears in the arterial blood (i.e., there is no storage of xenobiotic in the lung tissue and insignificant lung mass); and (5) vapor in the alveolar air and arterial blood within the lung compartment are in rapid equilibrium and are related by P_b, the blood/air partition coefficient (e.g., $C_{alv} = C_{art}/P_b$). P_b is a thermodynamic parameter that quantifies the distribution or partitioning of a xenobiotic into blood compared with air.


Figure 7-10. Simple model of gas exchange in the alveolar region of the respiratory tract.

Rapid exchange in the lumped lung compartment between the alveolar gas (*blue*) and the pulmonary blood (*light blue*) maintains the equilibrium between them as symbolized by the dashed line. Q_p is alveolar ventilation (L/h); Q_c is cardiac output (L/h); C_{inh} is inhaled vapor concentration (mg/L); C_{an} is concentration of vapor in the arterial blood; C_{ven} is concentration of vapor in the mixed venous blood. The equilibrium relationship between the chemical in the alveolar air (C_{alv}) and the chemical in the arterial blood (C_{an}) is determined by the blood/air partition coefficient P_b, e.g., $C_{alv} = C_{art}/P_b$.

In the lung compartment depicted in Fig. 7-10, the rate of inhalation of xenobiotic is controlled by the ventilation rate (Q_p) and the inhaled concentration (C_{inh}). The rate of exhalation of a xenobiotic is a product of the ventilation rate and the xenobiotic concentration in the alveoli (C_{alv}). Xenobiotic also can enter the lung compartment via venous blood returning from the heart, represented by the product of cardiac output (Q_c) and the concentration of xenobiotic in venous blood (C_{ven}). Xenobiotic leaving the lungs via the blood is a function of both cardiac output and the concentration of xenobiotic in arterial blood (C_{an}). Putting these four processes together, a mass balance differential equation can be written for the rate of change in the amount of xenobiotic in the lung compartment (L):

$$\mathrm{d}L/\mathrm{dt} = Q_p \times (C_{inh} - C_{alv}) + Q_c \times (C_{ven} - C_{an})$$

Because of some of these assumptions, the rate of change in the amount of xenobiotic in the lung compartment becomes equal to zero (dL/dt = 0). C_{alv} can be replaced by C_{art}/P_b, and the differential equation can be solved for the arterial blood concentration:

$$C_{an} = (Q_p \times C_{inh} + Q_c \times C_{ven}/(Q_c + Q_p/P_b)$$

This algebraic equation is incorporated into physiologic models for many volatile organics. Because the lung is viewed here as a portal of entry and not as a target organ, the concentration of a xenobiotic delivered to other organs by the blood, or the arterial concentration of that xenobiotic, is of primary interest. The assumptions of continuous ventilation, dead space, rapid equilibration with arterial blood, and no storage of vapor in the lung tissues have worked extremely well with many volatile organics, especially relatively lipophilic chemicals. Indeed, the use of these assumptions simplifies and speeds model calculations and may be entirely adequate for describing the chemical behavior of relatively inert vapors with low water-solubility.

Inspection of the equation for calculating the arterial concentration of the inhaled organic vapor indicates that the term P_b, the xenobiotic-specific blood/air partition coefficient, becomes an important term for simulating the uptake of various volatile organic xenobiotics. As the value for P_b increases, the maximum concentration of the xenobiotic in the blood increases. Additionally, the time to reach the steady-state concentration and the time to clear the xenobiotic also increase with increasing P_b. Fortunately, P_b is readily measured by using in vitro techniques in which a volatile chemical in air is equilibrated with blood in a closed system, such as a sealed vial (Gargas and Andersen, 1988).

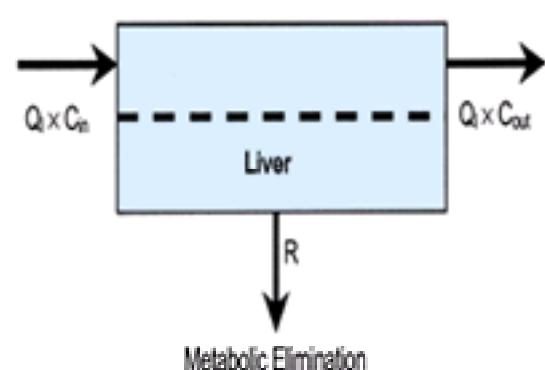
Liver The liver is often represented as a compartment in physiologic models because hepatic biotransformation is an important aspect of the toxicokinetics of many xenobiotics. The effects of multiple factors such as concentration, dose rate, and species on the metabolism of xenobiotics are important in assessing risk. Because the liver is often the major organ for the biotransformation of xenobiotics, the task of metabolism is generally assigned to the liver compartment in physiologic models. A simple compartmental structure for the liver is depicted in Fig. 7-11, where the liver compartment is assumed to be flow-limited. This liver compartment is similar to the general tissue compartment in Fig. 7-8, except that the liver compartment contains an additional process for metabolic elimination. One of the simplest expressions for this process is first-order elimination, which is written


Figure 7-11. Schematic representation of a flow-limited liver compartment in which metabolic elimination occurs.

R, in milligrams per hour, is the rate of metabolism. Q is hepatic blood flow, C_{in} is chemical concentration into the liver compartment, and C_{out} is chemical concentration out of the liver compartment.

$$R = C_l \times V_l \times K_f$$

R is the rate of metabolism (milligrams per hour), C_l is the free concentration of xenobiotic in the liver (milligrams per liter), V_l is the liver volume (liters), and K_f is the first-order rate constant for metabolism in units of h^{-1}. A widely used expression for metabolism in physiologic models is the Michaelis-Menten expression for *saturable metabolism* (Andersen, 1981), which employs two parameters, V_{max} and K_M, and is written as follows:

$$R = (V_{max} \times C_l)/(K_M + C_l)$$

where V_{max} is the maximum rate of metabolism (in milligrams per hour) and K_M is the Michaelis constant, or xenobiotic concentration at one-half the maximum rate of metabolism (in milligrams per liter). Because many xenobiotics are metabolized by enzymes that display saturable metabolism, the above equation is a key factor in the success of physiologic models for simulation of chemical disposition across a range of doses.

Other, more complex expressions for metabolism also can be incorporated into physiologic models. Bisubstrate second-order reactions, reactions involving the destruction of enzymes, the inhibition of enzymes, or the depletion of cofactors, have been simulated using physiologic models. Metabolism can be also included in other compartments in much the same way as described for the liver.

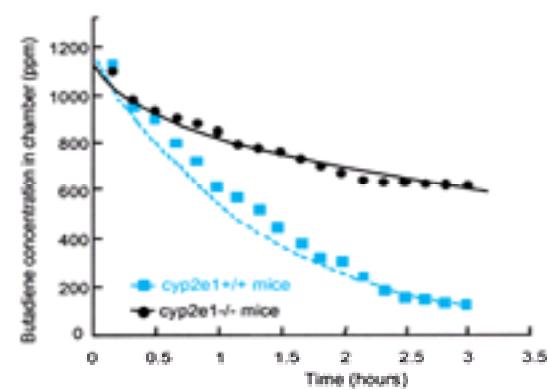
The usefulness of physiologic models for describing the complex toxicokinetic profiles resulting from saturable metabolism is responsible to a large extent for the popularity of these models. The ability of physiologic models to describe experiments in which metabolism is altered using enzyme inhibitors or genetically modified animals is illustrated in Fig. 7-12. The model used to produce the simulations in this figure accounted for inhalation of xenobiotic, distribution to and uptake by tissues, and various states of metabolism (Jackson et al., 1999). The curves in Fig. 7-12 show that when the maximum metabolic capacity, or V_{max}, is diminished, the uptake of the chemical from the inhalation chamber into the body is reduced.


Figure 7-12. Disappearance of butadiene vapor after injection (at t = 0) into a closed chamber containing mice.

The experimental data are the results of measurements of air samples taken from the chamber. The lines are physiologic model simulations of the experiments. After an initial period of equilibration, further decline in the chamber concentration is due to metabolism of butadiene by the mice. The greater the rate of metabolism the faster the decline in the butadiene concentration in the chamber. Mice that do not express the gene for the enzyme CYP2E1 (*black circles*) metabolize less butadiene than mice that do express the gene for CYP2E1 (*blue squares*). [From Jackson et al., 1999, p. 4. Reproduced with permission from CIIT Centers for Health Research.

Blood In a physiologic model, as in a living organism, the tissue compartments are linked together by the blood. Figure 7-5 and Figure 7-6 represent different approaches toward describing the blood in physiologic models. In general, a tissue receives a xenobiotic in the systemic arterial blood. Exceptions are the liver, which receives arterial and portal blood, and the lungs, which receive mixed venous blood. In the body, the venous blood supplies draining from tissue compartments eventually merge in the large blood vessels and heart chambers to form mixed venous blood. In Fig. 7-5, a blood compartment is created in which the input is the sum of the xenobiotic efflux from each compartment ($Q_i \times C_{vi}$). Efflux from the blood compartment is a product of the blood concentration in the compartment and the total cardiac output ($Q_c C_{bi}$). The differential equation for the blood compartment in Fig. 7-5 looks like this:

$$d V_{bi} \times C_{bi}/dt = Q_{br} \times C_{vbr} + Q_{tb} \times C_{vtb} \times Q_k \times C_{vk} + Q_c \times C_{vi} - Q_c \times C_{bl}$$

where V_{bi} is the volume of the blood compartment; C is concentration; Q is blood flow; bi, br, tb, k, and l represent the blood, brain, total body, kidney and liver compartments, respectively; and vbr, vtb, vk, and vi represent the venous blood leaving the organs. The venous blood is assumed to contain unbound chemical. Q_c is the total blood flow equal to the sum of the blood flows exiting each organ.

In contrast, the physiologic model in Fig. 7-6 does not have a blood compartment. For simplicity, the blood volumes of the heart and the major blood vessels that are not within organs are assumed to be negligible. The venous concentration of xenobiotic returning to the lungs is simply the weighted average of the xenobiotic concentrations in the venous blood emerging from the tissues:

$$C_v = (Q_l \times C_{vi} + Q_{rp} \times C_{vrp} + Q_{pp} \times C_{vpp} + Q_f \times C_{vf})/Q_c$$

where C is concentration; Q is blood flow; v, l, rp, pp, and f represent the venous blood, liver, richly perfused, poorly perfused, and fat tissue compartments, respectively; and vl, vrp, vpp, and vf represent the venous blood leaving the organs. Again the venous blood is assumed to contain unbound chemical. Q_c is the total blood flow equal to the sum of the blood flows exiting each organ.

In the physiologic model in Fig. 7-6, the blood concentration going to the tissue compartments is the arterial concentration (C_{art}) that was calculated above for the lung compartment. The decision to use one formulation as opposed to another to describe blood in a physiologic model depends on the role the blood plays in disposition. If the toxicokinetics after intravenous injection are to be simulated or if binding to or metabolism by blood components is suspected, a separate compartment for the blood that incorporates these additional processes is the best solution. If, as in the case of the volatile organics shown in Fig. 7-6, the blood is simply a conduit to the other compartments, the algebraic solution is acceptable.

CONCLUSION

This chapter provides a basic overview of the simpler elements of physiologic models and the important and often neglected assumptions that underlie model structures. Detailed descriptions of individual models of a wide variety of xenobiotics have been published. Several review articles describing how to construct a model step by step are included in the references. Computer software applications are available for numerically integrating the differential equations that form the models. Investigators have successfully used Advanced Continuous Simulation Language (Pharsight Corp., Palo Alto, CA), Simulation Control Program (Simulation Resources, Inc., Berrien Springs, MI), MATLAB (The MathWorks, Inc., Natick, MA), Microsoft Excel, and SAS software applications to name a few. Choice of software depends on prior experience, familiarity with the computer language used, and cost of the application.

The field of physiologic modeling is rapidly expanding and evolving as toxicologists and pharmacologists develop increasingly more sophisticated applications. Three-dimensional visualizations of xenobiotic transport in fish and vapor transport in the rodent nose, physiologic models of a parent chemical linked in series with one or more active metabolites, models describing biochemical interactions among xenobiotics, and more biologically realistic descriptions of tissues previously viewed as simple lumped compartments are just a few of the most recent applications. Finally, physiologically based *toxicokinetic* models are beginning to be linked to biologically based *toxicodynamic* models to simulate the entire exposure ® dose ® response paradigm that is basic to the science of toxicology.

CHAPTER 8

CHEMICAL CARCINOGENESIS

Henry C. Pitot III and Yvonne P. Dragan

Cancer resulting from exposure to chemicals in the environment, though known for millennia, has taken on new importance in this century. With the advent of advanced technology, new chemical agents enter the environment, although at relatively low levels in most cases, at a prodigious rate. It has been estimated (Korte and Coulston, 1994) that the number of organic chemicals that are continually being brought into the environment (about 300 million tons per year) may include more than 100,000 compounds. Chemical contamination of waste (Landrigan, 1983), the food chain (Foran et al., 1989), and the occupational environment (Anttila et al., 1993) is reportedly substantial. However, other researchers (Ames and Gold, 1990) have noted numerous misconceptions about the relationship of exposure to industrially based environmental chemicals and the incidence of human cancer. Therefore, knowledge about the mechanisms and natural history of cancer development as well as the epidemiology of human cancer is critical to the control and prevention of human neoplastic disease.

HISTORICAL FOUNDATION

The historical foundations for the induction of carcinogenesis by chemicals dates back several thousand years to the description of breast cancer in the Edwin Smith papyrus (Shimkin, 1977). In 1700, Ramazzini described the first example of occupational cancer. He noted the high incidence of breast cancer among nuns, which he attributed to their celibate life. A specific causal relationship between exposure to environmental mixtures and the induction of cancer was reported in 1775 by Percivall Pott, an eminent English physician and surgeon. Pott described the occurrence of cancer of the scrotum in a number of patients with a history of employment as chimney sweeps. With remarkable insight, Pott concluded that the occupation of those men was directly and causally related to their malignant disease. In addition, Pott suggested that the soot to which they were exposed was the causative agent of their condition. While Pott's publication soon led other observers to attribute cancer in various sites to soot exposure, his work had little impact on British public health practice during the succeeding century (Lawley, 1994). Thus, more than a century later, Butlin (1892) reported the relative rarity of scrotal cancer among chimney sweeps on the European continent compared with those in England. This difference was attributed to the relatively low standards of hygiene in Britain and the practice of exposing young "climbing boys" to the combustion products of coal. However, the lesson from Pott's findings has been a long time in the learning. A hundred years after the publication of Pott's monograph, the high incidence of skin cancer among certain German workers was traced to their exposure to coal tar, the chief constituent of the chimney sweeps' soot (Miller, 1978). Even today—more than 200 years after Pott's original scientific report on the association of soot and smoke products with cancer—a large percentage of the world's population is exposed to carcinogenic products that result from the combustion of tobacco and organic fuels.

During the nineteenth century, industrial chemicals, including cutting oils and dyes, were implicated as causative factors in the development of skin and bladder cancer, respectively (Lawley, 1994). Coal tar derivatives became the basis for the dye industry during the middle of the nineteenth century in Europe. Amine-containing aromatics such as 2-naphthylamine and benzidine were discovered and subsequently synthesized and used to yield a variety of chemical species of pigments for coloring a variety of materials. In 1895 Rehn reported the occurrence of bladder cancer in workers in the aniline dye industry. This finding was rapidly supported by other reports (Miller, 1978). Epidemiologic studies incriminated a number of aromatic amines, such as naphthylamines and benzidines, as the inciting agents (Hueper et al., 1938). Today 2-naphthylamine is not used in the U.S. chemical industry and exposure to a variety of other aromatic amines is regulated by law. Thus, the reader may appreciate that the human being was the first experimental animal in which chemical carcinogenesis was studied. Further on, both the development and the data derived from studies of chemical carcinogenesis in animals are considered.

DEFINITIONS

The term *cancer* describes a subset of lesions of the disease neoplasia. *Neoplasia* or the constituent lesion, a *neoplasm,* is defined as a heritably altered, relatively autonomous growth of tissue (Pitot, 1986a). The critical points of this definition are (1) the heritable aspects of neoplasia at the somatic or germ cell level and (2) the relative autonomy of neoplastic cells, reflecting their abnormal regulation of genetic expression, which is inherent in the neoplastic cell or occurs in response to environmental stimuli. Neoplasms may be either *benign* or *malignant.* The critical distinction between these classes is related to the characteristic of successful *metastatic* growth of malignant but not benign neoplasms. *Metastases* are secondary growths of cells from the primary neoplasm. Cancers are malignant neoplasms, whereas the term *tumor* describes space-occupying lesions that may or may not be neoplastic.

The nomenclature of neoplasia depends primarily on whether the neoplasm is benign or malignant and, in the latter case, whether it is derived from epithelial or mesenchymal tissue. For most benign neoplasms, the tissue of origin is followed by the suffix - *oma*: fibroma, lipoma, adenoma, and so on. For malignant neoplasms derived from tissues of mesenchymal origin, the term *sarcoma* is added to the tissue descriptor: fibrosarcoma, osteosarcoma, liposarcoma, and so on. Malignant neoplasms derived from tissues of ectodermal or endodermal (epithelial) origin are termed *carcinomas* with an antecedent tissue descriptor: epidermoid carcinoma (skin), hepatocellular carcinoma, gastric adenocarcinoma, and so on.

In general a *carcinogen* is an agent that causes or induces neoplasia. However, this definition is insufficient by current standards. The following definition may be more appropriate: "A *carcinogen* is an agent whose administration to previously untreated animals leads to a statistically significant increased incidence of neoplasms of one or more histogenetic types as compared with the incidence in appropriate untreated animals" (Pitot, 1986a).

This definition includes the induction of neoplasms that are usually not observed, the earlier induction of neoplasms that usually are observed, and/or the induction of more neoplasms than are usually found. Although it is important to distinguish between agents that induce neoplasms through direct action on the cells that become neoplastic and those which produce neoplasia through indirect actions in the animal as a whole, this is not always possible. Some agents, such as immune suppressants, can increase the incidence of neoplasms in tissues that were previously exposed to carcinogens through indirect effects on the host. When the action of a chemical in causing an increase in neoplasms is known to be indirect—that is, mediated by its effect on cells other than those undergoing carcinogenesis—that agent should not be designated as a carcinogen. Later in this chapter the stages and modifying factors of the process of chemical carcinogenesis are considered, necessitating a further refinement of the term *carcinogen* in relation to the action of specific chemicals in the carcinogenic process.

CARCINOGENESIS BY CHEMICALS

By the turn of this century, studies in humans showed that environmental and possibly internal chemical agents are causative factors in the development of cancer (Shimkin, 1977; Lawley, 1994). However, a systematic study of the mechanisms of chemical carcinogenesis was not possible without defined experimental systems. In 1915, the Japanese pathologists Yamagawa and Ichikawa (1915) described the first production of skin tumors in animals by the application of coal tar to the skin. These investigators repeatedly applied crude coal tar to the ears of rabbits for a number of months, finally producing both benign and later malignant epidermal neoplasms. Later studies demonstrated that the skin of mice is also susceptible to the carcinogenic action of such organic tars. During the next 15 years, extensive attempts were made to determine the nature of the material in the crude tars that caused malignancy. In 1932 Kennaway and associates reported the production of

carcinogenic tars by means of pyrolysis of organic compounds consisting only of carbon and hydrogen (Kennaway, 1955).

Organic Chemical Carcinogens

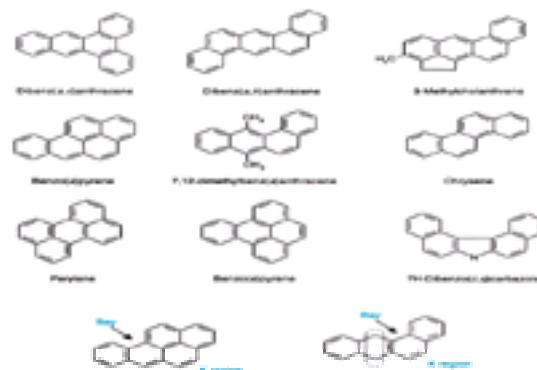
In the early 1930s, several polycyclic aromatic hydrocarbons were isolated from active crude tar fractions. In 1930, the first synthetic carcinogenic polycyclic aromatic hydrocarbon was produced (Miller, 1978). This compound, dibenz-(a,h)anthracene (Fig. 8-1), was demonstrated to be a potent carcinogen after repeated painting on the skin of mice. The isolation from coal tar and the synthesis of benzo(a)pyrene (3,4-benzpyrene) were achieved in 1932. The structures of several polycyclic aromatic hydrocarbons are shown in Fig. 8-1. Polycyclic hydrocarbons vary in their carcinogenic potencies; for example, the compound dibenz(a,c)anthracene has very little carcinogenic activity, while the a,h isomer is carcinogenic (Heidelberger, 1970). The more potent polycyclic aromatic hydrocarbon carcinogens are 3-methylcholanthrene and 7,12-dimethylbenz(a)anthracene. The carcinogenic dibenzo(c,q)carbazole, which has a nitrogen in its central ring, is also considered to be in this class of compounds. Benzo(ε)pyrene is reportedly inactive in inducing skin cancer in mice but can "initiate" the carcinogenic process. Perylene is inactive as a chemical carcinogen, whereas chrysene may have slight carcinogenic activity.


Figure 8-1. Chemical structures of some carcinogenic polycyclic hydrocarbons.

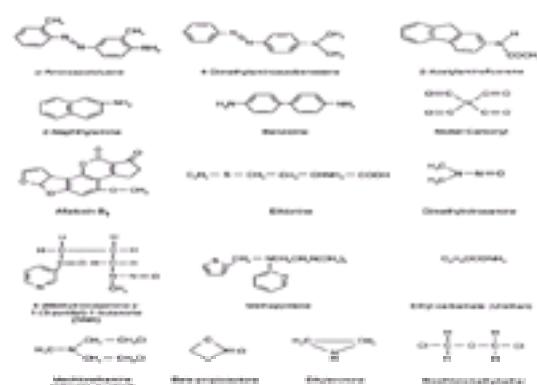
In 1935, Sasaki and Yoshida opened another field of chemical carcinogenesis by demonstrating that feeding of the azo dye, o-aminoazotoluene (3-dimethyl-4-aminoazobenzene) (Fig. 8-2), to rats can result in the development of liver neoplasms. Similarly, Kinosita (1936) demonstrated that the administration of 4-dimethylaminoazobenzene in the diet also causes neoplasms in the liver. A number of analogs of this compound were prepared and tested for carcinogenic potential. Unlike the polycyclic aromatic hydrocarbons, the azo dyes generally did not act at the site of first contact of the compound with the organism but instead at a remote site, the liver.


Figure 8-2. Chemical structures of other representative chemical carcinogens.

Another important carcinogen that acts at remote sites is 2-acetylaminofluorene (Fig. 8-2). This chemical induces neoplasms of the mammary gland, ear duct, and liver in rats (Miller et al., 1949) and neoplasms of the bladder in mice (Miller et al., 1964). The aromatic amine 2-naphthylamine and several other aromatic amines are carcinogenic for the urinary bladder in humans (Vainio et al., 1991). The carcinogenic chemical ethyl carbamate is carcinogenic for many tissues in the mouse. Ethyl carbamate was in use in Japan from 1950 to 1975 as a cosolvent for dissolving water-insoluble analgesic drugs (Miller, 1991), but this practice was stopped after 1975. No systematic study of the incidence of cancer in this cohort has been conducted. In addition, certain cytocidal alkylating agents, such as the nitrogen mustards (Fig. 8-2), have been used to treat cancer in humans and are also known to be potent carcinogens in both animals and humans (Vainio et al., 1991). The other three agents depicted on the bottom line of Fig. 8-2 are also alkylating agents that are used industrially. Bis(chloromethyl)ether, a popular intermediate in organic synthetic reactions, has been classified as carcinogenic to humans on the basis of epidemiologic and animal studies (Vainio et al., 1991).

Dimethylnitrosamine is the smallest of the class of dialkylnitrosamines in which the alkyl substituents on the nitrogen linked to the nitroso group may vary widely, including fusion to yield a cyclic aliphatic substituent. Dimethylnitrosamine (Fig. 8-2) is highly carcinogenic for the liver and kidney in virtually all the mammalian species tested (Schmähl and Habs, 1980). There is substantial epidemiologic evidence for a role of nitroso compounds in the induction of human cancer. The nitrosamine NNK (Fig. 8-2) is produced in tobacco smoke from nicotine, a tobacco alkaloid (Hecht, 1985). This is an extremely potent carcinogen that may play a role in the induction of tobacco-related cancers in humans. Methapyrilene was developed as an antihistamine but is a potent carcinogen in the rat (Mirsalis, 1987). Several investigators (Lijinsky, 1977; Magee and Swann, 1969; Mirvish et al., 1983) have shown that certain dietary components, especially in the presence of high levels of nitrite, may give rise to low levels of nitrosamines or nitrosamides and induce neoplasia of the gastrointestinal tract in experimental animals. The action of bacterial flora in the intestine may enhance the formation of these compounds. There is increasing evidence of an etiologic role for endogenously formed Λ-nitroso compounds in the development of certain human cancers (Bartsch et al., 1990).

Another important environmental and experimental hepatocarcinogenic agent is aflatoxin B $_1$. This toxic substance is produced by certain strains of the mold *Aspergillus flavus*. Aflatoxin B$_1$ is one of the most potent hepatocarcinogenic agents known and has produced neoplasms in rodents, fish, birds, and primates (Dragan and Pitot, 1994). This agent is a potential contaminant of many farm products (for example, grain and peanuts) that are stored under warm and humid conditions for some time. Aflatoxin B$_1$ and related compounds may cause some of the toxic hepatitis and hepatic neoplasia seen in various parts of Africa and the Far East (Wogan, 1992). Other products of molds and fungi are potentially carcinogenic in humans and animals (Schoental, 1985). A number of plants, some of which are edible, also contain chemical carcinogenic agents whose structures have been elucidated (Hirono, 1993).

Ethionine is an antimetabolite of the amino acid methionine. Farber (1963) was the first to show definitively that administration of ethionine in the diet for extended periods can result in the development of liver cancer in rats. This was the first example of direct interference with the metabolism of a normal metabolic constituent, resulting in the development of cancer.

We note here and discuss further later in the chapter that the dose of a chemical carcinogen is very important in relation to its effects just as with any pharmacologic agent. Even though many chemical carcinogens exert their effects by mechanisms somewhat different than many pharmacologic agents, the total administered dose, the rate at which it is given, and a number of other factors in the organism itself each play significant roles in the ultimate carcinogenic response.

Inorganic Chemical Carcinogenesis

In addition to organic compounds such as those illustrated in Fig. 8-1 and Fig. 8-2, a number of inorganic elements and their compounds have been shown to be carcinogenic in both animals and humans (Vainio and Wilbourn, 1993). Table 8-1 lists metals that are carcinogenic in some form to humans (part A) and experimental

animals (part B) (Sky-Peck, 1986). Many elements and their compounds have not been adequately tested for carcinogenicity in animals, and at this time there is no evidence that such elements exhibit effects in humans on the basis of epidemiologic studies. By contrast, compounds of cadmium, chromium, and nickel have induced malignant neoplasms in humans primarily in industrial and refining situations (Table 8-1, part A) (Magos, 1991). In the case of cadmium, the evidence for carcinogenicity in humans is somewhat limited (Waalkes et al., 1992) because of the variety of confounding factors that occur in situations of human exposure. However, its carcinogenic effect in animals is well documented. By contrast, organonickel compounds, especially nickel carbonyl (Fig. 8-2), are carcinogenic to humans in several tissues, as noted in Table 8-1. Exposures to several metals and their compounds, including lead (Verschaeve et al., 1979) and beryllium (Kuschner, 1981), have been implicated as causes of cancer in humans, but the data are not sufficient to demonstrate such an association unequivocally. In contrast, arsenic and its derivatives present an interesting paradox (Landrigan, 1981) in that there is essentially no experimental evidence to substantiate the carcinogenicity of this element and its compounds in lower animals, whereas the evidence for its carcinogenicity in humans is quite clear (Sky-Peck, 1986).

Table 8-1 Carcinogenicity of Metals

Film and Fiber Carcinogenesis

A class of chemical carcinogens different from those described thus far is the group of inert plastic and metal films or similar forms that cause sarcomas at the implantation site in some rodents (Brand et al., 1975). The implantation site is usually subcutaneous. Rats and mice are highly susceptible to this form of carcinogenesis, but guinea pigs appear to be resistant (Stinson, 1964). The carcinogenic properties of the implant are to a large extent dependent on its physical characteristics and surface area. Multiple perforations each greater than a certain diameter (for example, 0.4 μm), pulverization, or roughening of the surface of the implant (Ferguson, 1977) markedly reduced the incidence of neoplasms. Plastic sponge implants may also induce sarcomas subcutaneously, and in this instance the yield of tumors is dependent on the thickness of the sponge implant (Roe et al., 1967). The age of the animal at implantation also affects the time that elapses from implantation and tumor development (Paulini et al., 1975).

The chemical nature of the implant is not the critical factor in its ability to transform normal cells to neoplastic cells. Brand and associates (Johnson et al., 1970) studied this phenomenon intensively and demonstrated a variety of kinetic and morphologic characteristics of the process of "foreign-body tumorigenesis" in mice. These investigations have shown that DNA synthesis occurs in the film-attached cell population throughout the preneoplastic phase and that preneoplastic cells may be identified well before neoplasms develop (Thomassen et al., 1978). Brand suggested that such "preneoplastic" cells may be present in normal tissue before implantation and that the implant appears to "create the conditions" required for carcinogenesis of these cells (Brand et al., 1975). Other possible mechanisms for this unique type of carcinogenesis are discussed later in this chapter.

While the epidemiologic evidence that implants of prostheses in humans, such as those used for the repair of hernias and joint replacements, induce the formation of sarcomas is not substantial, there have been a number of isolated reports of neoplasms arising in association with such foreign bodies (Sunderman, 1989). A study in the rat of the carcinogenic potential of a number of materials used in such prostheses demonstrated a small increase in sarcomas in animals with certain metal alloy implants that contained significant amounts of cobalt, chromium, or nickel (Memoli et al., 1986). Of greater significance is the induction of malignant mesothelioma and bronchogenic carcinoma in humans by exposure to asbestos fibers. In this case, the induction of the malignant mesotheliomas appears to be dependent on the crystal structure rather than the composition of the asbestos both in experimental animals and in humans (Craighead, 1982). In experimental animals, fibers longer than 8 μm and with a diameter less than 1.5 μm induce mesothelioma fairly effectively. Similarly, certain types of asbestos, such as the crocidolite form, are most strongly associated with the occurrence of this neoplasm, whereas exposure to other forms, such as chrysotile, may not be as important a cause of malignant mesothelioma. Thus, in both humans and animals, film and fiber carcinogenesis is largely independent of the chemical nature of the inciting agent.

Hormonal Carcinogenesis

Hormones consist of amines, steroids, and polypeptides. Beatson (1896) was the first to point out that hormones may be causally associated with the development of specific neoplasms. He suggested that a relationship exists between breast cancer and the ovary, the major site of production of female sex hormones.

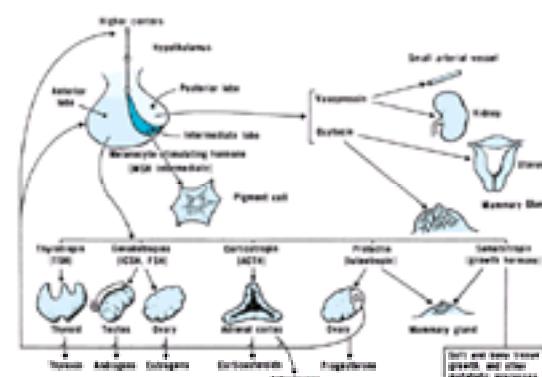
Hormones play an important physiological role in maintaining the "internal milieu" (Bernard, 1878, 1879). Some cancers may result from abnormal internal production of specific hormones. Alternatively, excessive production or the derangement of the homeostatic mechanisms of an organism may result in neoplastic transformation (Clifton and Sridharan, 1975). Furth (1975) was emphatic in his propositions and demonstrations that disruption of the cybernetic relation between peripheral endocrine glands and the anterior pituitary can result in neoplasia of one of the glands involved (Fig. 8-3). One of the classic examples is the experimental transplantation of normal ovaries into the spleen of castrated rodents (Biskind and Biskind, 1944). This results in a break in the pituitary-gonadal hormone feedback loop. The break occurs because estrogens produced by the ovary are carried by the splenic venous system to the liver. In the liver, the estrogens are metabolized and thus are prevented from entering the general circulation to suppress the pituitary production of gonadotropins. The excessive production of gonadotropins and their constant stimulus of the ovarian fragment in the spleen result ultimately in neoplasia of the ovarian implant.


Figure 8-3. Cybernetic relations of the pituitary gland (anterior, intermediate, posterior lobes) with the hypothalamus, other endocrine organs, and tissues of the organism. [After Furth (1975), reproduced with the permission of the author and publisher.]

A similar mechanism is likely to be involved in the production of thyroid neoplasms either by the administration of goitrogens (chemicals that inhibit the synthesis and/or secretion of normal thyroid hormone) or by a marked increase in the circulating levels of thyrotropin secreted by thyrotropin-secreting pituitary neoplasms transplanted into the host. In the former instance, there is a break in the feedback loop and the pituitary gland produces high levels of thyrotropin in the absence of the normal feedback regulation by the thyroid hormone (Furth, 1975). In fact, in humans there is substantial evidence that this may be the mechanism of the development of many thyroid cancers (Williams, 1989). In this case, high levels of circulating thyrotropin result from the unregulated production of this hormone by the transplanted

neoplasm (Ueda and Furth, 1967). Thyroidectomy and neonatal gonadectomy result in the development of neoplasms of the pituitary, presumably because of the lack of inhibition by the hormone from the target end organ (Furth, 1975). Chronic administration of pituitary growth hormone also induces a variety of neoplasms in the rat (Moon et al., 1950a, b). Theoretically, then, neoplasms of any of the end organs shown in Fig. 8-3 may be produced by some manipulation that breaks the feedback loop between the pituitary and the target organ.

Some examples of carcinogenesis resulting from the interruption of the cybernetics of hormonal relationships seen in Fig. 8-3 are listed in Table 8-2. In addition to effecting carcinogenesis in the ovary (Biskind and Biskind, 1944), endogenous gonadotropins are involved in the development of adrenocortical and interstitial (Leydig's) cell neoplasms in mice and rats, respectively (Table 8-2). Unleaded gasoline acts like an antiestrogen, thus removing the estrogen protection usually provided against the development of liver neoplasms in the mouse (Standeven et al., 1994) and leading to an increased number of hepatic neoplasms in the female. Phenobarbital acts to decrease serum levels of thyroid hormone (T_3) by stimulating enzymes that metabolize and eliminate the hormone before it can be recycled to the hypothalamus (McClain, 1989). This mechanism is very similar to the effects of goitrogens, which prevent T_3 formation and release from the thyroid. The induction of pituitary adenomas, which themselves produce large amounts of prolactin, is due to an inhibition of the formation of dopamine in the hypothalamus. Dopamine acts like an inhibitor of prolactin synthesis and release by the pituitary. When this inhibition is eliminated by estrogen inhibition of dopamine formation, prolactin-producing pituitary cells replicate at a very high rate. Furthermore, they produce extensive amounts of prolactin, which in turn, in the presence of estrogens, leads to mammary neoplasia (Neumann, 1991).

Table 8-2 Interrupted Cybernetics of Hormonal Carcinogenesis in Rodents

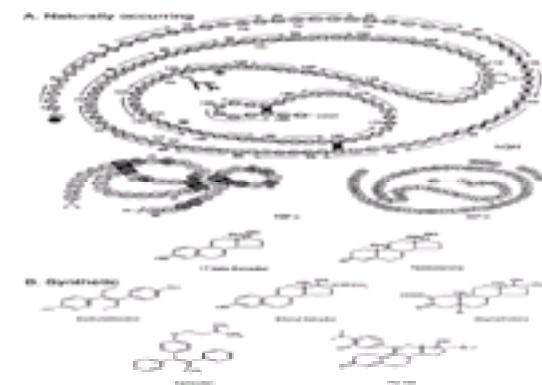
Figure 8-4 shows some representative structures of hormones, naturally occurring and synthetic, for which there is substantial evidence of carcinogenicity in lower animals and/or humans. In addition to the structure of growth hormone, two other growth factors expressed in adult tissues—transforming growth factor-a (TGF-a), which is expressed in the small intestine (Barnard et al., 1991), the major salivary glands (Wu et al., 1993), and other tissues (Lee et al., 1993), and insulin-like growth factor-II (IGF-II), which is expressed in the forebrain, uterus, kidney, heart, skeletal muscle, and to a very small degree the liver (Murphy et al., 1987)—may be considered as chemical carcinogens. The carcinogenic action of these two growth factor hormones in vivo has been demonstrated by the use of transgenic mice, among which animals overexpressing TGF-a developed liver neoplasms in dramatic excess of the number seen in controls (Lee et al., 1992), and animals expressing high levels of IGF-II developed excessive numbers of hepatocellular carcinomas and lymphomas (Rogler et al., 1994).


Figure 8-4. A. Structures of polypeptide hormones (hGH, human growth hormone; TGF-a, transforming growth factor alpha; IGF-II, insulin growth factor-II). B. Structures of some naturally occurring (beta-estradiol and testosterone) and synthetic steroid hormones and antihormones.

As noted in Table 8-2, neoplasms of the pituitary and the peripheral endocrine organs may be induced by the administration of steroid sex hormones. Although the kidney is not usually considered a peripheral endocrine organ, its cells produce erythropoietin. Synthetic or natural estrogen administration can induce renal cortical carcinomas in male hamsters (Li and Li, 1990), and estradiol induces Leydig cell tumors of the testes in mice (Huseby, 1980). However, a closely related structural analogue, 2-fluoroestradiol, which exhibits significant estrogenic potency, did not induce renal carcinoma in the same sex and species (Liehr, 1983). Recently, the synthetic antiestrogen tamoxifen was found to induce carcinomas of the liver in the rat as well (Williams et al., 1993). Evidence that male hormones by themselves are carcinogenic is not as strong as the data for the carcinogenicity of female hormones. The natural male hormone testosterone does exhibit a weak ability to "transform" hamster embryo cells in culture into a neoplastic phenotype (Lasne et al., 1990). The evidence that synthetic androgens are carcinogenic is somewhat greater, especially in humans. In addition, elevated serum testosterone levels are associated with an increased risk of hepatocellular carcinoma in humans (Yu and Chen, 1993). A number of reports (Mays and Christopherson, 1984; Chandra et al., 1984) have indicated a causative relationship between the administration of synthetic androgens such as oxymetholone (Fig. 8-4B) for various clinical conditions and the appearance of hepatocellular neoplasms, predominantly benign.

In addition to apparently direct induction of neoplasia by hormonal stimuli, hormones act in concert with known carcinogenic agents to induce neoplasia. One of the better studied examples of this phenomenon is the induction of mammary adenocarcinomas in rodents. Bittner (1956) demonstrated that three factors are essential for the production of mammary carcinoma in mice: genetic susceptibility, hormonal influence, and a virus transmitted through the milk. The importance of the first two factors has been demonstrated repeatedly in a variety of species, including humans, but incontrovertible evidence for the participation of a virus in mammary carcinogenesis has been obtained only in mice. In the rat, high levels of endogenous prolactin enhance the induction of mammary carcinomas by dimethylbenz(a)anthracene (Ip et al., 1980). Chronic treatment with synthetic or natural estrogens alone may induce mammary carcinomas in rodents. Thus, mammary carcinogenesis in rodents is a complicated process that requires several components that may differ from species to species.

Both male and female sex steroid hormones have also been shown to act in concert with known carcinogenic agents to increase the incidence of neoplasia. Various synthetic estrogens administered chronically to animals that had been dosed with a known carcinogen markedly enhanced the development of hepatocellular carcinomas in the rat (Yager and Yager, 1980). Both testosterone and synthetic androgens given with or after chemical carcinogens enhance the induction of adenocarcinomas of the prostate and other accessory sex organs of the male (Hoover et al., 1990). A combination of testosterone and estradiol-17b after treatment with methylnitrosourea also resulted in the development of adenocarcinomas of the prostate (Bosland et al., 1991).

Chemical Carcinogenesis by Mixtures: Defined and Undefined

While most of this chapter is concerned with the carcinogenic action of specific chemicals, it is relatively unusual for an individual to be exposed to a single carcinogenic agent. Despite this, relatively few detailed studies on mixtures of carcinogenic chemicals have been carried out experimentally. The most common environmental mixtures are those seen in tobacco smoke and other combustion products, including engine exhaust and air pollution (Mauderly, 1993). Interactions between the chemicals in mixtures may be additive, synergistic, or inhibitory (Berger, 1995). In the examples given above, however, the exact chemical nature of components in tobacco smoke or air pollution is not always known and their amounts determined. Thus, one may be forced to deal with a mixture as if it were a single

entity or, if the constituents are known, treat the effects of the mixture in an empiric way that usually is related to the most potent component in the mixture.

Studies on the carcinogenic action of defined mixtures of chemicals are usually done with a knowledge of the carcinogenic effect of the chemicals involved. Warshawsky and coworkers (1993) demonstrated that extremely low levels of benzo[*a*]pyrene, which produced no skin tumors on repeated application, resulted in a significant yield of neoplasms when applied in the presence of five noncarcinogenic polycyclic aromatic hydrocarbons. In an earlier study, the administration of two noncarcinogenic aminoazo dyes in the diet of the rat for a year resulted in the appearance of a variety of neoplasms (Neish et al., 1967). More recently, the administration of three to five *N*-nitrosamines resulted in either an additive or synergistic carcinogenic effect of the combinations of the compounds when given at low dose rates (Berger et al., 1987; Lijinsky et al., 1983). In contrast, the administration of a mixture of 40 chemical carcinogens to rats for 2 years at 50 percent of the dose normally used to induce neoplasms in 50 percent of the animals resulted in significant tumor incidences only in the thyroid and liver (Takayama et al., 1989). In a more recent study, ingestion of a mixture of 20 pesticides given at "acceptable daily intake levels" was found to exert no effect on carcinogenesis in rat liver (Ito et al., 1998).

Thus the toxicologic study of complex mixtures not only in the area of carcinogenesis but also as a more general problem in toxicology, is a critical field in human health, as evidenced by disease resulting from a variety of chemical mixtures such as tobacco smoke, diesel exhaust, solvent mixtures, petroleum distillates, and other components of outdoor air pollutants (Feron et al., 1998). As noted above, and as emphasized by others, exposures to chemicals at low, non-toxic doses of the individual constituents may well be of no significant health concern (Cassee et al., 1998). One of the most important chemical mixtures associated with human neoplasia is diet.

Chemical Carcinogenesis by Diet There is substantial evidence in humans to indicate that many dietary components—including excessive caloric intake (Osler, 1987; Lutz and Schlatter, 1992), excessive alcohol intake (IARC, 1987), and a variety of chemical contaminants of the diet including aflatoxin B $_1$ (Fig. 8-2) (Gorchev and Jelinek, 1985; Lutz and Schlatter, 1992)—are carcinogenic. Other general and specific studies have supported these views (Jensen and Madsen, 1988; Habs and Schmähl, 1980; Miller et al., 1994), whereas others have been more controversial (Willett and MacMahon, 1984; Pariza, 1984). Evidence for the association of dietary factors with cancer incidence in animals is more substantial and supports much of the evidence relating environmental factors to increased cancer incidence in the human (Kritchevsky, 1988; Rogers et al., 1993). A number of the dietary factors implicated in the nutritional etiology of specific human cancers may be seen in Table 8-3 (Trichopoulos, 1989). As noted in the table, the caloric content of diets as well as their individual chemical components are factors in cancer development. Although a relative lack of "antioxidant micronutrients" such as keratinoids, selenium, and the vitamins A, C, and E has been implicated as a factor in the incidence of neoplastic development (Blot et al., 1993; Byers and Perry, 1992), more studies are needed before the effectiveness of these agents in cancer prevention in the human can be established. In addition, food contaminants—either added, occurring endogenously, or as a result of the cooking process—may function as carcinogenic agents in the diet (McGregor, 1998).

Table 8-3 Nutritional Etiology of Human Cancer, by Site

Experimental evidence that the lack of available sources of methyl groups can actually induce liver cancer in rats is well documented (Mikol et al., 1983; Ghoshal and Farber, 1984). This observation may be closely related to the earlier studies by Farber (1963) on the induction of liver cancer in rats by the administration of ethionine, which indirectly may cause a lack of available methyl groups in this tissue. Thus, it is apparent that carcinogenesis induced by diet is an extremely complex effect of mixtures of a variety of chemicals. Its importance in human cancer etiology is emphasized further later in this chapter.

MECHANISMS OF CHEMICAL CARCINOGENESIS

Although the discovery that polycyclic hydrocarbons and other chemical compounds can induce cancer in experimental animals gave hope that the complete understanding of the nature of the genesis of neoplasia might be forthcoming, more than 60 years have elapsed since those initial findings, and it appears that we are still a long way from this goal. However, the realization that chemical carcinogens are altered within the living organism by metabolic reactions has brought us much closer to achieving a working understanding of the mechanisms of carcinogenesis.

Metabolism of Chemical Carcinogens in Relation to Carcinogenesis

When it became apparent from the studies of Yoshida and others that chemicals other than polycyclic hydrocarbons were carcinogenic by a variety of metabolic routes, the dilemma of understanding the mechanisms of action of this variety of agents appeared almost insurmountable. It was noted that the excretory metabolites of polycyclic hydrocarbons were hydroxylated derivatives, which usually had little or no carcinogenic activity. Similarly, hydroxylation of the rings of the aromatic amine carcinogens such as 2-acetylaminofluorene (AAF) and 4-dimethyl-amino-azobenzene often resulted in a complete loss of activity. The enzymatic production of these more polar metabolites facilitated the further metabolism and excretion of the parent compound. The beginning of our present understanding of this dilemma was reported by Elizabeth and James Miller, who first demonstrated that azo dyes became covalently bound to proteins of the liver, but not to proteins of the resulting neoplasms (Miller and Miller, 1947). These initial studies of the Millers led them to suggest that the binding of carcinogens to proteins might lead to the loss or deletion of proteins critical for growth control.

As an extension of this work, Elizabeth Miller (1951) demonstrated the covalent binding of benzo(*a*)pyrene or some of its metabolites to proteins in the skin of mice treated with the hydrocarbon. Later Abell and Heidelberger (1962) described the same phenomenon with another carcinogenic polycyclic hydrocarbon, 3-methylcholanthrene. These findings strongly suggested that a critical step in the induction of cancer by chemicals was the covalent interaction of some form of the chemical with macromolecules. Since the parent compound was incapable of covalent binding directly with macromolecules, the logical conclusion was that the interaction of the chemical with the macromolecule was the result of the metabolic alteration of the parent compound.

Although a number of studies in the 1950s (cf. Weisburger and Weisburger, 1958) demonstrated that ring-hydroxylation was a major pathway in the metabolism of AAF, the Millers and Cramer (Miller et al., 1960) reported that hydroxylation of the nitrogen of the acetylamino group also occurred. They isolated *N*-hydroxy-AAF from the urine of AAF-treated rats and found this metabolite to be more carcinogenic than the parent compound, AAF. Furthermore, *N*-hydroxy-AAF induced neoplasms not observed with the parent compound, such as subcutaneous sarcomas at the site of injection. In animals, such as the guinea pig, that convert little of the AAF to its *N*-hydroxy derivative, cancer of the liver was not produced by feeding the parent compound. These findings strongly supported the suggestion that the parent compound might not be the direct carcinogen; instead, certain metabolic derivatives were active in the induction of neoplasia. These studies paved the way to further investigations of the activation of carcinogens by means of their metabolism (Miller, 1970).

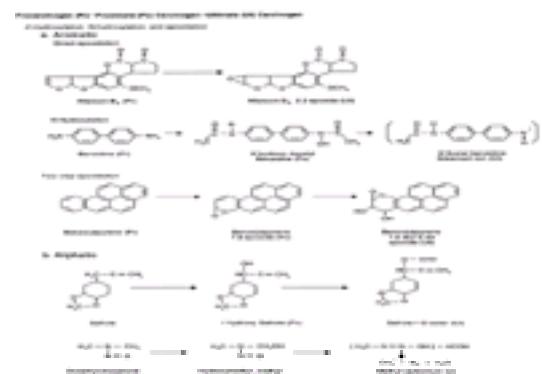
Figure 8-5 depicts a number of metabolic reactions involved in the "activation" of chemicals to the ultimate carcinogenic forms. One may divide such metabolic functions into two general classes (Goldstein and Faletto, 1993). Those involved in phase I metabolism (Fig. 8-5) occur within the endoplasmic reticulum. These reactions involve metabolism by cytochrome P-450 mixed-function oxidases and their reductase as well as the mixed-function amine oxidase. Generally, these metabolic reactions induce biotransformation by converting a substrate to a more polar compound through the introduction of molecular oxygen. Phase II metabolic reactions (Fig. 8-6) are biosynthetic reactions that involve conjugation and occur primarily in the cytosol of the cell. A detailed consideration of xenobiotic metabolism pathways is beyond the scope of this text; the reader is referred to several pertinent reviews (Porter and Coon, 1991; Guengerich, 1992) and Chap. 6 of this book.


Figure 8-5. Structures of representative chemical carcinogens and their metabolic derivatives, the proximate (Px) and ultimate (Ut) carcinogenic forms resulting from the action of phase 1 metabolism of procarcinogens (Pr).
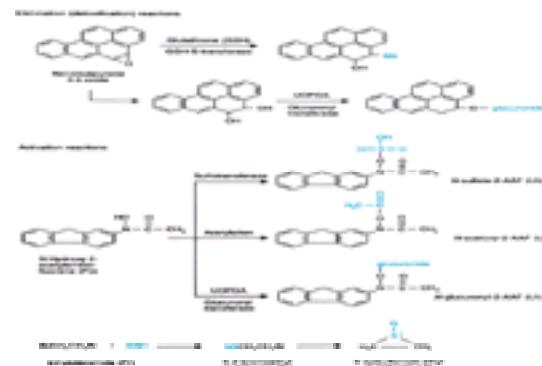

Figure 8-6. Structures of representative chemical carcinogens and their metabolic derivatives resulting from the action of phase II metabolism of procarcinogens.

As noted in Fig. 8-5, the *N*-hydroxylation of AAF can be followed by esterification of the *N*-hydroxyl group to yield a highly reactive compound capable of nonenzymatic reaction with nucleophilic sites on proteins and nucleic acids. The demonstration of the metabolism of AAF to a highly reactive chemical led the Millers to propose that chemical carcinogens are or can be converted into electrophilic reactants (chemicals with electron-deficient sites). These electrophilic agents exert their carcinogenic effects by covalent interaction with cellular macromolecules (Miller, 1978). Furthermore, the Millers proposed that chemical carcinogens requiring metabolism for their carcinogenic effect be termed procarcinogens, whereas their highly reactive metabolites were termed ultimate carcinogens. Metabolites intermediate between the procarcinogens and ultimate carcinogens were called "proximate" carcinogens. The "ultimate" form of the carcinogen, that is, the form that actually interacts with cellular constituents and probably causes the neoplastic transformation, is the final product shown in the pathways provided in Fig. 8-5. In some instances the structure of the ultimate form of certain carcinogenic chemicals is still not known, while in other cases there may be more than one ultimate carcinogenic metabolite.

After the demonstration by the Millers of the critical significance of electrophilic metabolites in chemical carcinogenesis, the ultimate forms of a number of compounds—specifically of the aromatic amines such as benzidine, naphthylamine, and 4-aminobiphenyl—were described. However, the carcinogenic polycyclic hydrocarbons still posed a problem. Pullman and Pullman (1955) had earlier proposed that the K region (Fig. 8-1) of polycyclic hydrocarbons was important in predicting their carcinogenicity. Boyland (1950) proposed the formation of epoxide intermediates in the metabolism of these chemicals. However, it was not until 1970 that Jerina and associates detected the formation of such an intermediate in a biologic system (Jerina et al., 1970). Other investigations showed that epoxides of polycyclic hydrocarbons could react with nucleic acids and proteins in the absence of any metabolizing system. Surprisingly, K-region epoxides of a number of carcinogenic polycyclic hydrocarbons were weaker carcinogens than the parent hydrocarbons. After this finding, scientific attention shifted to other reactive metabolites of these molecules. Benzo(*a*)pyrene has been used as a model compound in studies of carcinogenic polycyclic hydrocarbons, and some of the metabolic reactions observed in vivo are provided in Fig. 8-5 and Fig. 8-6. In 1974, Sims and his associates proposed that a diol epoxide of benzo(*a*)pyrene was the ultimate form of this carcinogen (Sims et al., 1974). Subsequent studies by a number of investigators have demonstrated that the structure of this ultimate form is (+)anti-benzo(*a*)pyrene-7,8-dihydrodiol-9,10-epoxide (Yang et al., 1976; also see reviews by: Conney, 1982; Harvey, 1981; Lowe and Silverman, 1984).

One of the ramifications of these findings is the importance of oxidation of the carbons of the "bay region" of potentially carcinogenic polycyclic hydrocarbons. Figure 8-1 indicated the bay regions of benz(*a*)anthracene and benzo(*a*)pyrene. Analogous bay regions may be identified in other polycyclic aromatic hydrocarbons (Fig. 8-1). The bay region is the sterically hindered region formed by the angular benzo ring. Although the bay-region concept has not been tested with all known carcinogenic polycyclic hydrocarbons, it appears to be generally applicable. Several authors (Levin et al., 1978; Conney, 1982) have proposed that epoxidation of the dihydro, angular benzo ring that forms part of a bay region of a polycyclic hydrocarbon may form the ultimate carcinogenic form. In addition, Cavalieri and Rogan (1992) have proposed that radical cations of polycyclic aromatic hydrocarbons formed by oxidation of the parent compound via the cytochrome P-450 pathway are also important intermediates in the formation of ultimate carcinogenic metabolites of these chemicals. Thus, oxidation can result in the metabolic activation of a number of procarcinogens including the PAHs.

Although administration of polypeptide hormones and growth factors can result in neoplasia, these compounds do not possess "ultimate" carcinogenic forms. There is, however, evidence that synthetic steroid hormones, especially estrogens, are metabolized to more reactive intermediates. In the intensively studied estrogen-induced renal neoplasia in hamsters, Zhu and colleagues (1993) have developed substantial evidence that synthetic estrogens are converted to catechol metabolites in significant amounts. These authors have proposed that such metabolites may act as ultimate carcinogenic forms of the synthetic estrogens.

While conjugation with glutathione usually inactivates chemical carcinogens and permits rapid urinary excretion of the conjugate due to water solubility, an exception has recently been described. Both haloalkanes and haloalkenes react with glutathione in a conjugation reaction catalyzed by glutathione *S*-transferase. Halogenated aliphatics may induce neoplasia in several organs, with the kidney as the predominant target site. The glutathione-dependent bioactivation of ethylene dibromide is provided as an example (Fig. 8-6). The proximate carcinogen of ethylene dibromide, glutathione *S*-ethylbromide, spontaneously forms an episulfonium ion as the ultimate carcinogenic form. This highly reactive chemical alkylates DNA at the N^7 position of guanine (Koga et al., 1986). In addition to glutathione conjugates, cysteine *S*-conjugates of several haloalkenes are nephrotoxic and mutagenic (Monks et al., 1990). The actual mechanism of the carcinogenic effect of these two carbon compounds is not clear despite these observations (Monks et al., 1990).

Free Radicals and the Metabolism of Chemical Carcinogens

While phase I and II reactions (see above) catalyze the formation of electrophilic ultimate forms of chemical carcinogens, substantial evidence has accumulated demonstrating a role for free radical reactions in the formation of the ultimate forms of chemical carcinogens (Sun, 1990; Clemens, 1991; Guyton and Kensler, 1993). Free radicals are chemical elements or their compounds that may be positively or negatively charged or neutral but possess a single unpaired electron. In living systems the principal initial source of such free radicals is from the reduction of molecular oxygen by a variety of metabolic pathways including the phase I cytochrome P450 system, mitochondrial oxidation and reduction of oxygen (Kowaltowski and Vercesi, 1999), and enzymes of peroxisomes that produce hydrogen peroxide as a metabolic product (van den Bosch et al., 1992). Several of these forms of "active" oxygen (Fig. 8-7) are also generated during the process of inflammation (Cerutti and Trump, 1991). The superoxide radical may oxidize nitric oxide to the highly reactive peroxynitrite ion which is capable of initiating lipid peroxidation and free radical formation in this species (Hogg and Kalyanaraman, 1999). Most free radicals formed in biological systems are extremely reactive, although a wide range of stabilities are known for a number of different free radical species. While hydrogen peroxide is itself not a free radical, it becomes a source of such on its interaction with transition metals, especially iron, resulting in the formation of the highly reactive hydroxyl free radical, HO· (Fig. 8-7). Although the biological reduction of molecular oxygen is the prime generative pathway for free radical development, free radical intermediates are sometimes formed during the metabolism of chemical carcinogens

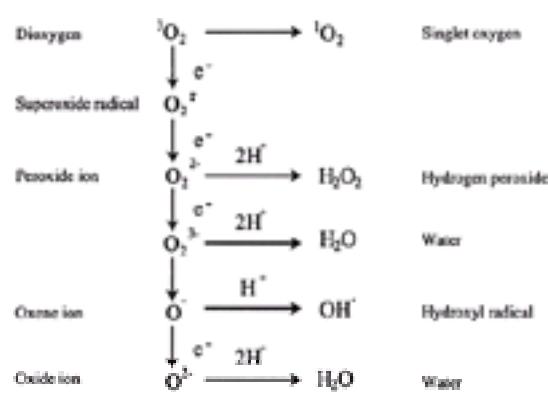
(Guengerich, 1992), and the metabolic reactions of a number of chemical carcinogens may proceed through free radical intermediates (Floyd, 1981, 1990). Chemical carcinogens—including nitrosamines (Bartsch et al., 1989), nitro compounds (Conaway et al., 1991), and diethylstilbestrol (Wang and Liehr, 1994)—may possess ultimate forms that are free radicals. The formation of free radicals also plays an important role in the carcinogenic effects of ionizing radiation (Biaglow, 1981).


Figure 8-7. Sequential and univalent reduction of molecular oxygen indicating various species produced. [Modified from Martínez-Cayuela (1995), with permission of authors and publishers.]

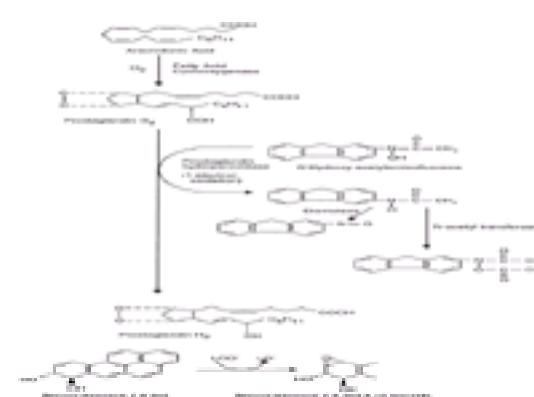
Pathways other than those of the mixed-function oxidase system may also be involved in the bioactivation of chemicals. Marnett (1981) has described the co-oxygenation of polyunsaturated fatty acids, especially arachidonic acid, and polycyclic aromatic hydrocarbons with bioactivation of the hydrocarbon. Such cooxygenation can occur during the synthesis of prostaglandins, a series of autocoids important in normal homeostasis. The prostaglandin H synthetase has two catalytic activities. In the first reaction, the cyclooxygenase activity of prostaglandin H synthetase catalyzes the oxidation of arachidonic acid to the endoperoxidase prostaglandin G_2 (Fig. 8-8). The associated peroxidase activity of prostaglandin H synthase reduces the hydroperoxide prostaglandin G_2 to the alcohol prostaglandin H_2. Many tissues that have a low expression of monooxygenases contain prostaglandin H synthase. In these tissues, compounds can be activated to reactive forms by prostaglandin H synthase, since oxidation by the peroxidase activity often yields a free radical product. The cooxidation of 2-aminofluorene is an example (Fig. 8-8). In the case of benzo(*a*)pyrene 7,8 diol, peroxidase-catalyzed transfer of the free radical from the hydroperoxide to the hydrocarbon results in formation of the ultimate carcinogenic form of benzo(*a*)pyrene, the 7,8 diol 9,10 epoxide. This pathway of metabolic activation of carcinogens, while not ubiquitous, is important in some extrahepatic tissues (Pruess-Schwartz et al., 1989). For example, Wise and colleagues (1984) demonstrated a marked metabolic activation of 2-naphthylamine via the prostaglandin synthase in dog bladder without activation in the liver. Mattammal and associates (1981) have suggested that a number of renal and bladder carcinogens may be activated by this pathway. Several reviews on the role of prostaglandin synthetase in the metabolism of compounds, including their bioactivation in extrahepatic tissues, can be consulted for additional information (Eling et al., 1990; Smith et al., 1991).


Figure 8-8. The metabolic activation of benzo(a)pyrene 7,8 diol and N-hydroxy 2-acetylaminofluorene during the peroxidation of arachidonic acid.

In addition to the activation of chemical carcinogens, free radicals may directly react with DNA to produce a variety of structural changes in bases. Many of these structures are due to attack by hydroxyl free radicals directly with the DNA base. In a sense such structures are analogous to DNA adducts of carcinogens. The more commonly found of these structures are 8-hydroxy(oxo)guanine and 5-hydroxy-6-hydrothymine. Because of the ubiquitous nature of oxygen free radicals, DNA of all living entities contains a variable number of such structures (Olinski et al., 1998). Under normal circumstances, in mammalian cells there is a quite significant formation of these oxidized DNA bases (see below).

Chemical Structure and Chemical Carcinogenesis

Knowledge of the metabolic activation of chemicals has dramatically advanced our understanding of carcinogenic mechanisms underlying the extreme diversity of chemical structures involved in cancer development. The relationship of chemical structure to carcinogenic activity plays a significant role in the potential identification and mechanism of potential chemical carcinogens. Computerized databases of carcinogenic and noncarcinogenic chemicals have been developed to relate structure to carcinogenic activity in a variety of carcinogens (Enslein et al., 1994; Rosenkranz and Klopman, 1994).

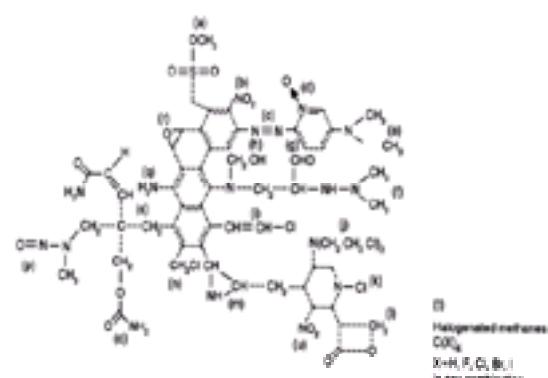
Using the results of rodent bioassays of more than 500 chemicals, Ashby and Paton (1993) studied the influence of chemical structure on both the extent and the target tissue specificity of carcinogenesis for these chemicals. From analysis of the presence of potential electrophilic sites (DNA-reactive), mutagenicity to *Salmonella,* and level of carcinogenicity to rodents, these authors have developed a list of chemical structures that possess a high correlation with the development of neoplasia in rodent tests (Ashby et al., 1989; Tennant and Ashby, 1991). These "structural alerts" signify that a chemical having such structures should be examined closely for carcinogenic potential. These authors have developed a composite model structure indicating the various "structural alerts" that appear to be associated with DNA reactivity or carcinogenicity (Fig. 8-9). The substantial database used to generate these structural alerts indicates the utility of this information for the identification of potential carcinogens and their mechanisms of their action in specific tissues. In addition, investigation of the metabolic activation of such functional groups during the carcinogenic process should provide insight into their role in the induction of cancer.


Figure 8-9. The substituents are as follows: (a) alkyl esters of either phosphonic or sulfonic acids; (b) aromatic nitro groups; (c) aromatic azo groups, not per se, but by virtue of their possible reduction to an aromatic amine; (d) aromatic ring, N-oxides; (e) aromatic mono and dialkylamino groups; (f) alkyl hydrazines; (g) alkyl aldehydes; (h) N-methylol derivatives; (i) monohaloalkenes; (j) a large family of N and S mustards (b-haloethyl); (k) N-chloramines (see below); (l) propiolactones and propiosultones; (m) aromatic and aliphatic aziridinyl derivatives; (n) both aromatic and aliphatic substituted primary

alkyl halides; (o) derivatives of urethane (carbamates); (p) alkyl-N-nitrosamines; (q) aromatic amines, their N-hydroxy derivatives and the derived esters; (r) aliphatic and aromatic epoxides.

The N-chloramine substructure (k) has not yet been associated with carcinogenicity, but potent genotoxic activity has been reported for it (discussed in Ashby et al., 1989). Michael-reactive a,b-unsaturated esters, amides, or nitriles form a relatively new class of genotoxin (e.g., acrylamide). However, the structural requirements for genotoxicity have yet to be established, and this structural unit is not shown in the figure. [Adapted from Tennant and Ashby (1991), with permission of the author and publisher.]

Mutagenesis and Carcinogenesis

Most chemical carcinogens must be metabolized within the cell before they exert their carcinogenic activity. In this respect, metabolism of some chemicals results in a bioactivation instead of elimination. Thus, metabolic capabilities may underlie how a substance that is not carcinogenic for one species may be carcinogenic for another. This becomes important for carcinogen testing in whole animals for both hazard identification and risk assessment. Such considerations impact directly on the choice of the most sensitive species or the species most similar to humans for these evaluations.

Studies on the induction of liver neoplasms by the food dye N,N-dimethyl-4-aminoazobenzene (DAB) provided the first evidence that metabolites of carcinogens could bind to macromolecules. This dye, known as butter yellow, was found to be covalently linked to proteins. Because DAB did not bind to purified protein in vitro and yet could not be extracted from protein after in vivo administration, it was deduced that DAB is metabolized in vivo to a reactive form which covalently binds to cellular macromolecules. The Millers (Miller and Miller, 1947) demonstrated that there was a high degree of correlation between extent of protein binding and carcinogenicity in different species. Because carcinogens are reactive per se or are activated by metabolism to reactive intermediates that bind to cellular components, including DNA, these electrophilic derivatives, which bound to a variety of nucleophilic (electron-dense) moieties in DNA, RNA, and protein, were considered the carcinogenic form of the compounds of interest. Several lines of evidence indicate that DNA is the critical target for carcinogenesis. The first hint that DNA was the target for heritable alterations due to carcinogen administration was from the increased incidence of cancer in genetically prone individuals with defective ability to repair DNA damage (xeroderma pigmentosum; Friedberg, 1992). The second major piece of evidence that DNA was the target of carcinogen action was the observation of carcinogen-induced mutations in specific target genes associated with neoplasia in a multitude of experimental systems. A comparison of DNA adduct formation with biologically effective doses of carcinogens with different potencies demonstrated that the level of DNA damage was relatively similar. Since covalent adducts in DNA could be derived from carcinogenic compounds, the mechanism by which mutations arise and their relationship to carcinogenesis was the next area to be examined in the quest for an understanding of cancer development.

The induction of mutations is due primarily to chemical or physical alterations in the structure of DNA that result in inaccurate replication of that region of the genome. The process of mutagenesis consists of structural DNA alteration, cell proliferation that fixes the DNA damage, and DNA repair that either directly repairs the alkylated base or bases or results in removal of larger segments of the DNA. Electrophilic compounds can interact with the ring nitrogens, exocyclic amino groups, carbonyl oxygens, and the phosphodiester backbone. The reaction of electrophiles with DNA results in alkylation products that are covalent derivatives of the reactive chemical species with DNA. Direct-acting alkylation agents induce preferential binding to highly nucleophilic centers such as the N^7 position of guanine. Less reactive species such as the active form of diethylnitrosamine will also react with the nucleophilic oxygens in DNA. Carcinogenic agents that result in formation of bulky adducts often specifically react with sites in the purine ring. For example, aromatic amines bind to the C^8 position of guanine, while the diol epoxide of polycyclic aromatic hydrocarbons binds to the N^2 and N^6 position of guanine. The position of an adduct in DNA and its chemical and physical properties in that context dictate the types of mutations induced (Essigmann and Wood, 1993). This indicates that different adducts can induce a distinct spectrum of mutations and additionally that any given adduct can result in a multitude of different DNA lesions. Observations on the need for metabolic activation of compounds to their ultimate reactive form were rapidly extended to a number of other compounds, including 2-acetylaminofluorene. In tests of mutagenicity, it was demonstrated that whereas 2-acetylaminofluorene itself is not mutagenic, its sulfate metabolite was highly mutagenic for transforming DNA (Maher et al., 1968). These findings led to the development of mutagenesis assays for the detection of chemical carcinogens from the premise that one could detect carcinogens in highly mutable strains of bacteria given exogenous liver microsomal preparations for in vitro metabolism of the test agent (see below). Cultured mammalian cells have also been developed for evaluation of the mutagenic action of potential carcinogenic agents. Compounds are evaluated in the presence (Michalopoulos et al., 1981) or absence (Li et al., 1991) of metabolic activation systems such as irradiated hepatic feeder layers or hepatic microsomes. The use of these *in vitro* screens of mutagenicity has permitted analysis of the mutational specificity of some carcinogens (Table 8-4). While the data shown in Table 8-4 were derived from bacterial mutagenesis studies, several other systems have also been utilized in attempts to determine mutagenic specificity of various agents (Essigmann and Wood, 1993).

MUTATION	AFB₁	BPDE	2-AAF

Table 8-4 A Comparison of the Mutagenic Spectrum of Aflatoxin B₁ (AFB₁), Benzo[a]pyrene Diolepoxide (BPDE), and 2-Acetylaminofluorene (2-AAF)*

Point mutations, frameshift mutations, chromosomal aberrations, aneuploidy, and polyploidization can be induced by chemicals with varying degrees of specificity that are, in part, dose–dependent. Mutagenesis can be the result of several different alterations in the physical and chemical nature of DNA. While alkylation of DNA with small alkyl groups or large bulky adducts can result in mutation, other processes may also be involved. Conformation of the DNA has a major impact on the potential mutagenic activity of a compound. This is best demonstrated by the related compounds 2-acetylaminofluorene and 2-aminofluorene, which both form bulky DNA adducts at guanine residues in DNA. The AAF adduct distorts the double helix, while the AF adduct remains outside the helix and does not distort it. The AAF adduct induces frameshift mutations, whereas that of AF induces primarily transversions (Bichara and Fuchs, 1985). Planar agents that can intercalate between the base pairs in DNA can effectively induce frameshift mutations by exacerbating slippage mispairing in repetitive sequences. In addition, agents that lie within the major or minor groove of DNA can perturb nucleosome formation and may alter DNA replication. Some of these agents are potential chemotherapeutic agents. Agents such as irradiation and topoisomerase inhibitors that induce double-strand breaks can also enhance mutagenesis (Eastman and Barry, 1992).

Several mechanisms of mutagenesis exist. The presence of certain alkylation products, such as the O^6 alkyl deoxyguanosine and the O^4 alkyl deoxythymidine, permits a degenerate base pairing able to base pair with the appropriate base as well as an inappropriate base. This can be demonstrated in vitro and in vivo as the induction of transition mutations after treatment with certain alkylating agents (Singer, 1986). Thus, methylating or ethylating agents result in mutations as a result of base mispairing. The active metabolites of numerous compounds, such as PAHs and aromatic amines, can form bulky DNA adducts that block DNA synthesis, resulting in a noncoding lesion. The synthetic machinery employs bypass synthesis to avoid the lethal impact of these unrepaired lesions (Friedberg, 1994). In this condition, the most prevalent base, frequently deoxyadenosine (Shearman and Loeb, 1979), is inserted opposite the offending adducted nucleotide base. Thus, DNA binding and repair, induction of point mutations, and clastogenicity have proven useful as endpoints in the identification of potential carcinogens as well as biomarkers of carcinogen exposure. The role of DNA repair in protection of the genome and in the induction of mutations is an essential component in the mutagenesis process (see below).

Not all chemical carcinogens require intracellular metabolism to become ultimate carcinogens. Examples of direct-acting mutagens include alkylating agents such as b-propiolactone, nitrogen mustard, ethyleneimine, and bis(chloromethyl)ether (Fig. 8-3). Direct-acting carcinogens are typically carcinogenic at multiple sites and in all

species examined. A number of the direct-acting alkylating agents, including some used in chemotherapy, are carcinogenic for humans (Vainio et al., 1991).

Macromolecular Adducts Resulting from Reaction with Ultimate Carcinogens

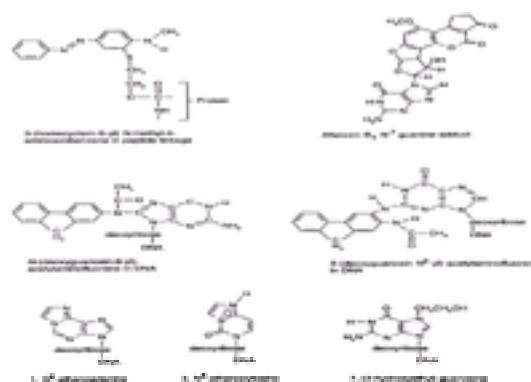
One of the most intriguing problems in chemical carcinogenesis is the chemical characterization of the covalent compounds derived from reactions between the ultimate metabolite of a chemical carcinogen and a macromolecule. The structures of several carcinogens covalently bound to protein and nucleic acids are provided in Fig. 8-10. As noted in the figure, the reaction of the ultimate form of N-methyl-4-aminoazobenzene with polypeptides involves a demethylation of methionine and reaction of the electrophilic position ortho to the amino group of the azobenzene with the nucleophilic sulfur of methionine and subsequent loss of the methyl of methionine. The most nucleophilic site in DNA is the N^7 position of guanine, and many carcinogens form covalent adducts at that site. Adducts formed with DNA exhibit stereospecific configurations, as exemplified by the reaction of the epoxide of aflatoxin B $_1$ with the N^7 position of guanine. The ultimate carcinogenic form of AAF also reacts with guanine at two positions on the DNA base, as shown in the figure. In contrast, ethylene oxide directly alkylates the N^7 position of guanine in DNA (Bolt et al., 1988). An interesting adduction occurs during the metabolism of 2-nitropropane, which results in the formation of 8-aminoguanine possibly from the spontaneous reaction with the highly reactive intermediate (NH_2^+) formed during the metabolism of the nitro group (Sodum et al., 1993). The formation of an additional ring structure in adenine and cytosine occurs with the ultimate form of vinyl chloride and structurally similar carcinogens (Bolt, 1988). For the detailed chemistry of the reactions involved in the formation of such adducts, several reviews are suggested (Miller, 1970, 1978; Weisburger and Williams, 1982 ; Hathway and Kolar, 1980; and Dipple et al., 1985).


Figure 8-10. Structures of some protein- and nucleic acid-bound forms of certain chemical carcinogens.

The macromolecular linkages are shown schematically. Esters of 2-acetylaminofluorene react predominantly with the 8-position of guanine, whereas the epoxide of aflatoxin B₁ reacts primarily with the N-7 position of guanine. The ethano-adenine and ethano-cytosine adducts result from the reaction of DNA with halogenated acetaldehydes or ultimate forms of vinyl chloride and related structures. 7-(2-Hydroxyethyl)guanosine is a product of the reaction of ethylene oxide with DNA.

Several carcinogens that adduct DNA by direct methylation, ethylation, or higher alkylations are of considerable experimental and environmental significance. The sites on the individual DNA bases that are alkylated by ethylating and methylating chemicals and the relative proportions of methylated bases present in DNA after reaction with carcinogen-methylating agents are seen in Table 8-5 (Pegg, 1984). The predominant adduct seen with methylating agents such as methylmethane sulfonate is 7-methylguanine. In contrast, ethylation of DNA occurs predominantly in the phosphate backbone. Pegg has argued that the principal carcinogenic adduct is the O^6-alkylguanine. In contrast, Swenberg and associates (1984) reported that O^4-alkylthymine may be a more important adduct for carcinogenesis because this DNA adduct is retained in the DNA for more extended periods than is the O^6-alkylguanine adduct. The importance of the persistence of DNA adducts of ultimate carcinogens are discussed below.

	Percentage of Total Alkylation by	
	DIMETHYLNITROSAMINE, N-METHYL-N-NITROSOUREA, 1,2-DIMETHYLHYDRAZINE	DIETHYLNITROSAMINE, N-ETHYL-N-NITROSOUREA
1-Alkyladenine	0.7	0.3
3-Alkyladenine	8.	4.
7-Alkyladenine	1.5	0.4
3-Alkylguanine	0.8	0.6
7-Alkylguanine	68.	12.
O⁶-Alkylguanine	7.5	8.
3-Alkylcytosine	0.5	0.2
O²-Alkylcytosine	0.1	3.
3-Alkylthymine	0.3	0.8
O²-Alkylthymine	0.1	7.
O⁴-Alkylthymine	0.1–0.7	1–4
Alkylphosphate	12.	53.

Table 8-5 Relative Proportions of Methylated Bases Present in DNA after Reaction with Carcinogenic Alkylating Agents

Another common structural change in DNA is the hydroxylation of DNA bases. Such changes have been found in all four of the bases making up DNA (Marnett and Burcham, 1993), but the most commonly analyzed are 5-hydroxymethylthymine (Srinivasan and Glauert, 1990) and 8-hydroxyguanine (Floyd, 1990). These hydroxylated bases have been found in DNA of target organs in animals administered chemical carcinogens but are also present in the DNA of organisms not subjected to any known carcinogenic agent (Marnett and Burcham, 1993). Estimates of a rate of endogenous depurination of DNA of 580 bases per hour per cell and DNA strand breaks at a rate of 2300/h per cell have been reported (Shapiro, 1981). These estimates are not incompatible with the presence of oxidative DNA lesions at a level of 10^6 per cell in the young rat and almost twice this in the old rat (Ames et al., 1993). The source of such oxidative damage is presumably from free radical reactions occurring endogenously in the cell that are capable of producing activated oxygen radicals (Floyd, 1990; Ames et al., 1993). Such oxidative reactions, occurring either as a result of an endogenous oxidative phenomenon or from the administration of exogenous chemical and radiation carcinogens, presumably are rapidly repaired by mechanisms discussed below. Thus, endogenous mutations are kept to a minimum.

The best-studied endogenous modification of DNA is the methylation of deoxycytidine residues by the transfer of a methyl group from S-adenosylmethionine by DNA methyltransferase (Holliday, 1989; Michalowsky and Jones, 1989). Such methylation results in the heritable expression or repression of specific genes in eukaryotic cells. Genes that are actively transcribed are hypomethylated, whereas those which are hypermethylated tend to be rarely transcribed. When such methylation occurs during development, the expression or repression of specific genes may be "imprinted" by DNA methylation at various stages during development (Barlow, 1993). Chemical carcinogens may inhibit DNA methylation by several mechanisms, including the formation of covalent adducts, single-strand breaks in the DNA alteration in methionine pools, and the direct inactivation of the enzyme, DNA S-adenosylmethionine methyltransferase, which is responsible for methylation (Riggs and Jones, 1983). Therefore, the inhibition of DNA methylation by chemical carcinogens may represent a further potential mechanism for carcinogenesis induced by chemicals. Mikol and colleagues (1983) demonstrated the importance of this mechanism in hepatocarcinogenesis; half the animals receiving a diet devoid of methionine and choline for 18 months developed hepatocellular carcinomas and cholangiomas. The methyl-deficient diet induces a drastic hypomethylation of hepatic nuclear DNA (Wilson et al., 1984), which may heritably alter the phenotype of the cell.

Finally, structural changes in DNA of largely unknown character have been reported through the use of ^{32}P-postlabeling (Reddy and Randerath, 1987). In this procedure (Fig. 8-11) DNA is digested to its constituent nucleotides by nucleases and each nucleotide is labeled by using g ^{32}P-labeled ATP and a bacterial kinase, an enzyme that transfers the terminal phosphate of ATP to the available 5' hydroxyl of the 39 nucleotides to convert all of the nucleotides to a radioactive, biphosphorylated form. Nucleotides of the normal DNA bases are removed by appropriate chromatographic procedures, leaving only those nucleotides that contain structural adducts. Although this technique has been used to demonstrate adduction of DNA by a variety of known chemical carcinogens, it is equally interesting that a number of adducts of unknown structure have been discovered in living cells. Some of these structurally unknown DNA adducts, termed I-compounds (Li and

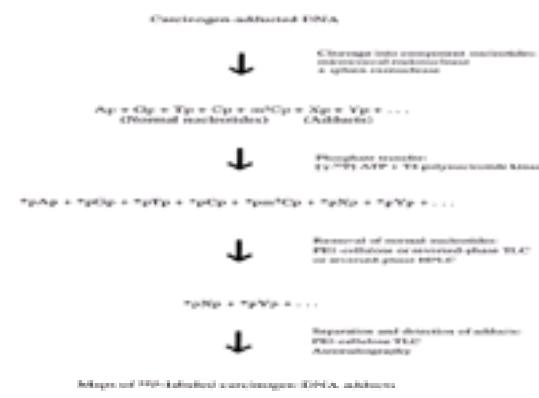
Randerath, 1992), change with dietary modifications, drug administration (Randerath et al., 1992), and species and tissue differences (Li et al., 1990). Li and associates (1995) have presented evidence that at least some of the I-compounds were related to peroxide derivatives of linoleic acid in particular one of the major adducts appears to be derived from 4-hydroxynonenal, a reactive intermediate lipid peroxidation product resulting from free radical reaction with polyunsaturated fatty acids (Chung et al., 1996). I-compounds occur in human fetal tissues (Hansen et al., 1993), increase with age and caloric restriction, but decrease during hepatocarcinogenesis (Randerath et al., 1991). The exact role, if any, of these DNA adducts of unknown structure in the process of carcinogenesis remains a question.


Figure 8-11. The basic features of ^{32}P-postlabeling assay for carcinogen-adducted DNA.

The ^{32}P-assay involves four steps: digestion of DNA, ^{32}P-labeling of the digestion products, removal of ^{32}P-labeled nucleotides not containing adducts, and thin layer chromatography mapping of the [^{32}P] nucleotides with adducts. (Asterisks indicate the position of the ^{32}P-label.) [Modified from Gupta et al. (1982), with permission.]

Thus, the role of structural adducts of DNA in carcinogenesis is not a simple one with adduct = mutation = carcinogenesis. Adducts of known carcinogens (Fig. 8-10) may play a significant role in carcinogenesis induced by their procarcinogenic forms, but the function of structurally undefined, endogenously produced adducts such as I-compounds in the carcinogenic process is not so clear. There is not substantial evidence that endogenously formed adducts lead to mutation. Whether a DNA adduct results in the formation is a consequence of its persistence through a period of cell proliferation, which in turn is partially a function of the process of DNA repair.

DNA REPAIR AND CHEMICAL CARCINOGENESIS

Persistence of DNA Adducts and DNA Repair

The extent to which DNA adducts occur after administration of chemical carcinogens depends on the overall metabolism of the chemical agent as well as the chemical reactivity of the ultimate metabolite. Once the adduct is formed, its continued presence in the DNA of the cell depends primarily on the ability of the cellular machinery to repair the structural alteration in the DNA.

It is from such considerations as well as the presumed critical nature of the adduct in the carcinogenic process that a working hypothesis on the relationship between mutagenesis and carcinogenesis has evolved. It has been postulated that the extent of DNA adduct formation and their persistence in the DNA should correlate with the biological effect of the agent (Neumann, 1983). In accordance with this hypothesis, several studies have correlated the persistence of DNA adducts during chemical carcinogenesis with the high incidence of neoplasms in specific tissues (Table 8-6). Among the earliest of these studies was that of Goth and Rajewsky (1974), who demonstrated the relative persistence of O^6-ethylguanine in DNA of brain but not liver of animals administered ethylnitrosourea at 10 days of age. The rapid loss of the adduct in liver DNA contrasted with the sevenfold slower loss in DNA of the brain. In this study, neoplastic lesions were observed in the brain but not the liver later in life. Swenberg and his associates (1985) demonstrated an analogous situation in the liver, wherein administration of dimethylhydrazine induced a high incidence of neoplasms in hepatic vascular endothelium, but a very low incidence in the hepatocytes. Examination of the analogous adduct O^6-methylguanine demonstrated its rapid removal from the DNA of hepatocytes but much slower removal from the DNA of vascular endothelial cells. Similarly, Kadlubar and his associates (1981) demonstrated that more 2-naphthylamine adducts of guanine persisted in bladder epithelium (urothelium) than in liver after administration of the carcinogen to dogs. The bladder but not the liver is a target for this carcinogen in that species. When the susceptibility to carcinogenesis by diethylnitrosamine was investigated in the same tissue in two different species, significant alkylation and the development of neoplasia were observed in the hamster but not the mouse lung. Thus, the difference in the persistence of DNA adducts plays an important role in target organ and species specificity of select carcinogens.

Table 8-6 Organ and Species Specificity of Chemical Carcinogenesis in Relation to Persistence of Adducts in DNA

Although the correlations noted in Table 8-6 support the working hypothesis of the importance of specific adducts during the carcinogenic process, the mere presence of DNA adducts is probably not sufficient for the carcinogenic process to proceed; equally or more important is the persistence of the adducts in the DNA of viable cells. For example, Swenberg and associate (1984) have demonstrated that the O^4-ethylthymine adduct but not the O^6-ethylguanine adduct is stable in liver parenchymal cells after the continuous exposure of rats to diethylnitrosamine. Furthermore, Müller and Rajewsky (1983) found that the O^4-ethylthymine adduct persisted in all organs after the administration of ethylnitrosourea to neonatal or adult rats. By contrast, persistence of DNA adducts of the carcinogenic *trans*-4-aminostilbene does not correlate with tissue susceptibility. While the liver and kidney exhibited the greatest burden and persistence of the adduct and the ear duct glands of Zymbal showed the lowest adduct concentration, it is the latter tissue that is most susceptible to carcinogenesis by this agent (Neumann, 1983). Such differences in susceptibility to carcinogenesis are undoubtedly the result of a number of factors, including replication of the target cells and repair of the carcinogen-DNA adduct (see below).

Despite exceptions to the working hypothesis, our knowledge of the persistence of covalent adducts of DNA in tissues has been utilized to quantitate the exposure of humans to carcinogenic chemicals and relate the potential risk of neoplastic development to such exposure. The occurrence of adducts of benzo(*a*)pyrene throughout the tissues of exposed animals at unexpectedly similar levels (Stowers and Anderson, 1985) further supports the rationale for the investigation of persistent adducts of DNA and protein as biomarkers of human exposure. Immunologic and highly sensitive chromatographic technologies have been used to demonstrate the presence of adducts of several carcinogenic species (Perera et al., 1991; Shields and Harris, 1991). DNA adducts of carcinogenic PAHs have been demonstrated at relatively high levels in tissues, especially blood cells, of smokers and foundry workers compared with nonexposed individuals (Perera et al., 1991). Huh and coworkers (1989) have demonstrated an increased level of O^4-ethylthymine in the DNA of liver from individuals with no known exposure to ethylating agents, and a statistically significant increased level of ethylation of this base was noted in cancer patients compared with controls. In a more recent study by Hsieh and Hsieh (1993), DNA

adducts of aflatoxin B_1 were demonstrated in samples of human placenta and cord blood from patients in Taiwan, an area of high liver cancer incidence. In addition to detection of specific structural DNA adducts, the ^{32}P-postlabeling assay has also been exploited to determine the presence of DNA adducts in human tissues (Beach and Gupta, 1992). As expected, a variety of adducts are found in both normal individuals and those potentially exposed to specific carcinogenic agents. In addition to DNA adducts, specific carcinogens also covalently bind to serum proteins. For example, Bryant and colleagues (1987) showed a five- to sixfold greater level of hemoglobin adducts of 4-aminobiphenyl in smokers than in nonsmokers. While this adduct has a finite lifetime, chronic exposure to cigarette smoke maintains the dramatic increase in the adduct level between these two groups, suggesting a potential use of such determinations in estimating exposure to carcinogenic agents. Thus, the persistence of macromolecular adducts of the ultimate forms of chemical carcinogens may be very important in the carcinogenic mechanism of such agents. However, as noted above, the presence and persistence of DNA adducts is only one factor in the complex process of cancer development.

Mechanisms of DNA Repair

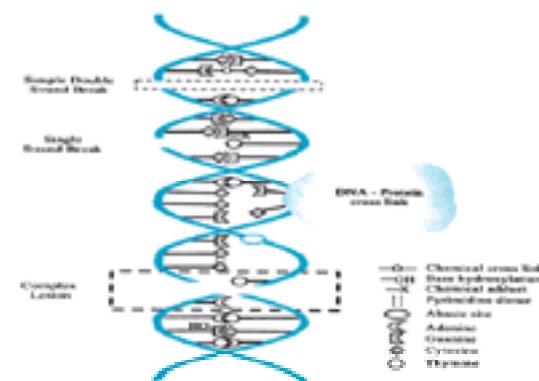
The persistence of DNA adducts is predominantly the result of the failure of DNA repair. The types of structural alterations that may occur in the DNA molecule as a result of interaction with reactive chemical species or directly with radiation are considerable. A number of the more frequently seen structural changes in DNA are schematically represented in Fig. 8-12. The reaction of DNA with reactive chemical species produces adducts on bases, sugars, and the phosphate backbone. In addition, bifunctional reactive chemicals may cause the cross-linking of DNA strands through reaction with two opposing bases. Other structural changes, such as the pyrimidine dimer formation, are specific for ultraviolet radiation, while double-strand DNA breaks are most commonly seen with ionizing radiation (see below). Most of the other lesions depicted in Fig. 8-12 may occur as a result of either chemical or radiation effects on the DNA molecule. To cope with the many structurally distinct types of DNA damage, a variety of mechanisms have evolved to effectively repair each of the types of damage shown in Fig. 8-12. It is estimated that over 100 genes are dedicated to DNA repair, emphasizing the essential nature of the genetic information. A summary of the types of DNA repair most commonly encountered in mammalian systems is given in Table 8-7.


Figure 8-12. Schematic representation of chemical- and radiation-induced lesions in DNA.

Table 8-7 Types of DNA Repair

Two types of damage response pathways exist: repair pathways and the tolerance mechanism (Friedberg, 1994). In repair mechanisms the DNA damage is removed, while tolerance mechanisms circumvent the damage without fixing it. Tolerance mechanisms are by definition error-prone. Certain repair mechanisms reverse the DNA damage, for example, removal of adducts from bases and insertion of bases into apurinic/apyrimidinic (AP) sites. An example of direct reversal is provided by the removal of small alkyl groups from the O^6 portion of guanine by alkyltransferases. Alkyltransferases directly transfer the alkyl (methyl or ethyl) group from the DNA base guanine to a cysteine acceptor site in the alkyltransferase protein (Pegg and Byers, 1992). In microorganisms, the intracellular concentration of the alkyltransferase protein is regulated by environmental factors, including the concentration of the alkylating agents. A similar adaptation may occur in certain mammalian tissues in response to DNA-damaging agents and to treatments causing an increase in cell proliferation. In mammalian tissues, the level of the alkyltransferase protein is a major factor in the resistance of some cancer cells to certain chemotherapeutic agents. At least for the alkyltransferase reaction, direct reversal of the premutational lesions restores normal base pairing specificity.

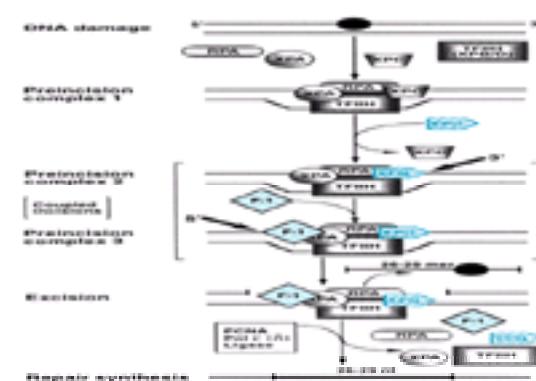
The excisional repair of DNA may involve either the removal of a single altered base having a relatively low-molecular-weight adduct, such as an ethyl or methyl group, and is termed *base excision repair,* or the repair may involve a base with a very large bulky group adducted to it, termed *nucleotide excision repair*. The linkage of two bases seen in the dimerization of pyrimidines by ultraviolet light is also repaired by the latter pathway. This nucleotide excision pathway is represented diagrammatically in Fig. 8-13.


Figure 8-13. Model for transcription-independent nucleotide excision repair of DNA in humans.

The damage is first recognized in an ATP-independent step by the short-lived XPA·RPA complex. In a second, ATP-dependent step, the damaged DNA-bound XPA·RPA complex recruits XPC and TFIIH, to form the preincision complex 1 (PIC1). TFIIH possesses both 3'-5' and 5'-3' helicase activities, respectively, through its XPB and XPD subunits and unwinds DNA by about 20 base pairs around the damage. 2. XPG binds the PIC1 complex while the molecular matchmaker XPC dissociates, leading to the more stable PIC2 excinuclease complex. 3. PIC2 recruits XPF·ERCC1 (F-1) to form PIC3. XPG makes the 3' incision and F-1 makes the 5' incision a fraction of a second later, in a concerted but asynchronous mechanism. 4. The excised damaged fragment is released by the excinuclease complex, leaving in place a post-incision complex whose exact composition is still unclear. The proliferating cell nuclear antigen (PCNA) forms a torus around the DNA molecule associating with DNA polymerase d and/or e [Pol e (d)] (Tsurimoto, 1998) and a DNA ligase replacing the postincision complex with these repair synthesis proteins. 5.

The gap is filled and the repair patch is ligated. [From Petit and Sancar (1999), with permission of authors and publisher.]

Nucleotide excision repair in multicellular organisms involves a series of reactions noted in the figure. These include recognition of the damage, unwinding of the DNA, 3' and 5' sequential dual incisions of the damaged strand, repair synthesis of the eliminated patch, and final ligation. Each of these steps as noted in the figure involves a number of different proteins. In Table 8-8 may be seen a listing of the various proteins occurring in different fractions and their functions in the process of nucleotide excision repair (Petit and Sancar, 1999).

Table 8-8 Proteins Involved in the Nucleotide Excision Repair Process in Humans

Other studies (cf. Sancar and Tang, 1993; Hanawalt, 1994) have also demonstrated that nucleotide excision repair in many instances occurs simultaneously with gene transcription. In fact, Hanawalt and his associates showed earlier (cf. Bohr et al., 1987) that nucleotide excision repair occurred preferentially in genes which were actively being transcribed. For the final resynthesis of the segment of excised DNA, both the proliferating cell nuclear antigen (PCNA) as well as at least two different DNA polymerases (d or e) are needed to complete the repair process together with a ligase (Sancar, 1994).

Since animal cell DNA polymerases are not absolutely faithful in their replication of the template strand, there is the potential for a mutation to occur in the form of one or more mispaired bases during the process outlined above. This possibility is greater in the case of nucleotide excision repair as compared to simple base excision since a much longer base sequence is removed and resynthesized during the nucleotide excision mechanism. The existence and ultimate characterization of a number of the proteins involved in nucleotide excision repair has been the result of human diseases in which defects in this mechanism are known. In particular, the disease, xeroderma pigmentosum, is an autosomal recessive condition in which most patients are highly sensitive to exposure to ultraviolet light. Thus, on chronic exposure to sunlight such individuals have a much greater risk of developing skin cancer than normal individuals. This fact emphasizes the potential importance of altered DNA repair in the development of neoplasia.

While the repair of adducts as indicated above involves several possible pathways, the repair of double DNA strand breaks is more complicated and as a result more prone to error than either the excisional or direct reversal pathways. Single-strand breaks may result from a variety of alterations by chemicals or radiation and, as noted above, during the repair process itself. Double-strand breaks in DNA are largely the result of ionizing radiation or high doses of alkylating carcinogens such as nitrogen mustard or polycyclic hydrocarbons, although even under normal conditions, transient double-strand DNA breaks occur as the result of the normal function of topoisomerases involved in the winding and unwinding of DNA.

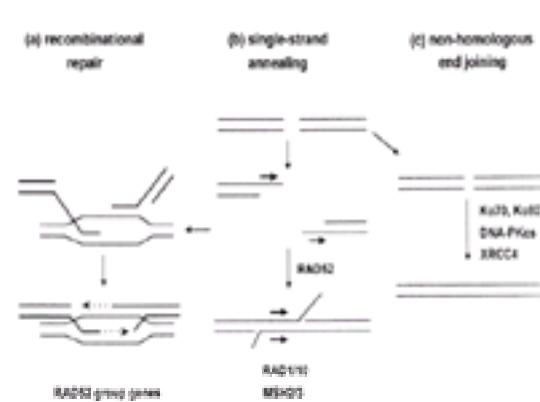
In Fig. 8-14 may be noted a schematic diagram of three forms of double-strand DNA repair. Recombinational repair or homologous recombination (HR) is more commonly seen in lower eukaryotes such as yeast while the nonhomologous end joining (NHEJ) pathway of double-strand DNA repair is more commonly seen in higher vertebrates (Van Dyck et al., 1999). The single-strand annealing pathway has not yet been well studied in higher vertebrates. While the exact mechanisms involved in each of these steps are not considered in detail here, the interested reader is referred to more detailed references (Pastink and Lohman, 1999; Lieber, 1998; Featherstone and Jackson, 1999). In general, in the HR and NHEJ pathways, specific proteins interact with the open ends of the DNA, members of the Rad52 group genes in the case of HR (Van Dyck et al., 1999) and the Ku70 and Ku80 proteins in the NHEJ pathway (Featherstone and Jackson, 1999). A DNA-dependent protein kinase (DNA-PKcs) as well as the protein interacting with the DNA ligase (XRCC4) is involved in this mechanism. It should be noted as indicated in the legend to the figure, however, that these mechanisms are quite error-prone and only under the best of circumstances result in a faithful recapitulation of the normal DNA sequence.


Figure 8-14. Schematic representation of pathways involved in the repair of double-strand breaks in DNA.

(a) The first step in recombinational repair is the formation of 3' single-stranded tails by exonucleolytic activity followed by invasion of a homologous undamaged donor sequence. Repair synthesis and branch migration lead to the formation of two Holliday junctions, i.e., a single DNA strand linking two double-stranded DNA molecules. Resolution of these intermediate structures results in the formation of two possible crossover and two possible noncrossover products (*not shown*). The fidelity of this repair is dependent on the exact complementation of the unaffected double-strand by the strands undergoing repair. (b) In the single-strand annealing pathway, exposures of regions of homology during resection of the 5'-ends allows formation of joint molecules. Repair of the double-strand break is completed by removal of nonhomologous ends and ligation. As a consequence, a deletion is introduced in the DNA. (c) Nonhomologous end joining is based on religation of the two ends involving a complex of proteins, some of which are indicated in the figure and may involve the deletion and/or insertion of nucleotides. [Adapted from Pastink and Lohman (1999), with permission of authors and publisher.]

Double-strand breaks may occur at sites of single-strand DNA resulting from adduction of bulky molecules, preventing further polymerase action and subsequent endonuclease cleavage and resulting in double-strand breaks and potential chromosomal aberrations (Kaufmann, 1989).

Incorrectly paired nucleotides may occur in DNA as a result of DNA polymerase infidelity, formation and/or repair of apurinic and nucleotide excision sites, double-strand DNA repair, and metabolic modification of specific bases. Mismatch repair can be distinguished from nucleotide excision repair and base excision repair by several characteristics. Nucleotide and base excision repair generally involves the recognition of nucleotides/bases that have been chemically modified or fused to an adjacent nucleotide. In contrast, mismatch repair recognizes normal nucleotides which are either unpaired or paired with a noncomplementary nucleotide (cf. Fishel and Kolodner, 1995). Thus, mismatch repair may become involved in virtually any of the types of DNA repair seen in Table 8-7 with the possible exception of the direct reversal of DNA damage. The various combination of gene products involved in several of the types of mismatch repair are seen in Fig. 8-15. While the

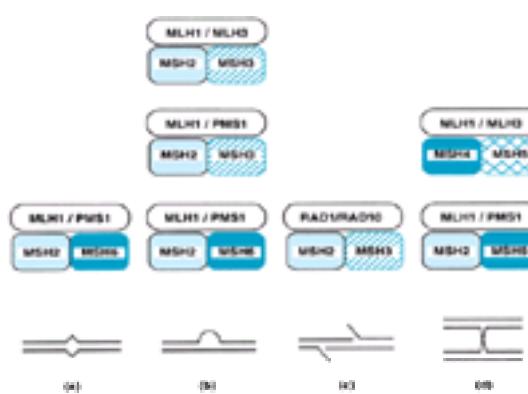
nomenclature of the various components varies depending on the phyla—e.g., eukaryotes, yeast, vertebrates—a functional similarity occurs throughout, most faithful in eukaryotes. As noted from the figure, recognition of the mismatch appears to be a major function of the MSH2 (hMSH2 in the human), while MSH3 and MSH6 are involved in the specificity of binding itself (Fishel and Wilson, 1997). Thus, these complexes act as sensors of mismatch as well as other structural changes in the genome (Modrich, 1997 ; Li et al., 1996 ; cf. Fishel and Wilson, 1997). As in the case of other types of repair following the recognition and interaction with the mismatch repair proteins, the normal sequence is restored following removal of the mismatch DNA, resynthesis, and ligation (cf. Jiricny, 1998).


Figure 8-15. Combinational specificities of heterocomplexes of gene products of mismatch repair genes.

(a) Base/base mispairs; (b) insertion/deletion mispairs; (c) 5' tailed DNA structures generated by single-strand DNA annealing following recombination, e.g. HR; and (d) Holliday junctions. [Adapted from Nakagawa et al. (1999), with permission of authors and publishers.]

As an example of the importance of mismatch DNA repair, the extent of endogenous DNA damage and subsequent repair processes in normal human cells in vivo is seen in Table 8-9. With the possible exception of some single-strand break repair, all the other types of damage are those monitored by the mismatch repair mechanism and repaired under normal conditions. Obviously, a defect in this repair system may result in a dramatic increase in mutational events and in neoplasia.

Table 8-9 Estimates of Endogenous DNA Damage and Repair Processes in Human Cells in Vivo

The critical importance of the fidelity of DNA repair in the maintenance of cellular and organismal homeostasis is apparent from this brief discussion. Because induction of DNA repair processes occurs as a response to genetic damage, the induction can be used as an endpoint for its detection indirectly. In addition, an increase in repair mechanisms above constitutive levels can increase the magnitude of the genotoxic insult. The relative importance of DNA repair in understanding mechanisms of chemical carcinogenesis is most apparent when relating DNA damage and repair to DNA synthesis and cell replication. This is required to exceed the intrinsic capacity of a cell to repair this damage.

DNA Repair, Cell Replication, and Chemical Carcinogenesis

The persistence of DNA adducts in relation to the development of neoplasia in specific tissues (Table 8-6) and differences in the repair of the adducts are critical factors in chemical carcinogenesis. The removal of methyl, ethyl, and similar small alkyl radicals from individual bases is to a great extent dependent on the presence of alkyltransferases (see above). While in some tissues, such as liver, it may be possible to increase the level of such enzymes in response to damage and hormonal or other influences, many tissues do not have an inducible repair mechanisms. Furthermore, some adducts are extremely difficult if not impossible for the cell to repair. An example of such a lesion, the 3-(deoxyguanosine)- N^2 -yl-acetylaminofluorene adduct first described by Kriek and his associates (Westra et al., 1976), is depicted in Fig. 8-10. This may in part account for the relatively wide spectrum of neoplasms inducible by this chemical carcinogen.

Of equal importance is the continuous damage to DNA that occurs within cells as a result of ambient mutagens, radiation, and endogenous processes including oxidation, methylation, deamination, and depurination. DNA damage induced by oxidative reactions (oxidative stress) is probably the source of most endogenous DNA damage. Ames et al. (1993) have estimated that the individual reactive "hits" in DNA per cell per day is of the order of 10^5 in the rat and 10^4 in the human as a result of endogenous oxidative reaction. Such reactions can produce alkylation through peroxidative reactions such as those described in Fig. 8-8 or hydroxylation of bases and single-strand breaks (Fig. 8-12). The end product of oxidative damage to DNA can also be interstrand crosslinks and double-strand breaks (Demple and Harrison, 1994) with the potential for subsequent major genetic damage noted below. A more complete listing of the estimates of endogenous DNA damage and repair processes in the human is seen in Table 8-9. The data of this table emphasize the considerable degree and significant variation in types of DNA damage and repair which occurs within each cell of the organism at a molecular level.

Experimental studies in mammalian cells have demonstrated that active oxygen radicals may contribute to clastogenesis directly (Ochi and Kaneko, 1989) and indirectly through the production of lipid peroxides (Emerit et al., 1991). While methods for the repair of some types of oxidative damage including base hydroxylation (Bessho et al., 1993) and single-strand breaks (Satoh and Lindahl, 1994), exist, such repair requires time and may be dependent on many other intracellular factors. Because the formation of a mutation occurs during the synthesis of a new DNA strand by use of the damaged template, cell replication becomes an important factor in the "fixation" of a mutation. The importance of the rate of cell division and DNA synthesis in carcinogenesis has been emphasized by several authors (Ames et al., 1993 ; Butterworth, 1991 ; Cohen and Ellwein, 1991). Thus, while many DNA repair mechanisms themselves may not be abnormal in neoplastic cells compared with their normal counterpart, a high rate of cell division will tend to enhance both the spontaneous and induced level of mutation through the chance inability of a cell to repair damage prior to DNA synthesis. An important pathway of DNA repair that is genetically defective in a number of hereditary and spontaneous neoplasms in the human (Umar et al., 1994) is the mismatch repair mechanism that corrects spontaneous and post-replicative base alterations and thus is an important pathway for avoidance of mutation in normal cells. Genetic defects in mismatch repair mechanisms lead to microsatellite DNA and instability with subsequent alteration in the stabilization of the genome itself (Modrich, 1994). Enhanced mitogenesis may also trigger more dramatic genetic alterations including mitotic recombination, gene conversion, and nondisjunction. These genetic changes result in further progressive genetic alterations with a high likelihood of resulting in cancer. The types of mutational events, the numbers of such mutations, and the cellular responses to them thus become important factors in our understanding of the mechanisms of chemical carcinogenesis.

CHEMICAL CARCINOGENS AND THE NATURAL HISTORY OF NEOPLASTIC DEVELOPMENT

A number of chemicals can alter the structure of the genome and/or the expression of genetic information with the subsequent appearance of cancer. However, cancer as a disease usually develops slowly with a long latent period between the first exposure to the chemical carcinogen and the ultimate development of malignant neoplasia. Thus, the process of carcinogenesis (the pathogenesis of neoplasia) involves a variety of biological changes which, to a great extent, reflect the

structural and functional alterations in the genome of the affected cell. However, when the biological changes occurring during carcinogenesis are assessed at the molecular level, a better understanding of the mechanisms of cancer development may be generated.

The Pathogenesis of Neoplasia: Biology

Although morphologic changes occurring during the early stages of neoplasia were described during the early decades of this century, it was in the 1940s that a better understanding of the biological changes that occurred following carcinogen exposure was obtained. The first and best-studied model system was that of mouse skin carcinogenesis. The early investigations of Rous and Kidd (1941), Mottram (1944), and Berenblum and Shubik (1947) used the development of benign papillomas as an endpoint for studies of epidermal carcinogenesis in mouse skin induced by polycyclic hydrocarbons. These investigators coined the term "initiation" to designate the initial alteration in individual cells within the tissue resulting from a single subcarcinogenic dose of the chemical carcinogen. In these circumstances, papillomas were obtained only with subsequent chronic, multiple doses of a second agent that by itself was essentially carcinogenic. This latter "stage" was termed *promotion*. Subsequent studies on a mammary adenocarcinoma model in the mouse led to the proposal that processes subsequent to initiation comprised a stage termed *progression* (Foulds, 1954). Foulds's description of this stage emphasized changes characteristic of malignant neoplasia and its evolution to higher degrees of autonomy.

During the last two decades, these investigations have been extended to a variety of tissue systems and to humans (Pitot, 1996). At present the pathogenesis of neoplasia is felt to consist of at least three operationally defined stages beginning with initiation followed by an intermediate stage of promotion, from which evolves the stage of progression. The third stage exhibits many of the characteristics described by Foulds. The biological characteristics of the stages of initiation, promotion, and progression are listed in Table 8-10 (Pitot and Dragan, 1994; Boyd and Barrett, 1990; Harris, 1991). It is in the first and last stage of neoplastic development—initiation and progression—that structural changes in the genome (DNA) can be observed. The structural changes previously discussed are most likely to be involved in the induction of these stages. The intermediate stage of promotion does not appear to involve direct structural changes in the genome of the cell but rather depends on an altered expression of genes.

Table 8-10 Morphologic and Biologic Characteristics of the Stages of Initiation, Promotion, and Progression during Carcinogenesis

Although it may be obvious to the reader, it is important to emphasize that the definition of neoplasia presented at the beginning of the chapter refers only to cells in the stage of progression. Initiated cells almost without exception cannot be identified, and their existence is presumed based on the natural history of neoplastic development. Cells in the stage of promotion are termed *preneoplastic* since their existence is entirely dependent on the continued presence of the promoting agent in the environment. Preneoplasia must be distinguished from premalignant in that the latter terminology also refers to cells in the stage of progression which have not yet expressed their full biologic malignant potential but do have all the characteristics of the stage of progression.

Initiation Until recently the stage of initiation had been characterized and quantitated well after the process of carcinogenesis had begun. As with mutational events (see above), initiation requires one or more rounds of cell division for the "fixation" of the process (Kakunaga, 1975; Columbano et al., 1981). The quantitative parameters of initiation noted in Table 8-10—dose response and relative potency—have been demonstrated in a variety of experimental systems (Pitot et al., 1987; Dragan et al., 1994); however, these parameters may be modulated by alteration of xenobiotic metabolism (Talalay et al., 1988) and by trophic hormones (Liao et al., 1993). The metabolism of initiating agents to nonreactive forms and the high efficiency of DNA repair of the tissue can alter the process of initiation.

One of the characteristics of the stage of initiation is its irreversibility in the sense that the genotype/phenotype of the initiated cell is established at the time of initiation, there is accumulating evidence that not all initiated cells survive over the lifespan of the organism or the period of an experiment. Their demise appears to be due to the normal process of programmed cell death or apoptosis (Wyllie, 1987).

Spontaneous preneoplastic lesions have been described in a number of experimental systems (Maekawa and Mitsumori, 1990; Pretlow, 1994) as well as in the human (Dunham, 1972; Pretlow, 1994; Pretlow et al., 1993). Thus, it would appear that the spontaneous or fortuitous initiation of cells in a variety of tissues is a very common occurrence. If this is true, then the development of neoplasia can be a function solely of the action of agents at the stages of promotion and/or progression.

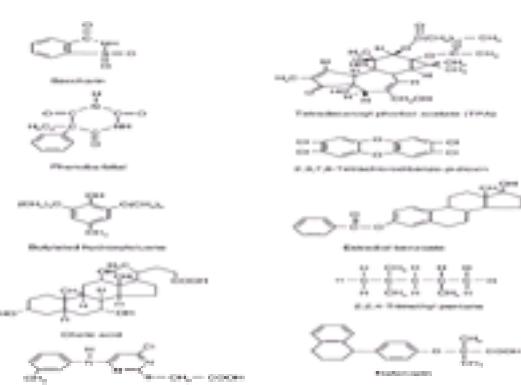
Promotion As in the stage of initiation, a variety of chemicals have been shown to induce this stage. However, unlike chemicals inducing the stage of initiation, there is no evidence that promoting agents or their metabolites directly interact with DNA or that metabolism is required at all for their effectiveness. In Fig. 8-16 may be seen some representative structures of various promoting agents. Tetradecanoyl phorbol acetate (TPA) is a naturally occurring alicyclic chemical that is the active ingredient of croton oil, a promoting agent used for mouse skin tumor promotion. Saccharin is an effective promoting agent for the bladder, and phenobarbital is an effective promoting agent for hepatocarcinogenesis.


Figure 8-16. Structures of representative promoting agents.

2,3,7,8-Tetrachlorodibenzo-*p*-dioxin (TCDD) is probably the most effective promoting agent known for rat liver carcinogenesis but is also effective in the lung and skin. Estradiol is shown as a representative of endogenous hormones that are effective promoting agents. Both androgens and estrogens, natural and synthetic, are effective promoting agents in their target end organ as well as in liver (Taper, 1978; Sumi et al., 1980; Kemp et al., 1989). Cholic acid enhances preneoplastic and neoplastic lesions in the rat colon (Magnuson et al., 1993), whereas 2,2,4-trimethylpentane and unleaded gasoline effectively promote renal tubular cell tumors in rats (Short et al., 1989). The final two structures noted—Wy-14,643 and Nafenopin—are two members of the large class of carcinogenic peroxisome proliferators that induce the synthesis of peroxisomes in liver, are effective promoting agents, and on long-term administration at high doses induce hepatic neoplasms (Reddy and Lalwani, 1983). Many other agents including polypeptide hormones (see above), dietary factors including total calories, many other halogenated hydrocarbons, and numerous other chemicals have been found to enhance the development of preneoplastic and neoplastic lesions in one or more systems of carcinogenesis, including

the human system.

The distinctive characteristic of promotion as contrasted with initiation or progression is the reversible nature of this stage [Pitot and Dragan, 1995 (Table 8-10)]. Boutwell (1964) first demonstrated that by decreasing the frequency of application of the promoting agent following initiation in mouse skin there was a lower yield of papillomas in comparison with that obtained by a more frequent application of the promoting agent. Other investigators (Andrews, 1971; Burns et al., 1978) later demonstrated that papillomas developing during promotion in mouse epidermal carcinogenesis regress in large numbers both on removal of the promoting agent and during its continued application. The regression of preneoplastic lesions upon withdrawal of the promoting agents may be due to apoptosis (Schulte-Herrmann et al., 1990). This proposed mechanism is supported by the demonstration that many promoting agents inhibit apoptosis in preneoplastic lesions (Schulte-Herrmann et al., 1993; Wright et al., 1994). Another potential pathway of this operational reversibility is "redifferentiation" or remodeling (Tatematsu et al., 1983). Thus, cells in the stage of promotion are dependent on continued administration of the promoting agent (Hanigan and Pitot, 1985) as implied by the early studies of Furth (1959) on hormonally dependent neoplasia.

Another characteristic of the stage of promotion is its susceptibility to modulation by physiologic factors. The stage of promotion may be modulated by the aging process (Van Duuren et al., 1975) and by dietary and hormonal factors (Sivak, 1979). Glauert and associates (1986) demonstrated that promotion of hepatocarcinogenesis was less effective in rats fed a semisynthetic diet than in those fed a crude, cereal-based diet. The promotion stage of chemically induced rat mammary cancer is also modulated by dietary factors (Cohen et al., 1991) and hormonal (Carter et al., 1988) factors. Many such modulating factors are themselves promoting agents. Several hormones can be carcinogenic. These hormones are effective promoting agents and thus may serve as an exogenous or endogenous source for modulation of cell proliferation during carcinogenesis (Pitot, 1991). Such physiologic agents may be one component of endogenous promotion of initiated cells.

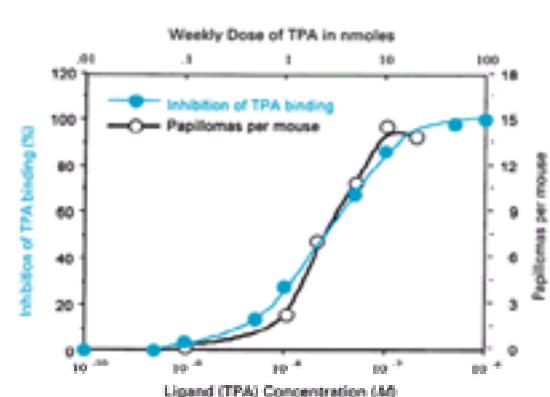
The dose–response relationships of promoting agents exhibit sigmoid-like curves with an observable threshold and maximal effect. Such relationships are depicted in Fig. 8-17, in which the dose–response curve for the binding of the phorbol TPA with its receptor is compared with a dose–response curve for the TPA promotion of dimethylbenzanthracene-initiated papillomas in mouse skin (Ashendel, 1985; Verma and Boutwell, 1980). The threshold effect of promoting agents may be considered a consequence of the reversible nature of their effects at the cellular level (see above). The maximal effect is due to a saturation of ligand binding in the former case and to the promotion of all initiated cells in the latter (Fig. 8-17). Although one may not directly equate the variables in the two processes, the similarity in the shape of the curves is striking (Fig. 8-17). The relative potency of promoting agents may be determined as a function of their ability to induce the clonal growth of initiated cells. Thus, the net rate of growth of preneoplastic lesions can be employed to determine relative potencies for promoting agents (Pitot et al., 1987).


Figure 8-17. Composite showing the specific interaction of the receptor for phorbol esters with its ligand determined as the inhibition of radioactive TPA binding (closed circles).

The tumor response expressed as papillomas per mouse on mice initiated with dimethylbenzanthracene and promoted with various weekly doses of TPA is noted in the open circles [composite graph from data of Ashendel (1985) and from Verma and Boutwell (1980) as published in Pitot (1986a).]

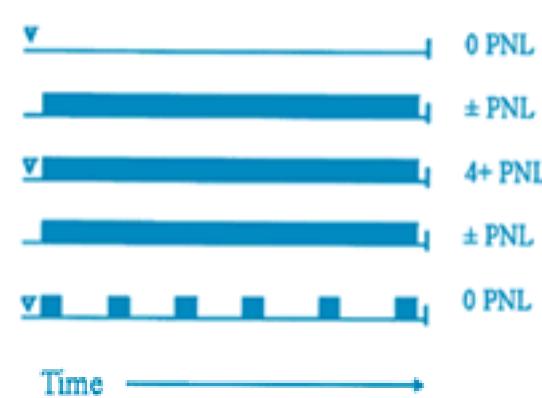
The format of an experimental protocol for the demonstration of initiation and promotion is provided in Fig. 8-18. As noted in the figure, the endpoint of the study, which usually takes from 3 to 6 months, depends on the tissue under investigation, the dose and nature of the initiating and promoting agents utilized, and factors, such as diet and hormonal status, mentioned above. The endpoint analyzed in such studies is properly a preneoplastic lesion (PNL) which develops clonally from initiated cells in the tissue under study. These are altered hepatic foci in the rat or mouse liver (Pitot, 1990), epidermal papillomas for mouse skin (Wigley, 1983), hyperplasia of terminal end buds for rat mammary carcinomas (Purnell, 1980; Russo et al., 1983), and enzyme-altered foci in rat colon carcinogenesis (Pretlow et al., 1993). Administration of the promoting agent for the entire period of the experiment after initiation results in many preneoplastic lesions, whereas alteration of the format of administration of the promoting agent results in the development of very few preneoplastic lesions. This reinforces the fact that the stage of promotion is operationally reversible (Boutwell, 1964) and indicates that a threshold dose effect level may exist.


Figure 8-18. General experimental format demonstrating initiation (v) and promotion ████████ , for use with carcinogenesis studies in rodent tissues. PN, preneoplastic lesions.

Progression The transition from early progeny of initiated cells to the biologically malignant cell population constitutes the major part of the natural history of neoplastic development. Foulds recognized the importance of the development of neoplasia beyond the appearance of any initial identifiable lesions (Foulds, 1965). The characteristics of malignant progression that he observed—growth rate, invasiveness, metastatic frequency, hormonal responsiveness, and morphologic characteristics—vary independently as the disease develops. These characteristics have been ascribed to the karyotypic instability during the irreversible progression stage (Pitot, 1993b). Environmental alterations can influence the stage of progression. For example, exposure to promoting agents can alter gene expression and induce cell proliferation. However, as growth of the neoplasm continues and karyotypic instability evolves, responses to environmental factors may be altered or lost (Noble, 1977; Welch and Tomasovic, 1985). Agents that act only to effect the transition of a cell from the stage of promotion to that of progression may properly be termed *progressor agents*. Some examples are listed in Table 8-11. Such agents presumably have the characteristic of inducing chromosomal aberrations, may not necessarily be capable of initiation, and in some cases may enhance the clastogenesis associated with evolving karyotypic instability. As with the two stages of initiation and promotion, spontaneous progression may also occur. In fact, spontaneous progression would be highly fostered by increased cell replication (Ames et al., 1993).

AGENT	INITIATING ACTIVITY	CLASTOGENIC ACTIVITY	CARCINOGENIC ACTIVITY
Arsenic salts	–	+	+
Asbestos fibers	?	+	+
Benzene	–	+	+
Benzoyl peroxide	–	+	±
Hydroxyurea	–	+	±
1,4-Bis(2-(3,5-dichloropyridyloxy))benzene	–	+	+
2,5,2′,5′-Tetrachlorobiphenyl	–	+	±

Table 8-11 Putative Progressor Agents in Carcinogenesis

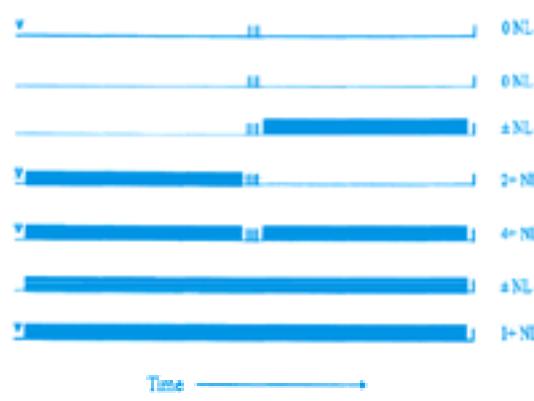
The experimental demonstration of the stage of progression is somewhat more complex than that of initiation and promotion. In Fig. 8-19 may be seen a general experimental format designed to demonstrate the effect of administration of a progressor agent after a course of initiation and promotion with all of the appropriate controls. However, in this instance the endpoint that is quantitated is the number of neoplastic lesions (NL). In experimental systems, the most effective development of neoplasia involves the continued administration of the promoting agent even after that of the progressor agent. This might be expected because cells early in the stage of progression respond to promoting agents, thus increasing the yield of neoplastic lesions in the experimental system (Table 8-10). As noted, a lower yield, usually still significant, may be obtained without additional administration of the promoting agent. Because of the duration of the experiment, preneoplastic lesions occur to varying degrees in each of the experimental groups. The difficulty in such studies is the quantitation of the neoplastic lesions which is usually carried out by determining the number and incidence and multiplicity of malignant tumors. However, premalignant lesions already in the stage of progression occur quite commonly (cf. Henson and Albores-Saavedra, 1986), and thus the appropriate endpoint is the quantitation of such lesions. This has been extremely difficult to do, and thus quantitative analyses of the effects of progressor agents remain crude.


Figure 8-19. General experimental format for demonstration of the stage of progression and the effect of progressor agents in experimental systems.

NL, neoplastic lesions; ±, occasional or infrequent; 1+, few; 2+, some; 4+, many; III, administration of progressor agent as single or several multiple doses; v, initiation; = promoting agent doses.

Cell and Molecular Mechanisms of the Stages of Carcinogenesis

Although the descriptive and morphologic characteristics of the stages of carcinogenesis are critical to our initial understanding of the pathogenesis of neoplasia, a complete knowledge of the molecular mechanisms of carcinogenesis may be necessary to control the disease through rational therapy, earlier diagnosis, and reasonable methods of prevention. However, our understanding of the molecular mechanisms of carcinogenesis is incomplete. Nonetheless, there has been an exponential explosion of knowledge in this area during the past decade.

Initiation While the morphologic and biological characterization of the stage of initiation has been somewhat limited, mechanistic studies of this stage have been more extensively reported. This is strikingly true in relation to the metabolic activation of chemical carcinogens and the structure of their DNA adducts. As indicated earlier, however, the molecular mechanisms of this stage must conform to the observable biological characteristics of this stage. At least three processes are important in initiation: metabolism, DNA repair, and cell proliferation. Perturbation of any of these pathways have an impact on initiation. While initiated cells are difficult to distinguish morphologically and phenotypically from their normal counterparts, the molecular alterations responsible for initiation may be equally subtle. Table 8-12 lists a number of the molecular mechanistic characteristics of the stages of initiation, promotion, and progression. As already indicated initiating agents or their metabolites are mutagenic to DNA. Thus, carcinogenic agents administered at doses that do not induce neoplasia (incomplete carcinogenesis) are capable of initiating cells in experimental models of multistage carcinogenesis (Boutwell, 1964; Dragan et al., 1994). Furthermore, such subcarcinogenic doses of initiating agents may induce substantial DNA alkylation (Pegg and Perry, 1981; Brambilla et al., 1983; Ward, 1987). The genetic changes necessary to induce the stage of initiation need not be those causing obvious or gross structural chromosomal alterations. Sargent et al. (1989) demonstrated normal karyotypes of cells from altered hepatic foci in the stage of promotion in the rat. A number of investigations have demonstrated specific point mutations in genes which are compatible with those induced in vitro by the adducts resulting from treatment with carcinogenic chemicals (Anderson et al., 1992). The potential genetic targets for initiating agents as well as progressor agents have now been elucidated to some extent. Individual variability, species differences, and organotropism of the stage of initiation are a balance of carcinogen metabolism, cell proliferation, and DNA repair.

INITIATION	PROMOTION	PROGRESSION
Simple mutations (transition, transversion, small deletions, etc.) involving the cellular genome.	Reversible enhancement or repression of gene expression mediated via receptors specific for the individual promoting agent.	Complex genetic alterations (chromosomal translocations, deletions, gene amplification, recombination, etc.) resulting from evolving karyotypic instability.
In some species and tissues, point mutations occur in proto-oncogenes and/or potential cellular oncogenes.	Inhibition of apoptosis by promoting agent.	Irreversible changes in gene expression including fetal gene expression, altered MHC gene expression, and ectopic hormone production.
Mutation in genes of signal transduction pathways may result in altered phenotype.	No direct structural alteration in DNA results from action or metabolism of promoting agent.	Selection of neoplastic cells for optimal growth genotype/ phenotype in response to the cellular environment and including the evolution of karyotypic instability.

Table 8-12 Some Cell and Molecular Mechanisms in Multistage Carcinogenesis

Molecular Genetic Targets of DNA-Damaging Carcinogenic Agents Although many genes are affected by the mutagenic action of certain chemical carcinogens, it has long been assumed that mutations in a relatively few specific genes may be most critical to neoplastic transformation. With the discovery and elucidation of the function of viral oncogenes (Bishop, 1985) and their cellular counterparts, proto-oncogenes (Garrett, 1986), the original assumption moved closer to reality. Three different classes of genes have been described that play major roles in the neoplastic process (Table 8-13). Although a variety of other genes involved in DNA repair (Friedburg, 1994; Jass et al., 1994), carcinogen metabolism (Nebert, 1991), and abnormalities in the immune system (Müller, 1990) generate inherited predispositions

to the development of neoplasia, it is the products of the proto-oncogenes and cellular oncogenes and the tumor suppressor genes that have been most closely associated with neoplastic transformation (Table 8-13).

PROTO-ONCOGENES	CELLULAR ONCOGENES	TUMOR SUPPRESSOR GENES
Dominant	Dominant	Recessive
Broad tissue specificity for cancer development	Broad tissue specificity for cancer development	Considerable tissue specificity for cancer development
Germline inheritance rarely involved in cancer development	Germline inheritance rarely involved in cancer development	Germline inheritance frequently involved in cancer development
Analogous in certain viral oncogenes	No known analogs in oncogenic viruses	No known analogs in oncogenic viruses
Somatic mutations activate during all stages of neoplastic development	Somatic mutations activate during all stages of neoplastic development	Germline mutations may initiate but mutation in neoplasia occurs only during the stage of progression

Table 8-13 Characteristics of Proto-oncogenes, Cellular Oncogenes, and Tumor Suppressor Genes

Table 8-14 shows a listing of a number of functions of proto-oncogenes and cellular oncogenes and tumor suppressor genes, with specific examples and their localization within the cell where known. It is immediately obvious that the oncogenes are involved primarily in cellular growth, signal transduction, and nuclear transcription. Interestingly, similar functions are attributed to known tumor suppressor genes, but in addition at least two of the latter are involved in regulation of the cell cycle. This table is not meant to be all inclusive, and the interested reader is referred to recent reviews and text for a more detailed discussion of these genes and their products (Hunter, 1991; Levine, 1993).

FUNCTIONS OF GENE PRODUCT	GENES	CELL LOCALIZATION
A. Oncogenes		
Growth factors	sis, fgf	Extracellular
Receptor/protein tyrosine kinase	met, neu	Extra-cell/cell membrane
Protein tyrosine kinase	src, src	Cell membrane/cytoplasmic
Membrane-associated G proteins	ras, gsp-2	Cell membrane/cytoplasmic
Cytoplasmic protein serine kinases	raf, pim-1	Cytoplasmic
Nuclear transcription factors	myc, fos, jun	Nuclear
Unknown, undetermined	bcl-2, crk	Mitochondrial, cytoplasmic
B. Tumor suppressor genes		
GTPase activation	NF1	Cell membrane/cytoplasmic
Cell cycle-regulated nuclear transcriptional repressor	RB-1	Nuclear
Cell cycle-regulated nuclear transcription factor	p53	Nuclear
Zinc-finger transcription factor	WT1	Nuclear
Mismatch DNA repair	hMLH1	Nuclear (?)
Zinc-finger transcription factor (?)	BRCA1	Unknown

Table 8-14 Functions of Representative Oncogenes and Tumor Suppressor Genes

Mutations in proto-oncogenes can result in their activation with subsequent neoplastic transformation similar to that observed following the altered expression of cellular oncogenes. Activation of proto-oncogenes and cellular oncogenes can occur by various means (Table 8-15). Scrutiny of these mechanisms suggests that only point mutations, small insertions and deletions, and possibly altered methylation status are potential events resulting in initiation. The other, more complex alterations in the genome listed would be characteristic of the stage of progression, as will be discussed below.

EVENT	CONSEQUENCE	EXAMPLE
Base mutation in coding sequence	New gene product with altered activity	c-ras gene, bladder carcinoma
Deletion in noncoding sequences	Altered regulation of normal gene product	Fibroblast transformation in vitro
Altered promoter for RNA polymerase	Increased transcription of mRNA (normal gene product)	Cell transformation in vitro, lymphoma in chicken
Insertion or substitution with repetitive DNA element ("transposon")	Altered regulation of gene product ("normal)	Cancer, several tumor, mouse systems
Chromosomal translocation	Altered mRNA, new gene product (?), or altered regulation of gene expression	Burkitt lymphoma in human, mouse plasmacytoma
Gene amplification	Increased expression of normal gene	Human colon carcinoma, human bladder carcinoma
Hypomethylation of c-ras gene	Altered regulation of gene expression(?), normal gene product	Human colon and lung cancer

Table 8-15 Potential Mechanisms of Oncogene Activation

The activation of proto-oncogenes and cellular oncogenes by specific base mutations, small deletions, and frameshift mutations results from DNA synthesis in the presence of DNA damage including the presence of adducts. Methods for determining such alterations in specimens that consist of only a few hundred or a thousand cells have been available only during the last decade (Mies, 1994). The analysis of mutations in specific genes potentially involved in the neoplastic transformation is possible from very small samples by various molecular techniques.

The *ras* genes code for guanosine triphosphatases, which function as molecular switches for signal transduction pathways involved in the control of growth, differentiation, and other cellular functions (Hall, 1994). Table 8-16 lists a number of examples in rodent tissues of specific mutation in two of the *ras* genes, the Ha-*ras* proto-oncogene and the Ki-*ras* cellular oncogene. With the exception of mouse skin, the frequency of such mutations in preneoplastic lesions in experimental animals in the stage of promotion is about 20 to 60 percent. In instances of multistage carcinogenesis in mouse skin, the frequency increases to nearly 100 percent (Bailleul et al., 1989). In general, the mutations noted are those which theoretically could result from DNA-adducts formed by the particular carcinogen. Interestingly, spontaneously occurring neoplasms in mice also exhibit a significant incidence of point mutations in the *ras* proto-oncogenes and cellular oncogenes (Rumsby et al., 1991; Candrian et al., 1991), but neoplasms in corresponding tissues in other species do not necessarily exhibit activating mutations in proto- or cellular oncogenes (Tokusashi et al., 1994; Kakiuchi et al., 1993; Schaeffer et al., 1990). In addition, mutated *ras* genes have been described in normal-appearing mouse skin after dimethylbenz(*a*)anthracene (DMBA) or urethane application (Nelson et al., 1992). By contrast, Cha and associates (1994) recently reported that a very high percentage of untreated rats contained detectable levels of Ha-*ras* mutations in normal mammary tissue. Thus, the mutations seen in neoplasms in untreated animals may result from the selective proliferation of cells containing preexisting mutations.

Table 8-16 Mutational Activation of *ras* Oncogenes during the Stages of Initiation and Promotion

Thus, while several classes of genes appear appropriate as targets for DNA-damaging carcinogens, the actual role of proto- and cellular oncogene mutations in establishing carcinogenesis is not entirely clear. Among the earliest preneoplastic lesions studied (Table 8-15), less than one-third exhibit mutations in the *ras* gene family, but it is quite possible that other proto- and cellular oncogenes may be targets. Evidence that tumor suppressor genes may be targets for the initiation of early malignant development come largely from studies of genetically inherited neoplasia. In these rare hereditary cancers, one of the alleles of a tumor suppressor gene contains a germline mutation in all cells of the organism (Paraskeva and Williams, 1992; Knudson, 1993).

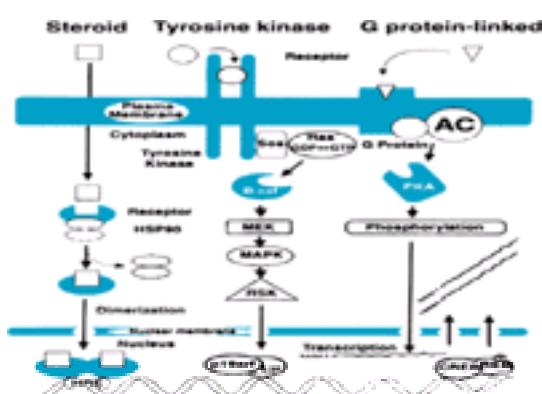
Promotion Boutwell (1974) was the first to propose that promoting agents may induce their effects through their ability to alter gene expression. During the past decade, our understanding of mechanisms involving the alteration of gene expression by environmental agents has increased exponentially (Morley and Thomas, 1991; Rosenthal, 1994). The regulation of genetic information is mediated through recognition of the environmental effector, hormone, promoting agent, drug, etc., and its specific molecular interaction with either a surface or cytosolic receptor. Several types of receptors exist in cells (Mayer, 1994; Pawson, 1993; Strader et al., 1994) (Fig. 8-20). Plasma membrane receptors may possess a tyrosine protein kinase domain on their intracellular region, while others have multiple transmembrane domains with the intracellular signal transduced through G proteins and cyclic nucleotides (Mayer, 1994). The other general type of receptor mechanism involves a cytosolic receptor that interacts with the ligand (usually lipid-soluble) that has diffused through the plasma membrane. The ligand receptor complex then travels to the nucleus before interacting directly with specific DNA sequences known as response elements.


Figure 8-20. Diagram of principal mechanisms of intracellular signal transduction initiated either within the cytosol or at the plasma membrane. [Modified from Mayer (1994), with permission.]

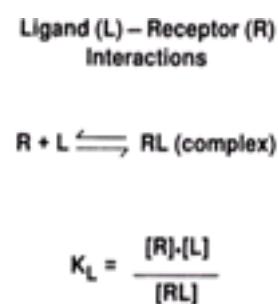
In both instances is shown in a highly simplified manner the cascade effect of various protein kinases resulting in alterations in transcription as well as cell replication within the nucleus. As shown in the figure, interaction of transmembrane receptors containing a tyrosine protein kinase domain involves initially their dimerization induced by ligand interaction. This activates the protein kinase domain of the receptor causing autophosphorylation. This in turn attracts a cytoplasmic complex, Grb2-Sos to the plasma membrane (Aronheim et al., 1994). Sos is a member of a family of regulatory proteins termed guanine-nucleotide exchange factors (GEFs) (Feig, 1994). Sos association with the G-protein, Ras, stimulates along with other protein interactions the exchange of GDP with GTP on the Ras a subunit. The GTP-Ras in turn interacts with a cytoplasmic serine-threonine protein kinase, raf, with subsequent activation of its catalytic activity and initiation of a kinase cascade ultimately resulting in the phosphorylation and activation of transcription factors including Jun, Fos, Myc, CREB, and ultimately E2F and Rb, the tumor suppressor gene (Lewis et al., 1998; Janknecht et al., 1995; Roussel, 1998). A number of other transcription factors are also activated by similar pathways involving other pathways such as phospholipase C, phosphatidylinositol kinase, and protein kinase C (Vojtek and Der, 1998; Takuwa and Takuwa, 1996). The rate-limiting step in this process is the mediation of the signal through the G-protein family. The G proteins are targeted to the plasma membrane through lipid moieties, both isoprenoid and fatty acyl, covalently linked to the carboxyl-terminal region of the protein (Yamane and Fung, 1993). In this way the initiation of the signal by the ligand-receptor interaction can be physically related to the rate-limiting G protein activation step. The activation cycle of the G-protein family involves GTP binding to the a subunit of the G protein, such binding being dramatically stimulated by GEF proteins such as Sos. Activation also involves dissociation of the a from the b and g subunits allowing the a subunit to interact with and activate downstream members of the pathway, a protein kinase, B-raf in the case of the growth factor related pathway or with other membrane molecules such as adenyl cyclase in the case of multiple transmembrane domain receptors (Fig. 8-20). The activated G protein has an extremely short half-life because of the action of RGS (regulator of G-protein signaling) proteins which stimulate GTP hydrolysis to GDP with subsequent reassociation of the G protein in its inactive state (Koelle, 1997).

The multiple transmembrane domain receptors (G protein–linked) are in direct association with G proteins and on activation of the receptor by interaction with a ligand may activate a kinase termed a G-protein receptor kinase (GRK) or another effector such as adenyl cyclase (Böhm et al., 1997; Rasenick et al., 1995). In turn, adenyl cyclase produces cyclic AMP, which interacts with the regulatory component of protein kinase A, with a subsequent phosphorylation cascade to the transcription apparatus. In addition to the plasma membrane receptors, gene expression can be regulated through the interaction of cytoplasmic receptors with their ligands as previously discussed. Just as with membrane receptors, the pathways of the cytoplasmic receptors involve multiple interactions with proteins, phosphorylation, and ultimate alteration of transcription through factor interaction with DNA (Weigel, 1996; Pratt and Toft, 1997). In all of these pathways, in addition to alteration of transcription and gene expression, enhancement or inhibition of cell replication may also be an endpoint which is achieved through transcriptional modulation of the cell cycle.

Many promoting agents exert their effects on gene expression through perturbation of one of the signal transduction pathways, as indicated in Fig. 8-20. One may, in general, classify receptor mechanisms into three broad classes, steroid, tyrosine kinase, and G protein–linked. The majority of the more commonly studied promoting agents exert their actions by mediation of one or more of the receptor pathways indicated in Fig. 8-20. In Table 8-17 are listed some of the best-studied promoting agents known or postulated to be effectors in signal transduction pathways. While protein kinase C (PKC) is not itself one of the three types of receptors noted in Fig. 8-20, it is a mediator of the signal transduction pathways of both the tyrosine kinase and G protein–linked transduction pathways. TPA interacts directly with membrane-bound PKC, displacing the normal activator diacylglycerol and serving to maintain the kinase in its active and soluble form (Ashendel, 1985). The continual activation of this kinase then stimulates further transduction pathways by phosphorylation of specific proteins (Stabel and Parker, 1991). TCDD acts in the steroid pathway via a specific receptor, the Ah receptor, the ligand-receptor complex together with other proteins ultimately altering the transcriptional rate of genes possessing specific regulatory sequences (HRE). In a similar manner, sex steroids, some synthetic antioxidants, and peroxisome proliferators interact with specific soluble receptors and altered gene expression by presumed similar mechanisms to that of TCDD. While in some instances the actual receptor is still not defined, those for polypeptide hormones and growth factors consist of either the tyrosine kinase or G protein–linked types depending on the structure of the polypeptide. The "receptors" for okadaic acid and cyclosporin have been reported to be protein phosphatase 2A and cyclophilin-A respectively (Fujiki and Suganuma, 1993). These proteins, like PKC, are involved in phosphorylation mechanisms of the tyrosine kinase and G protein–linked pathways, although specific sites and mechanisms have not been completely clarified at this time. Thus, the action of promoting agents in altering gene expression may be mediated through specific receptors. This hypothesis provides a reasonable explanation for the tissue specificity demonstrated by many promoting agents. The receptor-ligand concept of promoting agent action is based on the dose–response relationships involving pharmacologic agents. The basic assumptions of such interactions argue that the effect of the agent is


directly proportional to the number of receptors occupied by the ligand. The intrinsic activity of the chemical and the signal transduction pathways available in the tissue are important factors in the type and degree of response observed.

Table 8-17 Some Promoter-Receptor Interactions in Target Tissues

The Molecular Basis of the Reversibility of the Stage of Tumor Promotion

The theoretical and practical aspects of ligand-receptor interactions have been previously reviewed (cf. Pitot, 1995). Herein we will consider such relationships as they are concerned with the action of tumor promoters. The basic assumption of the ligand-receptor interaction is that the effect of the agent is directly proportional to the number of receptors occupied by that chemical ligand and that a maximum response of the target is obtained only when all receptors are occupied. As seen in Fig. 8-21, a simple bimolecular interaction between the ligand and receptor can be utilized to determine a dissociation constant, K_L of the receptor ligand complex, as noted in the figure. While a variety of mathematical relationships may be derived from this simple equation (cf. Ruffolo, 1992), herein we consider only the dose–response relationship. The dose–response of the receptor-ligand interaction takes the shape of a sigmoidal curve identical to that seen with the inhibition of TPA binding depicted in Fig. 8-17. The figure denotes a threshold response at very low doses and a maximal effect above a specific dose. Theoretically, the linear conversion of the sigmoidal curves such as seen in Fig. 8-17 may indicate effects at even lower doses than those usually studied, but such depends on the association constant of the ligand-receptor complex and the subsequent fate of the complex (Aldridge, 1986). Withdrawal of the ligand reverts the system to its original state. Thus, the regulation of genetic expression that occurs by the ligand-receptor mechanism predicts a threshold and reversible effect unlike that of genotoxic carcinogenic agents, in which an irreversible non-threshold response is assumed on theoretical grounds and can be demonstrated in a variety of instances (Druckrey, 1967; Zeise et al., 1987). Furthermore, at very low doses of some carcinogenic agents, an apparent reversal or "protective" effect of the agent can actually be demonstrated. This phenomenon has been termed *hormesis* (Teeguarden et al., 1998). Regardless of whether this latter effect can be more generalized, it is apparent that both the measured dose response and the receptor mechanisms of tumor promotion imply a no-effect or threshold level for the action of these agents during carcinogenesis. Thus, the stage of tumor promotion, unlike that of initiation and progression, does not involve mutational or structural events in the genome but rather is concerned with the reversible alteration of the expression of genetic information.

Figure 8-21. Representation of receptor-ligand interaction and dissociation with derivation of the K_L, dissociation constant of the receptor-ligand complex.

The selective induction of proliferation of initiated cell populations was first intimated by the work of Solt and Farber (1976), who used 2-acetylaminofluorene administration as a "selection agent" for the enhancement of proliferation of altered hepatic foci in a modified initiation-promotion protocol. A similar "selection" of certain initiated clones by TPA promotion has also been postulated as occurring during multistage carcinogenesis in mouse skin (cf. DiGiovanni, 1992). Later studies demonstrated that 2-acetylaminofluorene was acting as a promoting agent in this protocol (Saeter et al., 1988). Farber and his colleagues (Roomi et al., 1985) espoused the concept that the lowered xenobiotic metabolism of preneoplastic cell populations gave such cells a competitive advantage in toxic environments such as those provided by the chronic administration of carcinogens. Schulte-Hermann and his associates (1981) have demonstrated that several hepatic promoting agents including phenobarbital, certain steroids, and peroxisome proliferators selectively enhanced the proliferation of cells within preneoplastic lesions in rat liver. A similar effect was reported by Klaunig in preneoplastic and neoplastic hepatic lesions in mice responding to promotion by phenobarbital (Klaunig, 1993). The response of preneoplastic hepatocytes in the rat to partial hepatectomy is also greater than that of normal hepatocytes (Laconi et al., 1994). Preneoplastic hepatocytes in culture exhibit an inherent higher level of replicative DNA synthesis than normal hepatocytes (Xu et al., 1988). Thus, the characteristic of promoting agents at the cell and molecular level to increase cell proliferation of preneoplastic cell populations selectively more than that of their normal counterparts may be the result of altered mechanisms of cell cycle control within the preneoplastic cell.

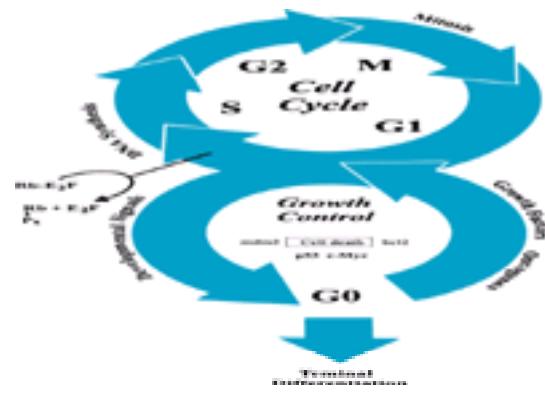
Cell Cycle Regulation Although the exact mechanism(s) by which promoting agents selectively enhance cell replication in preneoplastic cells is unknown, our understanding of the interaction of ligand-receptor signaling with the cell cycle and its regulation has dramatically increased in recent years. Figure 8-22 diagrams an integration of the cell cycle and apoptosis with the signal transduction pathways (Fig. 8-20). Phosphorylation of the mitogen-activated protein kinase (MAPK) via the signal transduction pathway activates this kinase (Fig. 8-22), which then activates various transcription factors, some of which are noted above in the figure as proto-oncogene products, c-*myc,* c-*jun,* and c-*fos* (Seger and Krebs, 1995). Rb, the retinoblastoma tumor suppressor gene, is made throughout the cell cycle. It becomes highly phosphorylated at the beginning of DNA synthesis (G,1S). This releases a transcription factor, E2F, which is complexed with the highly phosphorylated but not the hypophosphorylated Rb protein. E2F then is available to stimulate the transcription of a variety of genes needed for the transition from G1 and the initiation of DNA synthesis. As we noted above, ligand-receptor interactions can result in the activation of E2F and thus the transcription of genes needed for continuation of the cell cycle. This continuation involves a variety of protein kinases and proteins, known as *cyclins,* which are listed in the figure. Another tumor suppressor gene, the *p53* gene, also plays a role as a transcription factor, preventing continuance of the cell cycle on the occasion of DNA damage (Wu and Levine, 1994). Such a pause allows the cells to repair such damage or, if the damage is excessive, to undergo apoptosis (Fig. 8-22). If the *p53* gene is mutated or absent, such a pause does not occur, and the cell cycle continues replicating despite the presence of damage resulting in mutations and clastogenesis (Lane, 1992; Sander et al., 1993; Dulic et al., 1994). Obviously, the missing mechanistic link is a clear understanding of the selective enhancement of the cell cycle in preneoplastic cells by promoting agents. A variety of possibilities exist, including increased concentrations of receptors or any one or more of the components of the signal transduction pathway, as well as mutations in transcription factors, cyclins, cdks, or other components of the cell cycle. As yet, however, definitive studies to pinpoint such mechanisms have not been performed.


Figure 8-22. Diagram of the cell cycle and its associated cycle to apoptosis or terminal differentiation with potential to return to the active cycle under the influence of growth factors and related components.

Signal transduction may regulate the cell cycle through kinase activation involving the E_2F-Rb interaction or other kinases and related molecules involved in the cell cycle.

Progression The stage of progression usually develops from cells in the stage of promotion but may develop directly from normal cells, usually as a result of the administration of relatively high, usually cytotoxic doses of complete carcinogenic agents capable of inducing both initiation and progression. In addition, the incorporation into the genome of genetic information such as oncogenic viruses, the stable transfection of genetic material, or from spontaneous chromosomal alterations may induce the stage of progression. As noted in Table 8-10, Table 8-12 and Table 8-12, the major hallmark of the stage of progression is evolving karyotypic instability. It is this molecular characteristic of cells in the stage of progression that potentially leads to multiple "stages" or changes in malignant cells which were first described by Foulds (1954) as "independent characteristics." Foulds noted that cells in the stage of progression might evolve in such a way that the characteristics of invasion, metastatic growth, anaplasia, as well as the rate of growth and responses to hormonal influences changed toward higher and higher degrees of malignancy. Such "independent characteristics" may all be understood as resulting from karyotypic changes that are constantly evolving in cells during the stage of progression. Included in these "characteristics" may be such things as fetal gene expression, the expression of the major histocompatibility complex (MHC) class I and II surface proteins, and the ectopic production of hormones by cells derived from non-hormone-producing tissues as well as several other characteristics of neoplastic cells (Hanahan and Weinberg, 2000). Thus, in some tissues it may be possible to describe multiple "stages" that reflect the evolving karyotypic instability of neoplasms such as in the evolution of colonic (Fearon and Vogelstein, 1992) and other neoplasms (Nowell, 1990). Simultaneous with these changes may be the occurrence of mutated proto- and cellular oncogenes (Liu et al., 1988) and tumor suppressor genes (Yokota and Sugimura, 1993). However, since karyotypic instability is unlikely to lead directly to point mutations in oncogenes and tumor suppressor genes, it is more likely that their appearance reflects the selection of cells better suited to the growth environment of the neoplasm.

The critical molecular characteristic of the stage of progression is karyotypic instability. As pointed out by Harris (1991), the genetic instability of this stage is primarily a reflection of the karyotypic changes seen rather than point mutations or gene amplification. Mechanisms that can lead to karyotypic instability are numerous and include disruption of the mitotic apparatus, alteration in telomere function (Blackburn, 1994), DNA hypomethylation, recombination, gene amplification, and gene transposition (cf. Cheng and Loeb, 1993). The recent demonstration of the role of alterations in mismatch repair genes (see above) in some forms of cancer suggests a potential for both karyotypic and genetic instability. Many neoplasms exhibit one or more of these events, which very likely play a role in the evolution of the carcinogenic process. Numerical and structural genetic changes can occur in populations of cells without adequate repair such as in those with mutant *p53* genes (see above). Histologically distinct neoplasms may exhibit different pathways during their evolution throughout the stage of progression (Heim et al., 1988; Fearon and Vogelstein, 1992).

The Bases for the Stages of Initiation, Promotion, and Progression

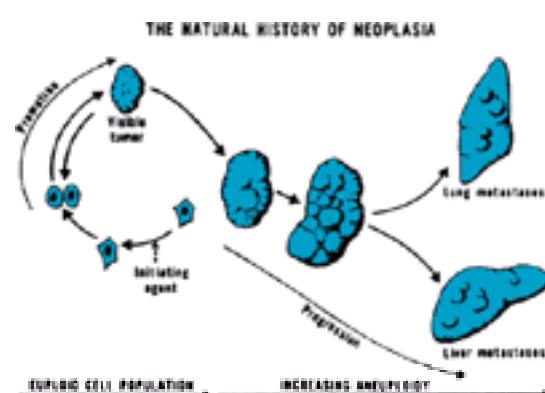
In Fig. 8-23 may be seen an artist's conception of the natural history of neoplastic development, beginning with a single initiated cell and resulting in metastatic neoplastic lesions. The bases for the cell and molecular biology of the stages of neoplastic development may be considered in a relatively simple format, as follows:


Figure 8-23. The natural history of neoplasia, beginning with the initiated cell after application of an initiating agent (carcinogen), followed by the potentially reversible stage of promotion to a visible tumor, with subsequent progression of this tumor to malignancy.

The relation to karyotype is presented as a generalization on the lower arrows. The reader should again be cautioned that not all neoplastic cells undergo this entire natural history. It is theoretically possible, although this has not yet been definitively shown, that some neoplasms, such as those induced in animals by radiation or high doses of chemical carcinogens, may enter this sequence in the stage of progression, exhibiting aneuploidy, and thus bypass the early euploid cell stages.

Initiation results from a simple mutation in one or more cellular genes controlling key regulatory pathways of the cell.
Promotion results from the selective functional enhancement of signal transduction pathways induced in the initiated cell and its progeny by the continuous exposure to the promoting agent.
Progression results from continuing evolution of a basically unstable karyotype.

These seminal characteristics of the three stages of carcinogenesis readily distinguish one from the other and also form a basis for the molecular action of chemicals acting at each of these stages.

Based on a knowledge of the seminal characteristics of each of the stages of carcinogenesis, it is reasonable to classify chemical agents in regard to their primary action during one or more of the stages of carcinogenesis. Table 8-18 presents such a classification. Agents that are capable of initiation and thus are true incomplete carcinogens are unusual, if they exist at all. Although the "pure" initiating activity of certain chemicals in specific tissues has been reported (cf. DiGiovanni, 1992), in most instances, at higher doses or in different tissues, such agents can be shown to be carcinogenic, usually acting as complete carcinogens. On the other hand, in distinguishing experimentally between the stages of initiation and promotion, low single doses of complete carcinogens may act to initiate cells, but since they cannot sustain the stage of promotion, they may act de facto as pure initiating agents or incomplete carcinogens. The list of promoting agents and putative promoting agents is, like that of complete carcinogens, growing steadily. Progressor agents in the strict sense of inducing the characteristics noted in Table 8-10 and Table 8-12 have not been well characterized. It should be noted, however, that in order to designate a chemical as a complete carcinogen, its ability to induce each of the stages of carcinogenesis is a prerequisite by definition.

Initiating agent (incomplete carcinogen): a chemical capable only of initiating cells

Promoting agent: a chemical capable of causing the expansion of initiated cell clones

Progressor agent: a chemical capable of converting an initiated cell or a cell in the stage of promotion to a potentially malignant cell

Complete carcinogen: a chemical possessing the capability of inducing cancer from normal cells, usually possessing properties of initiating, promoting, and progressor agents

Table 8-18 Classification of Chemical Carcinogens in Relation to Their Action on One or More Stages of Carcinogenesis

Genetic and Nongenetic Mechanisms of Chemical Carcinogenesis in Relation to the Natural History of Cancer Development

Some agents, specifically initiating and progressor agents, possess as a primary aspect of their carcinogenic mechanism the ability to alter the structure of DNA and/or chromosomes. Such "genotoxic" effects have been linked directly to the induction of neoplasia. However, when administered chronically to animals, a number of chemicals induce the development of neoplasia, but there is no evidence of their direct "genotoxic" action on target cells. Considering the effects of chemicals on the development of neoplasia via a multistage process, one may quickly classify such agents as promoting agents acting to expand clones of spontaneously initiated cells. The consequent selective enhancement of cell replication in such initiated cell clones sets the stage for the spontaneous transition of an occasional cell into the stage of progression as discussed above. However, this explanation of "nongenotoxic" carcinogenesis may be oversimplified. Table 8-19 lists a representative sample of chemicals that are nonmutagenic as assessed by induction of mutations in bacteria or mammalian cells, but which, on chronic administration, are carcinogenic in experimental systems. As indicated in the table, a number of these chemicals have been shown to be promoting agents, but some are not. Several of those that are not promoting agents may be classified as putative progressor agents as evidenced by their effectiveness as clastogens in experimental systems (see above). A number of other chemicals (Tennant, 1993) have not been tested for their action at specific stages of carcinogenesis and thus cannot neatly be placed into the classification of Table 8-19.

Table 8-19 Some Nonmutagenic Chemical Carcinogens

In addition to the several potential progressor agents such as benzene noted in Table 8-19, other nongenotoxic mechanisms have been proposed to account for carcinogenesis by some of these chemicals (Grasso and Hinton, 1991). One such class are the so-called peroxisome proliferators, so named because on administration they induce an increase in the number and proteins of peroxisomes, primarily in the liver. These compounds now make up a relatively large list of chemicals (Reddy and Lalwani, 1983), which are generally nongenotoxic (Stott, 1988); but many are hepatocarcinogenic and are promoting agents for hepatocarcinogenesis in the rat (Cattley and Popp, 1989). Because of the peroxidative function of many of the enzymes in peroxisomes, Reddy and others (Reddy and Rao, 1989) have proposed that the carcinogenic action of these chemicals may be mediated by an increased oxidative potential for DNA damage in cells treated with such agents. The demonstration of such increased oxidative damage to DNA in livers of peroxisome proliferator–treated rats has been variable (Kasai et al., 1989; Hegi et al., 1990). It should also be remembered that many of the peroxisome proliferators exert their effects through a specific receptor (Issemann and Green, 1990; Motojima, 1993).

Another series of chemical carcinogens that induce renal cell neoplasms in rodents have been found also to induce a dramatic increase in the accumulation of urinary proteins in renal tubular cells. This is observed only in the male rat in which there is an accumulation of the male-specific urinary protein, a α_{2u}-globulin, which is correlated with the production of renal neoplasms in male but not female rats. This is found with d-limonene (Dietrich and Swenberg, 1991) and unleaded gasoline (Short et al., 1989). Several halogenated hydrocarbons induce a α_{2u}-globulin and renal neoplasms in male rats (Konishi and Hiasa, 1994). Compounds that induce α_{2u}-globulin dramatically increase cell proliferation in the kidney as a result of the chronic accumulation of the protein with subsequent cell degeneration. However, this α_{2u}-globulin nephropathy is not itself carcinogenic (Dominick et al., 1991).

Agents that are not mutagenic or genotoxic may induce direct toxicity with sustained tissue damage and subsequent cell proliferation. Both direct DNA toxicity and increased cell proliferation may lead to clastogenesis (Scott et al., 1991) or damage genetic DNA indirectly through oxidative mechanisms. Finally, the cell proliferation resulting from toxicity may selectively induce enhanced replication of an already damaged genome in the initiated cell population. While cell toxicity does not directly induce carcinogenesis, it is capable of enhancing the process. Because many agents that are tested at chronic doses induce at least a mild degree of toxicity, it has been argued that the format of the testing system leads to the induction of neoplasia. Thus, neoplastic development observed with test compound administration may occur as a result of the toxicity and cell proliferation associated with chronic high doses utilized rather than from a direct carcinogenic effect of the agent (Ames and Gold, 1990). Thus, nongenotoxic or nonmutagenic mechanisms of carcinogenesis involve mechanisms as yet uncharacterized. Several types of compounds appear to have primarily a promoting type of effect, including agents that induce P-450s, other mitogenic agents, cytotoxic agents, and many that act through receptor-mediated processes.

CHEMICAL CARCINOGENESIS IN HUMANS

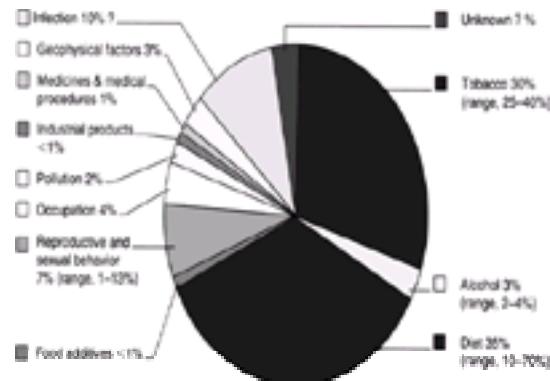
There is substantial evidence that chemical agents can cause cancer in the human. Ramazzini reported in 1700 that breast cancer occurred in a very high incidence in celibate nuns (Wright, 1940). Ramazzini proposed that the development of this neoplasm in this occupational group was the result of their lifestyle, a thesis compatible with present knowledge that endogenous hormone exposure plays a causal role in breast cancer development (Henderson et al., 1982). The initial evidence of an exogenous chemical cause of cancer in the human was related by Hill, who described the association of the use of tobacco snuff with the occurrence of nasal polyps (Hill, 1761). As discussed earlier in this chapter, Pott demonstrated the causal relationship of chimney soot to scrotal cancer in young individuals employed as chimney sweeps. During the last 150 years a number of specific chemicals or chemical mixtures, industrial processes, and lifestyles have been causally related to the increased incidences of a variety of human cancers. The proportion of human cancer caused by a variety of environmental agents is provided in Fig. 8-24 (Doll and Peto, 1981). While this chart is more than two decades old, substantial evidence has accrued in support of these proportional differences. How these proportions were determined and the specific chemicals associated with those segments related to chemical carcinogenesis are the subject of this section.


Figure 8-24. Proportions of cancer deaths attributed to various environmental factors [After Doll and Peto (1981), with permission.]

Epidemiologic and Animal Studies as Bases for the Identification of Chemical Carcinogens in Humans

Epidemiology has been defined as the study of the distribution and determinants of disease (Stewart and Sarfaty, 1978). Epidemiologic methodologies develop their findings from observation rather than controlled experimentation. Animal studies of carcinogenesis provide data from controlled experiments in vivo and in vitro. Because human beings cannot and should not be treated as experimental animals, epidemiologic observations may take a number of forms (Rogan and Brown, 1979; Pitot, 1986a), including the following:

1. *Episodic observations.* Observations of isolated cases of cancer in relation to a specific environmental factor(s) have yielded information in the past as to cause-and-effect relationships. However, deductions from these types of observations must be carefully evaluated in properly designed studies.
2. *Retrospective studies.* Retrospective studies, which are investigations of the histories and habits of groups of individuals who have developed a disease, have been frequent sources of epidemiologic data. An important factor in such investigations is the use of case controls, i.e., individuals not exposed to the variable under study. In many instances, the suitable designation of such controls is the critical component in the study. This type of study is usually the first step in attempting to identify factors that may be causative in the development of human cancer.
3. *Prospective studies.* Prospective investigations involve analyses of the continuing and future development of cancers in individuals with specific social habits, occupational exposures, and so on. Such investigations require large populations, long follow-up periods (usually 10 to 30 years), with a large percentage of both controls and test groups continuing for the duration of the study. Many such investigations are presently under way in the United States and throughout the world.

Epidemiologic studies may be concerned with a single factor or with multiple factors potentially causative of specific human cancers. However, it is rarely possible to identify a single chemical as the sole causative factor in the development of a specific type of human cancer because of the numerous other environmental variables to which the human population or cohort (group under study) is exposed. In addition, environmental factors in the causation of human cancer—including chemical exposure, infection with various parasites, ultraviolet and ionizing radiation, and individual genetic background—may be additive, synergistic, or antagonistic in relation to one another. As a confounding factor, an agent may act at the same or different stages in carcinogenesis.

Epidemiologic studies can identify only factors that are different between two populations and that are sufficiently important in the etiology of the condition under study to play a determining role under the conditions of exposure. Furthermore, on the basis of epidemiologic studies alone, it is usually very difficult to determine whether a specific chemical is or is not carcinogenic to humans. The reasons for this difficulty are the extended periods between first exposure and clinical occurrence of the neoplasm, the high background incidence for many cancers in the general population, the relatively imprecise knowledge of the nature of the exposure in most instances, and other confounding variables. Thus, many negative epidemiologic studies must be considered as inconclusive for indicating the risk factor of relatively weak carcinogens or low doses of carcinogens for the induction of neoplastic disease in the human population (Pitot, 1986a). In view of the fact that epidemiologic studies in themselves are many times insufficient to establish the carcinogenicity of an agent for humans, laboratory studies with laboratory animals in vivo and cells in vitro have been employed to complement or in some cases supplant epidemiologic observations where they exist.

Utilizing both epidemiologic and experimental animal data, several agencies throughout the world have proposed classification of agents based on the evidence for their carcinogenicity in humans. The first scheme that was generally recognized was devised by the International Agency for Research on Cancer (IARC). In the IARC scheme (Table 8-20), the evaluation is based on demonstration of the carcinogenicity of the agent. The terminology that is utilized is as follows (Pitot, 1986a):

Table 8-20 IARC Classification of the Evaluation of Carcinogenicity for Human Beings

1. *Sufficient evidence* of carcinogenicity, which indicates that there is a causal relationship between the agent(s) and human cancer.
2. *Limited evidence* of carcinogenicity, which indicates that a causal interpretation is credible but that alternative explanations, such as chance, bias, or confounding variables, could not be completely excluded.
3. *Inadequate evidence,* which indicates that one of three conditions prevailed: (a) there were few pertinent data; (b) the available studies, while showing evidence of association, did not exclude chance, bias, or confounding variables; (c) studies were available that did not show evidence of carcinogenicity.

For an agent to be classified as carcinogenic to humans (group 1), there must be substantial epidemiologic evidence to support the claim. While epidemiologic studies attempt to examine the human evidence with exposures at biologically relevant doses, such studies are often limited by their expense and the prolonged duration necessary for the detection of clinically relevant malignancy. In addition, numerous confounding variables exist, and the studies usually occur after exposure to a compound (retrospective). In the case of chemicals administered for therapeutic purposes as well as in some industrial exposures, the studies may be well controlled with respect to exposure conditions, but the number of individuals and duration of the exposure are generally limited. Thus, in many investigations with animals, primarily rodents, short-term tests (see below) are used to provide weight to the argument for the potential risk from exposure to the compound. In this instance, the stipulation should be that the endpoint is a qualitative one concerned primarily with hazard identification.

Several other classification schemes exist including that of the Environmental Protection Agency (EPA), the Chemical Manufacturers Association, and the European Community (EC). These classifications agree with respect to classification of compounds that are known human carcinogens but place different emphasis on the results of animal and genotoxicity studies. This is particularly true for single sex or strain-specific effects such as induction of a $_2$-microglobulin in the rat kidney, peroxisome proliferation in the rodent liver, and thyroid neoplasia in the rodent. Thus, in assessing potential human cancer risk from compound exposure, several factors are considered to provide a greater or lesser concern as to a potential for induction of human cancer from exposure (Table 8-21). Many of these factors are based on the pharmacokinetic and pathologic response similarities of humans and the surrogate test species.

GREAT CONCERN	LESS CONCERN
Human epidemiologic evidence	Negative human epidemiologic data
Genotoxic	Not genotoxic
Multiple species	Single species effect
Tumor site concordance between species	Tumors are species-specific
Multiple tumor sites	No human equivalent to rodent tumor site
Tumors not associated with toxicity	Toxicity associated tumors
Similar metabolism in species	Inconsistent metabolism between species
Induction by multiple routes of exposure	Exposure route not relevant for human
Structural alert	

Table 8-21 Factors Relating to Concern for Potential Human Cancer Induction in Evaluation of Cancer Data

In spite of the limitations of these classifications, an agent cannot be proven to be carcinogenic for the human unless substantial epidemiologic evidence supporting such a claim is available. Despite this restriction, a number of chemical agents, processes, and lifestyles have been shown to be carcinogenic in humans according to the IARC classification.

Lifestyle Carcinogenesis

Historians have noted that the cancer incidence in the human population appears to go up with the "advancement of civilization." Thus, the more affluent populations tend to have higher general incidences of cancer. A major factor is related to the style of life that the more affluent individual can choose, such lifestyles not always being the most healthy. Chemical factors involved in the development of cancer from lifestyle practices may be related to complex chemical mixtures or, in some instances, related to specific external or internal environmental chemicals. Table 8-22 lists chemical carcinogenic agents associated with lifestyle. Of the agents listed, three—alcoholic beverages, aflatoxins, and dietary intake—are related to the nutritional status of the individual. While aflatoxin has been shown to be a complete carcinogen in experimental animals, the carcinogenic effect of alcoholic beverages and dietary intake is not readily apparent. As noted from the table, elevated risks of several neoplasms in the human result from excessive intake of alcoholic beverages. Since all types of alcoholic beverages are implicated in the variety of studies supporting these claims, ethanol itself and its metabolites appear to be the common components of these beverages that have been implicated as the effective moieties (Blot, 1992). Ethanol is metabolized directly to acetaldehyde, which has been shown to be mutagenic (Garro and Lieber, 1990). There is, however, no evidence that ethanol or alcoholic beverages are complete carcinogens in any system. However, chronic ethanol administration after initiation in rat liver may act to enhance carcinogenesis. In several other organs, ethanol, when given simultaneously with a carcinogenic agent, acts as a cocarcinogen (Seitz and Simanowski, 1988). In support of the promoting action of ethanol in the human, cancer of the oral cavity and pharynx is markedly increased when the individual smokes tobacco as well as abuses alcoholic beverages (Blot, 1992). Furthermore, individuals who are infected with the hepatitis B virus and drink alcoholic beverages excessively are prone to the more rapid appearance of hepatic neoplasms (Ohnishi et al., 1982).

CHEMICAL(S), PHYSIOLOGIC CONDITION, OR NATURAL PROCESS	ASSOCIATED NEOPLASM(S)	EVIDENCE FOR CARCINOGENICITY
Alcoholic beverages	Esophagus, liver, oropharynx, and larynx	Sufficient
Aflatoxins	Liver	Sufficient
Betel chewing	Mouth	Sufficient
Dietary intake (fat, protein, calories)	Breast, colon, endometrium, gallbladder	Sufficient
Reproductive history		
1. Late age at 1st pregnancy	Breast	Sufficient
2. Zero or low parity	Ovary	Sufficient
Tobacco smoking	Mouth, pharynx, larynx, lung, esophagus, bladder	Sufficient

Table 8-22 Carcinogenic Factors Associated with Lifestyle[a]

Aflatoxins, especially aflatoxin B_1, which are produced by some strains of a ubiquitous mold *Aspergillus flavus,* are potent hepatocarcinogens in the rodent (Eaton and Groopman, 1994). Epidemiologic studies have demonstrated that in some geographic areas where there has been extensive contamination of foodstuffs by *A. flavus* and its product, aflatoxin, these areas exhibit a high incidence of human liver cancer (Wogan, 1992). Other dietary contaminants—produced directly by organisms such as molds, substances naturally occurring in plants such as the pyrrolizidine alkyloids, and products of the metabolism of dietary components by contaminating molds, which include carcinogenic nitroso compounds (Shixin et al., 1979)—have been demonstrated as carcinogenic in experimental systems. In most of these examples epidemiologic studies are not sufficient to identify them as known human carcinogens (class I in Table 8-20). A number of other known carcinogenic contaminants reportedly also occur in the average diet, and Lutz and Schlatter (1993) have argued that, from risk estimates, one could account for much of the "dietary induced" cancer in the human. Among the contaminants listed are ethanol and a group of carcinogenic heterocyclic amines that are products of the cooking of food; however, Gold and associates (1994) have argued that exposures to any or all of these contaminants in the usual western diet do not pose any significant risk of cancer development to humans.

According to Doll and Peto (1981), the causal relationship between dietary factors and human cancer is quite substantial. To justify this statement, they proposed several mechanisms whereby dietary factors could be causally associated with the induction of human neoplasia, as shown in Table 8-23. We have discussed the first point in relation to aflatoxin and other dietary contaminants that are known carcinogenic agents. With regard to the second point, the exogenous production of heterocyclic amines during cooking leads to their presence in the ingested food (Bogen, 1994). Another potential mechanism is the endogenous formation of carcinogenic agents from dietary constituents as a result of endogenous processes. A principal pathway for the formation of such chemicals is the nitrosation of secondary amines either naturally present in the diet or formed during ingestion, digestion, or metabolism. The source of the nitroso group is from nitrite, most of which is produced endogenously in the human (Leaf et al., 1989). The products of the endogenous nitrosation include nitrosoproline as well as minute amounts of other carcinogens (Bartsch et al., 1990). In addition, a wide variety of other chemicals, most of which may be taken in the diet, are potentially nitrosatable, thus affording the presence of potential carcinogenic nitrosamines (Shephard et al., 1987). While endogenous exposure to such nitroso compounds appears to be fairly ubiquitous, their relevance to the development of human neoplasia is still questionable (Bartsch and Ohshima, 1991). The third point in Table 8-23 involves primarily dietary factors that inhibit the development of cancer. In some instances, as with ethanol (see above), an agent's cocarcinogenic effect when it is given together with a carcinogenic agent is to enhance the production of neoplasia by a mechanism that enhances the activation of the carcinogenic agent. By contrast, many dietary components have been shown to inhibit the carcinogenic process at the stage of promotion, such as retinoids, while antioxidants such as vitamin E, b-carotene, selenium, etc., may serve to inhibit the metabolic activation of chemical carcinogens by the cytochrome P-450 system or the oxidative changes in DNA that may facilitate spontaneous development of the stage of progression (see above).

1. Ingestion of complete carcinogens or initiating or progessor agents	Aflatoxin
2. Exogenous or endogenous production of carcinogens from dietary constituents	Heterocyclic amines N-nitrosation
3. Alteration of transport, metabolic activation, or inactivation of carcinogens	Ethanol, vitamins A, E
4. Serve as promoting agents to act on spontaneously initiated cells	Calories, dietary fat

Table 8-23 Possible Mechanisms of Dietary Carcinogenesis

The most common mechanism of diet-associated carcinogenesis in the human is through the action of major dietary constituents (fat, carbohydrate, and protein) as promoting agents. Considerable experimental evidence has developed to demonstrate that carbohydrate and lipid are effective promoting agents in the development of several tissue types of neoplasms in different species (Freedman et al., 1990; Wynder et al., 1983).

There is substantial epidemiologic evidence that overnutrition resulting in overweight may increase the incidence of a variety of human cancers (Doll and Peto, 1981). The fact that overnutrition in experimental animals is carcinogenic has been described in numerous publications over several decades (Kritchevsky et al., 1986; Boutwell, 1992). This is most evident when one compares the spontaneous cancer incidence in animals fed a calorically restricted diet with those fed ad libitum. The cancer incidence may differ by four- to sixfold in the two groups. Relatively high levels of dietary fat are associated with increased death rates from cancer of the prostate, colon, and breast in humans (Statland, 1992). However, Willett and associates have argued that, at least for mammary cancer, the fat content of the diet itself does not appear to be the definitive causal agent. Others have argued that the increase in mammary cancer may be related to an increased production of estrogenic and hypophyseal hormones, especially prolactin, as a result of the dietary composition (Henderson et al., 1982).

Endogenous hormone production is also probably related to the phenomenon of the enhanced risk of breast cancer in patients who wait until the fourth decade or more to have their first child. This finding is quite similar to the original observations of Ramazzini on the high incidence of breast cancer in celibate nuns. Doll and Peto (1981) pointed out that cancers of the endometrium, ovary, and breast are significantly less common in women who have borne children early than in women who have had no children. In addition to late first full-term pregnancy, early menarche and late menopause appear to increase the risk of breast cancer in humans (Pike et al., 1983).

Perhaps the most common exogenous cause of human cancer is tobacco smoking and other forms of tobacco abuse. On the basis of their epidemiologic data, Doll and Peto (1981) estimated that 85 to 90 percent of annual lung cancer cases in the United States are a direct result of tobacco use. If we add to this statistic the numbers of cancers of the bladder, gastrointestinal tract, and upper respiratory passages that can be attributed to tobacco smoking, one may conclude that about 30 percent of all cancer deaths in the United States result from this habit. There are substantial data to demonstrate that the complete cessation of tobacco smoking results in a decreasing risk of lung cancer with increasing time after smoking cessation (Reif, 1981). Zatonski and associates (1990) noted that interruption of the smoking habit leads to a significant decrease in laryngeal cancer even when the habit is resumed after the cessation. This finding is very comparable to the intermittent format for promoting agent administration described by Boutwell (1964), which results in little or no tumor promotion even though the final total dose of the promoting agent remains the same. Thus, the stage of tumor promotion occupies the most time and poses the greatest risk in the development of cancer in smokers.

The chewing of tobacco leads to cancer of the mouth. This may also be seen in the Far East, where betel nuts are chewed with or without tobacco in the form of a quid (a packet of betel, tobacco, and other materials). Extracts of the quid have been shown to be carcinogenic in several species (Bhide et al., 1979).

The least is known about the mechanisms of cancer induction by lifestyle factors, but cancers resulting from lifestyle account for two-thirds or more of the chemical induction of this human disease (Fig. 8-24). The stage involved in lifestyle-induced human cancer is primarily that of promotion.

Chemical Carcinogens Associated with Occupations

We have already discussed at least two examples of occupations associated with the development of specific cancers: the report of Ramazzini on the incidence of breast cancer in celibate nuns and that of Pott on the observation of scrotal cancer in men who had been employed as chimney sweeps during their childhood. After these observations, a number of reports of the association of specific cancers with the mining, smelting, dyeing, and lubrication processes and industries were published. It was not until after 1970 that the IARC began intensive studies to establish the carcinogenic risk of chemicals and chemical processes in industry. Table 8-24 lists a number of chemical processes for which there is an established (sufficient) amount of data to implicate these agents as carcinogenic to humans. The same table lists a number of chemicals, some of which are designated as having limited evidence of carcinogenicity in humans (IARC), and for some of which there is established carcinogenic activity only in animals.

Table 8-24 Exposures to Chemical Carcinogens in the Workplace

The association of occupational exposure to asbestos with the subsequent development of bronchogenic carcinoma and malignant mesothelioma has been well established. The development of bronchogenic carcinoma is seen much more commonly following asbestos exposure than is malignant mesothelioma in those with a history of cigarette smoking. In fact, Muscat and Wynder (1991) found no association between cigarette smoking and mesothelioma incidence in studying patients with the latter disease. Furthermore, Sandén and coworkers (1992), in a study of nearly 4000 shipyard workers exposed to asbestos, found no increased risk of bronchogenic carcinoma 7 to 15 years after exposure to asbestos had ceased. These authors argue that asbestos exposure may act as a promoting agent in relation to the development of bronchogenic carcinoma. In contrast, they argue that the continued risk of mesothelioma years after asbestos exposure indicates its complete carcinogenic action in the development of the latter neoplasm. Other fibrous materials such as fiberglass have been shown to be carcinogenic in the rodent (Stanton et al., 1977), but evidence in the human is not sufficient (Merchant, 1990). Although the mechanism of asbestos induction of cancer is unknown, the type and size of asbestos fibers are significant factors for the carcinogenicity of this material, indicating that a mechanism similar to "plastic film" carcinogenesis is operative (Stanton et al., 1981). In cell culture of Syrian hamster embryo cells, asbestos fibers induce both karyotypic abnormalities and neoplastic transformation (Oshimura et al., 1984). Wood dust carcinogenesis may also be related mechanistically to asbestos carcinogenesis. The induction of cancer by metallic compounds and arsenic has been discussed in this chapter. Aromatic amines used in the chemical and dye industries were known to induce cancer in the human well before the disease was reproduced in experimental animals. In the last century, up to 100 percent of individuals involved in the purification of 2-naphthylamine for use in the dye industry developed bladder cancer (Connolly and White, 1969). Prolonged exposure to benzene has been implicated by several epidemiologic studies in the induction of acute myelogenous leukemia in humans, usually exposed in an occupational setting (Snyder and Kalf, 1994). However, Wallace (1989) has emphasized the

ubiquitous nature of benzene exposure to the population in general. Just as with 2-naphthylamine for the demonstration of its animal carcinogenicity in 1938 (Hueper et al., 1938), the induction of leukemia in lower animals by benzene has not yet been reported, although some solid tumors of other organs have been described (Snyder and Kalf, 1994).

There is considerable controversy about several of the agents on the list of suspected human carcinogens to which there is exposure in the workplace. Formaldehyde is a ubiquitous chemical intermediate and is also utilized by several fields in the health sciences. The IARC has labeled the evidence of the carcinogenic potential of formaldehyde in the human as inadequate. However, at relatively high doses, formaldehyde gas is carcinogenic to rodents, but only in the presence of extensive cytotoxicity and cell proliferation (Starr and Gibson, 1985).

Among the most controversial suspected human carcinogenic agents are the phenoxyacetic acids and their contaminating halogenated dioxins. A review by Bond and Rossbacher (1993) indicated no clear evidence of human carcinogenicity of phenoxy herbicides, but a more recent investigation by Hardell and coworkers (1994) that extended earlier investigations argues strongly for a causative relationship with lymphoma. The controversy extends farther because these chemicals are contaminated with polyhalogenated dioxins, specifically TCDD. As noted earlier, this chemical is one of the most potent promoting agents of neoplasia in rodent liver and has an extended half-life of more than 7 years in the human (Pirkle et al., 1989). Fingerhut and colleagues (1991) concluded from a large study of industrial workers that dioxin had induced a small number of soft tissue sarcomas in this cohort. This finding has been disputed by a number of other investigators (Johnson, 1992). The U.S. government has undertaken an extensive study of TCDD as a risk factor in human cancer development.

A less controversial subject is the association of angiosarcoma of the liver with exposure to monomeric vinyl chloride, the basic chemical used in the production of a number of plastics. Although the incidence of this neoplasm even in workers with a history of exposure to vinyl chloride is relatively low (Cooper, 1981), suggesting that the potency of vinyl chloride as a carcinogen is relatively low, the rarity of hepatic angiosarcoma in the general population gives strong support to a causal relationship between exposure to this organic halogen and the induction of hepatic angiosarcoma.

In regard to the general causative relationship between exposure to chemicals in the workplace and the development of human cancer, Doll and Peto (1981) have presented compelling arguments that only about 4 percent of all cancer deaths in the United States could be attributed to occupational circumstances. With strict government regulation of actual and potential industrial health hazards during the last two decades, it is likely that this figure will decrease to even lower levels in the future.

Chemical Carcinogenesis Resulting from Medical Therapy and Diagnosis

In the modern practice of medicine, the original dictum of Hippocrates that a physician should do no harm to a patient has changed as a result of a consideration of the potential benefit to the patient of a specific procedure or therapy in relation to the risk of the procedure or therapy. In general, the risk of intervention to the patient has been unknown or unsuspected, but at a later date the toxic consequences of the therapy have become apparent. A dramatic example of this has been seen with the administration of the synthetic estrogenic compound diethylstilbestrol to pregnant women in order to avert a threatened abortion. While this therapy was originally thought to be beneficial, its risk did not become obvious until many years later. A small percentage of the female offspring of mothers treated with diethylstilbestrol during pregnancy developed clear cell carcinomas of the vagina, usually within a few years after puberty (Herbst, 1981) (Table 8-25). The use of oral contraceptives that contain synthetic steroidal estrogens as the predominant or sole component results in the development of liver cell adenomas (Goldfarb, 1976; Barrows et al., 1988). Regression of a number of adenomas occurred upon withdrawal of the oral contraceptive, suggesting that the effect of these agents is reversible (Steinbrecher et al., 1981). In addition, prolonged use of oral contraceptives has been associated with increases in the incidence of premenopausal breast cancer in some (White et al., 1994; Olsson et al., 1989; Thomas, 1991) but not all epidemiologic studies (Stanford et al., 1989; Schlesselman et al., 1988). Estrogen therapy has been used successfully to treat a variety of symptoms in postmenopausal women. The administration of estrogens unopposed by progestin is associated with a significantly increased risk of the development of endometrial carcinoma, ranging from 8- to 16-fold (Mack et al., 1976; Henderson et al., 1988). However, when progestogen is given simultaneously with estrogen, no risk of endometrial carcinoma is present, and there is some evidence for protection (Gambrell, 1986). Androgenic steroids, usually in the form of synthetic congeners of testosterone, are associated with hepatocellular carcinomas in humans treated for extended periods for conditions such as aplastic anemia (Hoover and Fraumeni, 1981). Interestingly, recent evidence has suggested that endometrial cancer may be induced by long-term treatment with the antiestrogen tamoxifen (Fisher et al., 1994).

COUNSE FS OR DRUG	ASSOCIATED NEOPLASMS	EVIDENCE FOR CARCINOGENICITY
Alkylating agents (cyclophosphamide, melphalan)	Bladder, leukemia	Sufficient
Inorganic arsenicals	Skin, liver	Sufficient
Azathioprine (immunosuppressive drugs)	Lymphoma, reticulum cell sarcoma, skin, Kaposi's sarcoma (?)	Sufficient
Chlornaphazine	Bladder	Sufficient
Chloramphenicol	Leukemia	Limited
Diethylstilbestrol	Vagina (clear cell carcinoma)	Sufficient
Estrogens		
Premenopausal	Liver cell adenoma	Sufficient
Postmenopausal	Endometrium	Limited
Methoxypsoralen with ultraviolet light	Skin	Sufficient
Oxymetholone	Liver	Limited
Phenacetin	Renal pelvis (carcinoma)	Sufficient
Phenytoin (diphenylhydantoin)	Lymphoma, neuroblastoma	Limited
Thorotrast	Liver (angiosarcoma)	Sufficient

Table 8-25 Carcinogenic Risks of Chemical Agents Associated with Medical Therapy and Diagnosis

While there are risk-benefit considerations in the use of a number of drugs and hormones in the human, the most striking is the utilization of known carcinogenic agents in the chemotherapy of neoplasia. As noted in Table 8-25, alkylating agents utilized in the treatment of a number of neoplasms are carcinogenic. The development of second neoplasms after chemotherapy and radiation therapy has been most striking in the earlier modalities used to treat Hodgkin's disease. One of the more common secondary neoplasms after treatment with several chemotherapeutic agents is acute my-elogenous leukemia, which occurs within the first decade following the curative treatment (Blayney et al., 1987; Swerdlow et al., 1992). Recently, a similar phenomenon has occurred following treatment with a new class of drugs that inhibit DNA topoisomerases, the epipodophyllotoxins (Winick et al., 1993). In a study utilizing combination chemotherapy including epipodophyllotoxins for the treatment of small cell lung cancer, the odds of dying of a secondary or new malignancy were 8 to 1 if the patient survived at least 4 years after therapy (Heyne et al., 1992). In a similar vein, methoxypsoralen, which directly alkylates DNA, has been used in combination with ultraviolet light exposure for the treatment of the autoimmune skin condition psoriasis. Although this treatment is in many ways the treatment of choice, there is distinct evidence that squamous cell carcinoma of the skin is induced by it (Green et al., 1992).

Immunosuppression as a result of genetic abnormalities, therapeutic immunosuppression (as for transplants), and immunosuppression resulting from diseases such as advanced cancer or the acquired immunodeficiency syndrome (AIDS) are associated with increased incidences of a variety of different cancers (Penn, 1989). In these instances, the development of neoplasia is the result of a loss of host resistance to the growth of neoplastic cells, especially those infected with viruses such as the Epstein-Barr virus or one of the herpes simplex viruses (Purtilo and Linder, 1983).

Besides the chemicals listed in Table 8-25, a number of other chemicals that are carcinogenic in lower forms of life are used as drugs in the therapy of a variety of human diseases (Griffith, 1988). Thus, it is clear that some forms of medical therapy and diagnosis pose a carcinogenic risk to humans under certain circumstances. The decision as to which is greater, the benefit to the patient or the risk of producing further pathology, must be made ultimately by the patient in consultation with his or her physician.

THE PREVENTION OF HUMAN CANCER INDUCED BY CHEMICALS

Definitive epidemiologic observations and investigations are the surest way to relate a specific etiologic agent—chemical, physical, or biological—causally with human neoplasms, but epidemiologic studies are still relatively insensitive for identifying causative factors in human cancer. Such studies can identify only factors that are different between two populations and that are sufficiently important to play a determining role under the conditions of exposure. Furthermore, on the basis of epidemiologic studies, it is extremely difficult to determine whether a specific chemical is or is not carcinogenic to humans because of the extended lag period between exposure and clinical occurrence of a neoplasm, the high background incidence of many cancers in the general population, the relatively imprecise

knowledge of the nature of the exposure in most instances, and a number of other confounding variables. Only under exceptional circumstances such as the induction of rare and infrequent neoplasms—e.g., vinyl chloride and angiosarcoma (Dannaher et al., 1981)—is it possible to identify an agent as carcinogenic solely on the basis of epidemiologic studies when the incidence of cancer induced by that agent is less than 50 percent more than the occurrence of the resulting cancer in the general human population. Therefore, a "negative" result of an epidemiologic investigation must be considered as inconclusive for determining whether a relatively weak carcinogenic agent has a role in the etiology of human neoplasia. How, then, is it possible to identify actual and potential carcinogenic agents in our environment by methods other than epidemiologic studies? This question has been answered in part by relating the results of additional studies, usually carried out with experimental animals, to the problem of the etiology of human cancer and the risks of environmental agents to populations and/or specific individuals. It is from such studies that government agencies make decisions that ultimately regulate the production and use of, and accordingly the exposures of populations to, agents determined to be actually or potentially carcinogenic for the human.

The ultimate goal of such epidemiologic and basic studies is the prevention of human cancer. There is today sufficient scientific knowledge to allow the prevention of more than 60 percent of human cancers. The failure to achieve such a goal is largely the result of personal and societal decisions well beyond the realm of science. However, since the prevention of disease is by far the most effective and inexpensive mode of health care, it is appropriate that there be a constant and sustained effort to utilize the ever-expanding knowledge of neoplasia to accomplish its control through cancer prevention.

Cancer prevention in humans may in general be grouped into two approaches: active and passive. Table 8-26 depicts an outline of various methods of cancer prevention with an indication of the stage of carcinogenesis toward which the preventive measure is directed. The passive prevention of cancer involves the cessation of smoking, dietary restrictions, and modification of other personal habits such as those of a sexual nature. Active prevention of cancer development is usually accomplished by the administration of an agent to prevent infection by carcinogenic viruses and other organisms or by the intake of chemicals, nutrients, or other factors that may modify or prevent the action of carcinogenic agents. Theoretically, passive cancer prevention or the alteration of one's "carcinogenic" habits can be the most effective and unintrusive method of cancer prevention. However, for many individuals, passive prevention requires external persuasion, such as governmental regulation or peer pressure, to force an alteration of their habits. Obviously, in many instances such methods are doomed to failure. Active cancer prevention, which many consider a form of preventive "therapy," is likely to be the most effective method in this area.

MODE	STAGE
Passive	
Smoking cessation	Pr. Pg
Dietary restriction	Pr
Moderation of alcohol intake	Pr
Modification of sexual and reproductive habits	I, Pr
Avoidance of excessive ultraviolet exposure	I, Pr
Active	
Dietary modification and supplements	Pr
Vaccination against oncogenic viruses	I, Pr
Application of ultraviolet blocking agents in appropriate situations	I, Pr
Selective screening for certain preneoplastic lesions	I, Pr
Determination of genetic background in relation to neoplastic disease	I, Pr
Administration of antihormones	Pr

KEY: I, initiation; Pr, promotion; Pg, progression.

Table 8-26 Modes of the Prevention of Cancer

Individuals with hereditary conditions involving alterations in specific oncogenes or tumor suppressor genes constitute a relatively small part of the population. However, genes that may modify the susceptibility of an individual to the development of certain types of neoplasms probably represent significant factors in the development of an important fraction of human cancers (Spitz and Bondy, 1993). In reviewing Table 8-26, one can see that most methods of cancer prevention are linked to action at the stage of promotion. Because this is the reversible stage of neoplastic development, such a finding is not surprising. However, since we still do not know all or even most of the causes of human cancer, the continued identification of agents, especially chemicals, that might induce human cancer is important. While the results of epidemiologic studies, when exhibiting sufficient evidence for a causal relationship, may be considered the "gold standard," such detailed studies, even where feasible, for all the potentially carcinogenic agents existing and entering into our environment would be impossible. Therefore, during the last half century, as knowledge of the mechanisms of carcinogenesis has increased, a significant effort backed by a number of governmental agencies throughout the world was directed toward the development of methods for the identification of potentially carcinogenic agents in the environment by a variety of different systems from bacteria to whole animals. This chapter deals with the identification, characterization, and ultimate estimation of human risk from chemical, biological, and physical agents.

IDENTIFICATION OF POTENTIAL CARCINOGENIC AGENTS

A major factor in determining the carcinogenic potential of an agent is its identification as being carcinogenic. While this statement appears obvious and even redundant, identification of a carcinogen is necessary but not sufficient for determining carcinogenic potential. Still, identification is the starting point, and for this reason it has received the most attention. Generally speaking, the various tests that have been applied to identifying agents with carcinogenic potential may be classified into several general areas. These are seen in Table 8-27. As noted in the table, the time involved in the assay has been arbitrarily separated into short, medium, and long. Short-term assays usually involve days to a few weeks for development of an endpoint; medium-term assays require weeks to some months but much less than a year. Long-term bioassays usually involve 1½ to 2 years of treatment of animals with a test agent. Each of these general categories consists of specific methods. Each of these general categories is considered below in somewhat greater detail.

METHODS	TIME FRAME
Short term	
Mutagenesis assays	Several weeks
Transformation in cell culture	1–3 months
Medium term	
Qualitative and quantitative analysis of preneoplasia	2–8 months
Long term	
Chronic bioassay in animals	18–24 months

Table 8-27 General Methods for Identification of Potential Carcinogens

Short-Term Tests—Mutagenesis Assays

A variety of short-term tests, almost all of which are involved in direct or indirect assays of mutagenicity, both in vivo and in vitro, have now been developed and are used to aid in the identification of potential carcinogens. However, virtually all of these methods are of limited use in directly establishing the estimation of the risk that such chemicals pose for the human population. As noted earlier, a ubiquitous characteristic of neoplastic cells is the presence of a variety of different types of mutations. The fact that many but not all carcinogenic agents are mutagenic or may be metabolized to mutagenic forms further establishes the importance of mutations in the development of the neoplastic process. It is on this basis that short-term tests for mutagenicity were developed to identify potential carcinogenic agents on the basis of their capacity for inducing mutations in DNA in cells in vitro or in vivo.

Table 8-28 lists many of the more commonly used short-term tests for mutagenicity and thus carcinogenic potential. The most widely utilized of these mutagenicity assays was originally developed in *Salmonella typhimurium* by Bruce Ames and associates (Ames et al., 1975). In this assay, bacterial cells that are deficient in DNA repair and lack the ability to grow in the absence of histidine are treated with several dose levels of the test compound, after which reversion to the histidine-positive

phenotype is ascertained. Because bacteria differ in their metabolic capabilities compared with mammals, a drug-metabolizing system is added to these assays. Specifically, the 9000 *g* supernatant (S9) that results from centrifuging a liver homogenate prepared from a rat treated with an inducer of multiple P-450s, such as Aroclor 1254, is used in combination with an NADPH regenerating system. The method for performing the *Salmonella* assay (the Ames assay) is depicted in Fig. 8-25. Several different lines of *Salmonella* have been generated to permit the detection of point mutations (TA100, TA1535) and frameshift mutations (TA98, TA1537, TA1538), and the assay is continuously being refined. Typically, five dose levels of the test compound are used in addition to the solvent control. Activation-dependent and activation-independent positive control mutagenic substances are tested concurrently. Certain types of carcinogens are not detected by these bacterial mutagenicity assays, including hormonal carcinogens, metals, agents that have a multiple-target-organ mode of action, and agents with a nongenotoxic mode of action. This bacterial reverse mutation system, when performed in the presence of a mammalian S9 activation system, is, however, a very sensitive screen for the detection of many mutagenic agents.

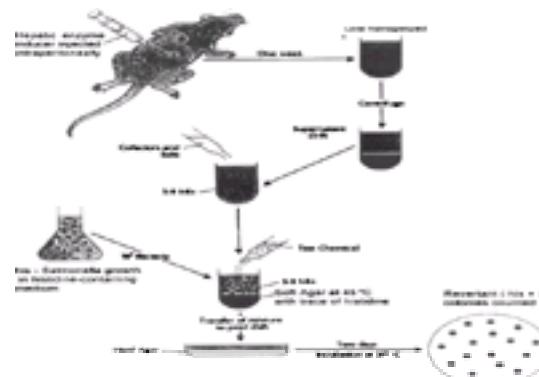
Table 8-28 Short-Term Tests for Mutagenicity


Figure 8-25. Scheme of the Ames test for mutagenesis of chemicals in Salmonella *bacterial strains.*

The upper part of the figure outlines the preparation of the S-9 mixture of enzymes and particulates prepared from rodent liver taken from animals previously administered an agent to induce the concentration of such metabolizing enzymes. The *Salmonella,* which require histidine for their growth (his⁻), are grown in the presence of histidine, separated from the growth media, and added with the test chemical and S-9 mix as well as soft agar containing a trace of histidine, which allows the cells to undergo one or two divisions (required for mutation fixation). The 5-9 and soft agar mix is transferred to a Petri dish while still warm, incubated for several days, and the colonies that develop in the absence of histidine are counted. [Modified from McCann (1983), with permission of author and publisher.]

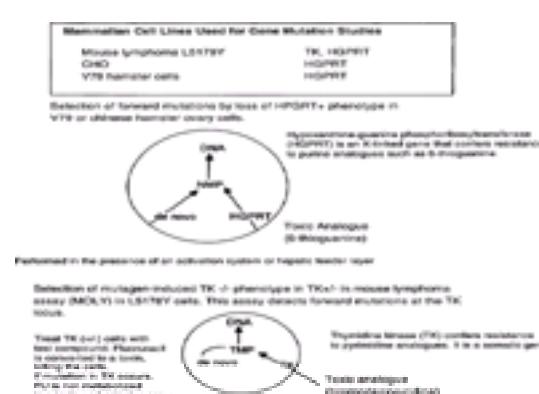
In addition to the bacterial mutational assay, several in vitro mammalian cell mutation assays exist, including the mouse lymphoma L5178Y (MOLY) assay and the Chinese hamster ovary (CHO) assay. These mammalian mutagenicity assays use either the hypoxanthine-guanine phosphoribosyltransferase (HGPRT) or the thymidine kinase (TK) gene as the endpoint. The basis for these assays is seen in Fig. 8-26. They are similar to the Ames assay in that the phenotypic expression of a mutation in a single-copy gene is compared in treated and untreated cells. These assays are frequently performed in the presence of an exogenous metabolizing source such as an epithelial cell layer that has been irradiated. The mammalian mutation test systems are forward mutation assays in which the heterozygous state of a gene is used as a tool to detect genetic damage that might result in the loss of a phenotype, e.g., growth in the presence of a toxic compound. In CHO cells, the X-linked HPGRT locus is used as the target gene for analysis. This enzyme is important in purine salvage and allows the incorporation of toxic purine analogues such as 6-thioguanine and 8-azaguanine into DNA, resulting in inhibition of cell growth and/or cell death. Alternatively, a mutation in this gene that results in phenotype loss may permit colony formation in the presence of toxic analogs. Assays based on the forward mutation of TK are similar in that colony formation in the presence of a DNA-damaging agent is scored in the presence of a pyrimidine analog. Because these short-term tests are based on the premise that carcinogens damage DNA, their concordance with the chronic bioassay in vivo (see below) is only between 30 and 80 percent. In addition, the results of tests are coincident with each other and tend to detect the same types of carcinogens without providing the battery approach that has been suggested. Among the short-term mutagenicity tests that use mutation as the endpoint, the Ames assay has been the best studied and has been applied to the greatest number of compounds.


Figure 8-26. Outline of chemically induced mutation in mouse cell lines with thymidine kinase (TK) or hypoxanthine-guanine phosphoribosyltransferase (HGPRT) as the target gene. [Reproduced from Pitot and Dragan (1996), *with permission of authors and publisher.]*

Gene Mutation Assays in Vivo Until relatively recently, a mea-surement of mutational effects in vivo was rather difficult to perform. One of the more popular assays utilized in this area was the dominant lethal assay, in which male mice are exposed to a potential genotoxic stimulus, mated with untreated female mice, and the percentage of pregnancies or number of implants is determined (Lockhart et al., 1992). While the method is relatively easy to perform, relatively few carcinogenic agents have been studied by this method. Similarly, the production of sperm abnormalities in mice by the administration of chemical agents in vivo has not found general use as a short-term mutagenic assay (Wyrobek and Bruce, 1975).

In recent years, with a variety of genetic tools available, genetically engineered cells and animals have been developed that have found use in short-term mutagenesis assays. The four examples given in Table 8-28 are those most commonly used for mutational analysis in vivo. The first three involve genetically engineered animals containing transgenes within which are components of the *lac* operon of *Escherichia coli,* a set of coordinately regulated genes involved in lactose metabolism. A schematic representation of the *lac* operon is seen in Fig. 8-27. Some details of the function of the *lac* operon are given in the figure legend. Basically,

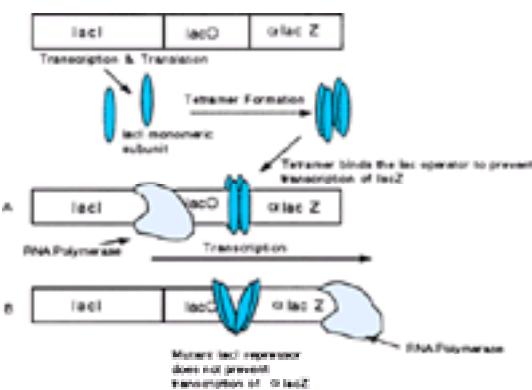
the *lacI* and *lacZ* genes are the ones utilized in the mutational assays. As noted in the figure, mutations in the *lacI* gene will alter the regulation of expression of the *lacZ* gene, which codes for b-galactosidase activity. Thus, the transgene contains either one or the other of the operons. Mutations in the bacterial transgene are determined by the methods seen in Fig. 8-28. In this technique, DNA is extracted from the tissue of interest, and because of the nature of the transgene, construct may be packaged into a bacterial virus, lambda, which then infects the bacteria, *E. coli,* on a lawn of bacterial growth on a dish as noted in the figure. By selecting appropriate bacterial strains and media, one can isolate mutant phage and analyze the sequence of the *lacI* or *lacZ* gene as appropriate. Thus, one may obtain both the number of mutations per unit DNA from the mouse or, more importantly, the actual sequence changes induced by the mutagenic action of the original agent. The *rpsL* transgene works by a similar mechanism but by a different metabolic pathway (Gondo et al., 1996).


Figure 8-27. Schematic representation of the lac operon in E. coli.

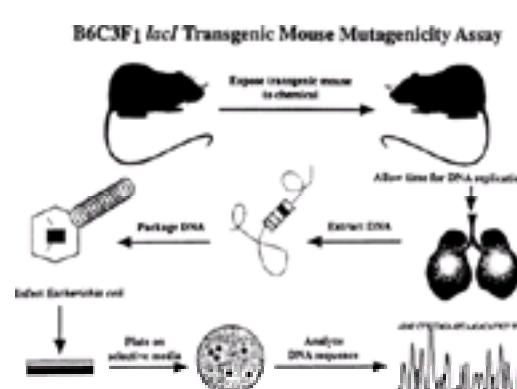
A. The *lacI* gene codes for protein that forms a homotetramer that binds to the *lacO* operator sequence. Binding of the repressor to *lacO* prevents transcription of *lacZ*. *B.* Transcription of *lacZ* occurs in the presence of the inducing agent, isopropyl-b-thiogalactoside (IPTG). Mutations of the *lacI* may result in partial or complete inactivation of the *lac* repressor, the *lacI* tetrameric protein. Furthermore, mutations in the *lacZ* gene may prevent interaction with the repressor or may be nonfunctional, resulting in no production of the structural gene, *lacZ*. [Reproduced from Provost et al. (1993), with permission of authors and publisher.]


Figure 8-28. Sequence of steps utilized in the determination of the mutagenicity of chemicals in transgenic rodent mutagenicity assays in vivo.

The details of the test are briefly discussed in the text or the reader is referred to the original article. [From Recio (1995), reproduced with permission of author and publisher.]

Since several of the transgenic animals are commercially patented, this assay may entail some expense, but is relatively versatile for an in vivo assay for mutagenic identification, and its ability to detect nonmutagenic carcinogens is doubtful. Of interest is the fact that with at least one carcinogenic agent, ethylnitrosourea, the relative sensitivities of mutations induced in the *lacI* transgene and an endogenous gene, *hprt,* were essentially identical (Skopek et al., 1995). Species differences occur with different carcinogens in that, for example, aflatoxin B_1 treatment resulted in a much greater number of mutations in the *lacI* rat than in the *lacI* mouse (Dycaico et al., 1996). External ionizing radiation was not very mutagenic in the *lacZ* transgenic mouse (Takahashi et al., 1998), but of interest is the finding that the promoting agent, phenobarbital, enhanced mutation frequency in the livers of *lacZ* transgenic mice treated with diethylnitrosamine (Okada et al., 1997). While a significant number of spontaneous mutations occur in the transgene, as yet this does not appear to be an insurmountable problem (de Boer et al., 1998). Thus, the potential for utilizing such transgenic models for the in vivo assay of mutagenesis is clearly bright. However, their effectiveness in identifying promoting and progressor agents has yet to be validated.

Chromosomal Alterations Chromosomal alterations are extremely common if not ubiquitous in all malignant neoplasms, as was originally suggested by Boveri (1914). Therefore, the induction of chromosomal abnormalities by chemicals in relatively short-term in vivo and in vitro methodologies would logically be considered as an excellent test for carcinogenic potential. Although this has been true in general, the application of various tests for clastogenicity, aneuploidy, and chromatid alterations has not formed the basis for determining potential carcinogenicity of chemicals. In part, the technology involved is more complicated and expensive than most of the gene mutation assays, and the molecular basis for at least one of the more common tests, that of sister chromatid exchange, is not fully understood. Theoretically, short-term assays for the induction of clastogenicity and related abnormalities would allow the rapid identification of potential progressor agents.

Analysis of chromosomal alterations in vivo was studied in germ cells two decades ago by Generoso et al. (1980) in mice. This procedure, as carried out by these workers, involves the administration of an agent to male mice shortly before breeding and subsequent examination of male offspring for sterility and/or chromosomal abnormalities in both germ and somatic cells. The test is somewhat complex, and thus far only a few very potent mutagenic agents have been found positive in this test. A more commonly employed short-term test for clastogenesis is the micronucleus test, which measures induced clastogenesis in rodent bone marrow in vivo by morphologic evaluation of micronuclei containing chromosome fragments in cell preparations from bone marrow (Heddle et al., 1983). However, this assay also has an occasional false positive, such as vitamin C (Tinwell and Ashby, 1994). With the LEC rat, which exhibits a defect in copper metabolism leading to hepatitis and hepatomas, an increased frequency of chromosome aberrations was seen in the bone marrow after administration of direct-acting alkylating agents that did not need metabolic activation (Ito et al., 1994). However, carcinogenic agents requiring metabolic activation, especially in the liver, induced a lesser amount of chromosomal abnormalities in the bone marrow of these rats than in normal rats.

Studies in vitro of chromosomal alterations have been carried out both in yeast and in cultured mammalian cells. In the former, various genetic end-points are studied, the abnormalities seen being the result of chromosomal alterations (Wintersberger and Klein, 1988). In mammalian cell lines, most of the systems used the same lines as for the gene mutation assays, e.g., Galloway et al. (1985). Relatively few analyses of induced chromosomal alterations have been carried out in normal diploid cells in culture. This test is used much more extensively than most of the other short-term tests involving chromosomal alterations (cf. Ishidate et al., 1988). As might be expected, some discrepancies have arisen between the mutagenic and clastogenic effects of chemicals by these two different systems (cf. Ashby, 1988). Furthermore, chromosomal alterations in these cell lines are sensitive to oxidants (Gille et al., 1993; Shamberger et al., 1973; Kirkland et al., 1989), and preferential targets of chemicals in these aneuploid cell lines are chromosomes bearing amplified genes, already indicative of the karyotypic instability of the cell lines being used (Ottagio et al., 1993).

Another short-term test involving changes in chromosomal structure by mechanisms not entirely understood is the technique of "sister chromatid exchange" (SCE). During metaphase, sister chromatids, each of which is a complete copy of the chromosome, are bound together by mechanisms that involve specific proteins (Nasmyth, 1999). SCE reflects an interchange between DNA molecules within different chromatids at homologous loci within a replicating chromosome (Latt, 1981). The detection of SCEs requires methods of differentially labeling sister chromatids. The usual technique is to allow a cell to incorporate a label, usually a halogenated pyrimidine such as bromodeoxyuridine (BrdU), for one replication cycle and then it undergoes a second replication cycle in which the presence of the labeled precursor is actually optional. The procedure has been used in vivo as well as in vitro (DuFrain et al., 1984). In an extensive examination and comparison of the SCE

method with cytogenetic changes, the two methods were about 70 percent congruent, again indicating that clastogenesis and SCEs are not identical phenomena (Gebhart, 1981).

Primary DNA Damage The measurement of DNA damage and repair induced by exogenous chemicals, both in vivo and in vitro, has been a relatively common technology used in short-term tests for potential carcinogenicity. The most generally utilized technology involves the analysis of non-replicative DNA synthesis with appropriately labeled precursor nucleotides (cf. Harbach et al., 1991). More sophisticated techniques involve the measurement of DNA strand breakage by eluting DNA fragments from columns to which the DNA is bound with an alkaline solution (Sina et al., 1983; Miyamae et al., 1997). These techniques have been applied to a variety of tissues in cell culture, both primary and cell lines. Primary liver cell cultures have been among the most popular of the tissues utilized (Williams et al., 1989; Strom et al., 1981; Swierenga et al., 1991). While primary hepatocyte cultures have the advantage of an extensive endogenous metabolic apparatus, other workers have attempted to obviate the problem of metabolism of the agent to the active form by administration of the test chemical in vivo, with subsequent explantation of specific organ tissues to culture and measurement of unscheduled DNA synthesis in such cultures (cf. Furihata and Matsushima, 1987). Just as with all of the short-term tests indicated above, the use of DNA repair analysis has limitations, as evidenced by the fact that in an extensive investigation by Williams and his associates (1989) of 167 chemicals testing negative, 44 were carcinogenic. This and the other points raised in this section demonstrate both the usefulness and limitations of short-term tests of mutagenicity and DNA damage for indicating potential carcinogenicity. Regulatory agencies have chosen to approach this problem by requiring a number of different tests to be performed during the study of a particular compound, and these data are taken into account with all of the other information, especially that developed by studies in vivo, as discussed below.

Short-Term Tests—Transformation and Cell Culture

As with other of the short-term tests listed in Table 8-28 and discussed above, determination of the "neoplastic" transformation in cultured cells has also taken the direction of the use of a primary (directly from the animal) culture system in which the cells are diploid and normal in all measurable respects. Another direction is the use of a number of cell lines exhibiting aneuploidy but having reasonably defined cultural characteristics. The techniques for the latter have been somewhat standardized (Dunkel et al., 1991), and an extensive degree of study has been carried out with primary Syrian hamster embryo (SHE) cells in primary culture for predicting the carcinogenic potential of a variety of chemicals (cf. Isfort et al., 1996; Barrett et al., 1984). While these techniques are relatively straightforward, although somewhat more difficult to score in the SHE system, for the most part they suffer from the inability of the cells to metabolize test agents to their ultimate forms. In addition, given the expense required for the establishment and use of tissue culture methodology, this has been a less than popular short-term test for carcinogenic potential.

Chronic Bioassays for Carcinogenicity—Medium- and Long-Term

The ability to induce neoplasia in lower animals has been the basis for our understanding of the pathogenesis of neoplasia. Early studies showing the induction of skin cancer in mice by coal tar derivatives and of liver cancer by organic dyes led to the establishment of model systems in these and other tissues, both for the investigation of cancer development and ultimately for testing of agents for their carcinogenic potential. The administration of chemicals in the diet for extended periods, pioneered in the 1930s by Yoshida and his colleagues (Sasaki and Yoshida, 1935), formed the basis for the establishment of the chronic bioassay of carcinogenicity that is used today. This methodology was espoused by the National Cancer Institute some 30 years after Yoshida's findings (Hadidian et al., 1968), and almost 200 assays of chemicals for their carcinogenic potential by the prolonged feeding to animals was carried out over the next decade (Hottendorf and Pachter, 1985). Parallel to the use of this lifetime model of carcinogenesis in small rodents was the development of various organ-specific model systems, multistage models, and most recently the use of transgenic animals in carcinogen testing. A listing of these animal models is seen in Table 8-29.

Table 8-29 Animal Models of Neoplastic Development

Chronic 2-Year Bioassay Today the "gold standard" for determining potential carcinogenic activity of a chemical is through the use of the chronic 2-year bioassay for carcinogenicity in rodents. This assay involves test groups of 50 rats and mice of both sexes and at two or three dose levels of the test agent. The animals should be susceptible but not hypersensitive to the tested effect. In general, two strains are typically used by regulatory agencies in the United States, the B6C3F1 mouse and the F344 rat. The format for the bioassay is seen in Fig. 8-29. Quite simply, animals at about 8 weeks of age are placed on the test agent at the various doses for another 96 weeks of their life span. The test agent may be administered by dietary feeding, by gavage on a regular basis, or by inhalation in rather complex chambers. A variety of pretest analyses are carried out, such as those for acute toxicity, route of administration, and determination of the maximum tolerated dose (MTD). The use of the MTD has been challenged by many, arguing that the toxic effects of high doses of an agent can cause a replicative response in normal cells that could lead to an increase in neoplasia quite secondary to the effects of the agent itself (Cutler et al., 1997; Haseman and Lockhart, 1994). This is supported by the finding of a very high percentage, nearly half in some instances, of agents exhibiting no potential for mutagenicity but inducing neoplasia at the MTD (Gold et al., 1993). Furthermore, these two strains of rodents have a significant spontaneous tumor incidence, as can be noted in Table 8-30.

Because so many research dollars go into carcinogenicity testing and the data resulting from such studies are expected to be useful not only in hazard identification but also in risk estimation, an acceptable scientific protocol with quality assurance must be followed to produce scientifically and statistically valid data. A variety of factors relevant to the acceptable outcome of a carcinogenicity study are considered, including animal husbandry; the identity and purity of the test compound and identification of any contaminants; the homogeneity, stability, and physical properties of the test compound under various storage conditions; and the solubility, stability, and availability of the test compound in the solvent. In addition, the formulation should be either that which is to be administered to humans or that which permits bioavailability in the test organism. The environment of the rodent is also important, and care should be taken to control for sources of variability in the animals, their diet, and their housing. While the usual comparison in animal studies is the concurrent control, for a number of situations historical controls may be more appropriate (Haseman et al., 1997).

The underlying basis for risk extrapolation from animals to human is that the animal is a good model for human cancer development. In fact, 2-year bioassay models have been used to detect the compounds listed by IARC (Vainio et al., 1991) as known human carcinogens. Also, most known human chemical carcinogens have a carcinogenic potential in animals that supports the results of epidemiologic studies (Vainio et al., 1985). Exceptions include ethanol and arsenic. In addition, it has now become evident that some neoplastic responses to chemicals in animals are unique to the rodent and species as well as the sex involved. These include such responses as thyroid neoplasia (McClain, 1989), the induction of a_{2u}-globulin (Swenberg et al., 1985) resulting in renal neoplasms in male rats, and peroxisome proliferation (Ashby et al., 1994) associated with the induction of hepatic neoplasia in rats. In addition, a significant problem that has arisen in the continued use of the chronic bioassay is the requirement for ad libitum feeding. This results in animals, especially in rats, of extreme weight by the end of the 2 years; many will have died spontaneously prior to the end of the test. Such complications are now being remedied by the use of dietary restriction in the chronic bioassay for the 2-year period. This phenomenon reduces spontaneous cancer incidence and extends lifespan in rodents, and its usefulness in the refinement of the 2-year chronic bioassay is now becoming more appreciated (Keenan et al., 1996; Allaben et al., 1996).

The statistical analysis of results obtained in chronic bioassays has also been difficult when the analysis results in relatively few neoplasms in test animals. As can be seen from Table 8-31, a relatively high percentage of animals must bear tumors before a statistically significant result can be obtained in the face of significant development of spontaneous lesions. Since the latter phenomenon is clearly a problem in these animals (Table 8-30), borderline results become a very difficult problem for regulatory agencies in determining whether or not a compound actually is carcinogenic in the assay or not. An exception to this is when a very unusual histogenetic type of neoplasm not seen spontaneously is found in the test animals at a significant, even very low level (Chu et al., 1981; Basu et al., 1996). The enumeration of all neoplasms versus those in specific tissues also can raise difficulties in interpretation of the bioassay. Despite these criticisms and problems, the chronic 2-year bioassay continues to be the major basis for regulatory action in this country and in many countries throughout the world.

Table 8-31 Percentage of Animals with Tumors (Rx) Administered a Test Agent Required to Obtain Statistical Significance when Compared with Control Animals with Tumors (Co)

Tissue-Specific Bioassays During the performance of long-term bioassays, it became obvious that certain tissues in specific species exhibited neoplasms more frequently than others when a test agent was administered. From these observations, several tissue-specific bioassays were developed with the objective of a reasonably sensitive assay carried out in a shorter time than the usual chronic 2-year bioassay. The best known of tissue-specific assays is that utilizing the mouse liver. In a recent analysis of chronic bioassays carried out by the National Toxicology Program, Crump et al. reported that 108 of 390 studies indicated a positive carcinogenic response to the test chemical. In 81 of these studies, female mice exhibited significant increases in the incidence of hepatic neoplasms. As noted in Table 8-30, there is a high incidence of spontaneous hepatoma development in mice, more so in the male. This has led to controversy in the interpretation of the significance of the development of mouse hepatomas, especially if they are the only statistically significant increased neoplastic response in the test animals. As a result of this controversy, the interpretation of the significance of the induction of mouse hepatic lesions has been called into question (cf. Dragan et al., 1998; Moch et al., 1996). A further complication of this assay is the fact that in at least one study the majority of the chemicals testing positive exhibited no evidence of an ability to induce DNA damage or mutation (Carmichael et al., 1997).

Another tissue-specific bioassay that was developed by Shimkin and his associates more than two decades ago (Shimkin and Stoner, 1975) is the development of pulmonary adenomas and carcinomas, primarily in strain A mice. The assay was shown to effectively identify a number of relatively potent carcinogenic agents, including a few inorganic carcinogens (Stoner et al., 1976). However, the assay has not been generally accepted as a major component for the determination of carcinogenicity of chemicals, but it has found usefulness in the determination of the molecular mechanisms of pulmonary carcinogenesis in this strain of animals (You et al., 1989; Nuzum et al., 1990). In addition, as noted from Table 8-29, induction of gliomas in the rat brain and of mammary neoplasms in both the rat and the mouse may yield potential for tissue-specific bioassays. There have also been attempts to utilize lower vertebrates in the development of tissue-specific bioassays, such as the rainbow trout embryo (Hendricks et al., 1980).

Medium-Term Bioassays While tissue-specific bioassays were directed in part at decreasing the time required for the analysis of carcinogenic potential in vivo, at least two assays have been specifically designated as having reduced the time for the development of an endpoint. The one most intensively used today, primarily in Japan, is the model developed by Dr. Nobuyuki Ito and his colleagues (Ogiso et al., 1990; Shirai, 1997). A diagram of the format for this assay is seen in Fig. 8-30. The entire assay takes only 8 weeks, and the endpoint is nodules and focal lesions in the liver of rats that stain for glutathione S-transferase pi (GST-P). The initial "programming" of the liver by administration of a necrogenic dose of diethylnitrosamine poses some problems in that this dose by itself is carcinogenic, but only after a year or more. Furthermore, this high dose is also clastogenic to rat hepatocytes in vivo (Sargent et al., 1989). However, these authors and their colleagues have demonstrated a significant degree of correlation between long- and medium-term results, indicating the usefulness of this assay as a potential surrogate for the chronic bioassay (Ogiso et al., 1990). More recently these authors have used a slightly modified protocol in which five potent carcinogenic agents are administered for a 4-week period, followed by administration of the test chemical for a subsequent 24- to 32-week period (Ito et al., 1996). Unlike the assay depicted in Fig. 8-29, this more complicated procedure may allow the detection of promoting and progressor agents as well as complete carcinogens in a variety of different tissues. However,

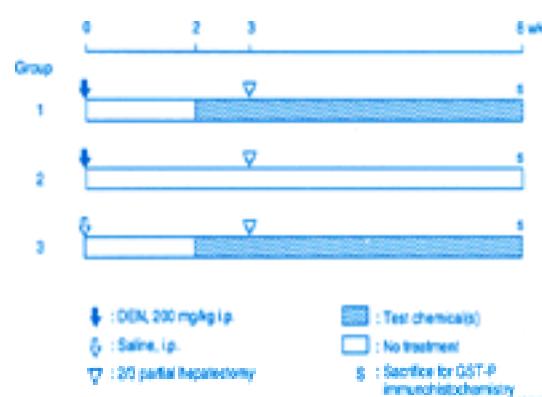
outside of Japan these assay procedures have not been generally utilized.


Figure 8-30. The medium-term liver bioassay protocol for identification of potentially carcinogenic agents.

DEN, diethylnitrosamine; GST-P, glutathione *S*-transferase–p. [Reproduced from Shirai (1997), with permission of author and publisher.]

The newborn mouse model of chemical carcinogenesis was initially described by Shubik and his colleagues (Pietra et al., 1959) and later used extensively in studies of mouse hepatocarcinogenesis by Vesselinovitch and his colleagues (1978) . More recently, Fujii (1991) has utilized this procedure in the determination of the carcinogenic potential of 45 different chemicals with quite reasonable results. The endpoint of neoplasms in a variety of different tissues, including lung, liver, lymphoid and hematopoietic tissues, is determined within a 1-year period. The assay is relatively inexpensive, utilizing small amounts of the test materials. As yet, however, this assay has not found general usefulness in the determination of carcinogenic potential by regulatory agencies.

Multistage Models of Neoplastic Development

As we have previously noted, the original studies on multistage models of carcinogenesis were developed with the epidermis of the mouse. It was not until some 40 years after those initial experiments that there was some attempt at standardization of the multistage model of carcinogenesis in mouse skin for the analysis of the carcinogenic potential of specific chemicals (Pereira, 1982). The format for such assays was essentially that depicted in Fig. 8-18. Few refinements in the procedure were added with the exception of the use of a genetically susceptible strain of mice, the SENCAR strain, which is now utilized in such tests (Slaga, 1986). This system may also be extended to the potential analysis of progressor agents (Hennings et al., 1993; Warren et al., 1993).

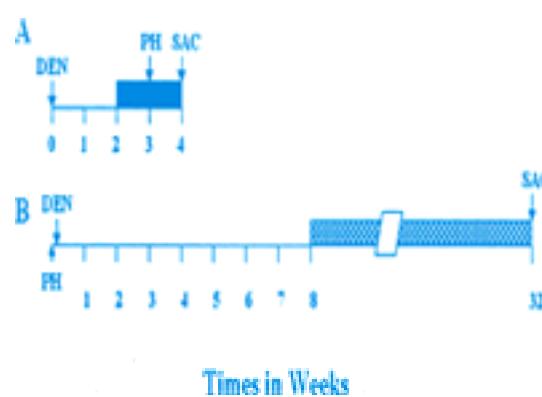
Considerably later than the initial reports of the mouse skin system, Hicks et al. (1975) demonstrated the cocarcinogenic or promoting action of several agents in the development of bladder cancer in the rat. Subsequently, other promoting agents have been demonstrated with this or a related assay, some of which appear to be relatively unique to this tissue for both anatomical and chemical reasons (Cohen and Lawson, 1995; Ito and Fukushima, 1989). At about the same time as the initial report of the multistage bladder model of carcinogenesis, Peraino and associates (1977) reported a multistage model of carcinogenesis in the rat liver. This finding has led to the development of a number of models of multistage carcinogenesis in the rat liver. Solt and Farber (1976) reported a model somewhat analogous to that of Ito and his colleagues, but with an aim directed primarily at studying mechanisms of hepatocarcinogenesis rather than utilizing it as an assay system for potential carcinogens. Shortly thereafter, Pitot et al. (1978) developed a model wherein initiation was performed with a nonnecrogenic dose of the initiating agent, subsequently followed by chronic administration of a promoting agent. The format of these two assay systems are noted in Fig. 8-31. The endpoint of these systems is the quantitative analysis of altered hepatic foci measured by one of several enzymatic markers, the most sensitive being the expression of GSTP (Hendrich et al., 1987). Several studies have investigated the potential for such analyses in the detection of chemical carcinogens (Pereira and Stoner, 1985; Williams, 1989; Oesterle and Deml, 1990). A similar format has been used to study the preneoplastic aberrant crypt foci in the colon of animals administered potential carcinogens (Ghia et al., 1996). However, as yet all such assays utilizing preneoplastic endpoints have not found general usefulness in the identification of potential carcinogenic agents. It is possible that in the future such assays may be useful in distinguishing between agents exerting their carcinogenic effect primarily at one or another of the stages of carcinogenesis.


Figure 8-31. Formats of short-term models of multistage hepatocarcinogenesis in the rat.

A. The Solt-Farber model, in which animals are administered a necrogenic dose of diethylnitrosamine followed 2 weeks later by the administration of 0.02% acetylaminofluorene (*shaded bar*) with a 70 percent partial hepat-ectomy performed after 1 week of AAF feeding and sacrifice 1 week following the surgery. *B.* The Pitot et al. (1978) model, in which a nonnecrogenic dose (10 mg/kg) of DEN is administered 24 h after a partial hepatectomy (PH) and animals are fed a normal diet for 8 weeks, at which time they are placed on a diet containing 0.05 percent phenobarbital for a subsequent 24 weeks and then sacrificed. The endpoint of both models is the quantitation of altered hepatic foci.

Transgenic and Knockout Mice as Models of Carcinogenesis

With the advent of the development of transgenic animals as well as gene targeting in mice, recent efforts have been directed towards the development of animal models with specific genetic alterations that make them more susceptible to carcinogenesis by external agents. As noted from Table 8-29, the most popular of these are mice exhibiting one defective allele of the *p53* tumor suppressor gene and a transgenic mouse line (TG·AC) carrying a v-Ha- *ras* oncogene fused to a zeta globin promoter. *p53*-deficient mice develop a high frequency of a variety of spontaneous neoplasms. The incidence of such tumors varies but, in general, all of the homozygous *p53*-defective mice develop neoplasms by 10 months of age, while the heterozygous mice have a 50 percent incidence by 18 months, with over 90 percent incidence by 2 years of age (Donehower, 1996). However, the heterozygous animals did not show an accelerated carcinogenesis of the liver, even when hepatocarcinogens were administered (Dass et al., 1999). In addition to this model system, which mimics the Li-Fraumeni syndrome in humans, a large number of other gene-targeted mutations have been developed in mice but have not yet been utilized as model systems for identifying potential carcinogenic agents (Rosenberg, 1997).

The TG·AC transgenic mouse is one of a large number of potential transgenic mice and rats that might be considered for the study of the development of neoplasia in response to test agents. However, in most cases the expression of the transgene is targeted to a specific tissue, and thus one deals with a tissue-specific development of neoplasia (cf. Goldsworthy et al., 1994). The TG·AC transgenic mouse is very effective in the identification of potential promoting agents for the skin. Administration of the well-known skin-promoting agent, TPA, could induce the development of papillomas after only three to ten applications (Spalding et al., 1993). These investigators also studied several other potential promoting and progressor agents, all of which exhibited a short latency period and high incidence of papilloma induction. Thus, it is apparent that each of these genetic models of carcinogenesis has a role to play in the identification of potential carcinogenic agents. It

will require considerable effort to validate each of the models with respect to tissue-specific carcinogenesis by complete carcinogens or by promoting and/or progressor agents (cf. Tennant, 1998).

EVALUATION OF CARCINOGENIC POTENTIAL

The multiple in vivo and in vitro tests described thus far present the experimentalist or the regulator with an extensive amount of data from which to draw conclusions about the carcinogenic potential of the test agent. In addition, epidemiologic studies provide perhaps the most definitive means of estimating the carcinogenic potential to humans from exposure to a specific agent. While such studies, if definitively positive, are the best evidence for carcinogenic potential of an agent to humans, the evidence is usually obtained after an exposure has occurred in a population. In general, epidemiological studies can only detect differences between populations when there is approximately a twofold increase above the background incidence of neoplasia in the control population. Since many more agents than those classified as group 1 by IARC exhibit carcinogenic potential, the in vitro and in vivo tests described earlier have been used as surrogates in attempting to determine carcinogenic potential and risk to the human population. The results of such tests clearly offer qualitative information with respect to the identification of agents exhibiting some potential hazard with respect to one or more aspects of the process of carcinogenesis as we know it today. Major difficulties remain in attempting to extrapolate in a scientific and meaningful way information obtained from in vitro and *in vivc* tests to an estimation of the potential risk of such agents to the human population as inducers of disease, especially neoplasia. As might be expected, a number of problems are involved in the scientific and practical application of information developed from short- and long-term tests to the estimation of human risk.

The Problem of Extrapolation

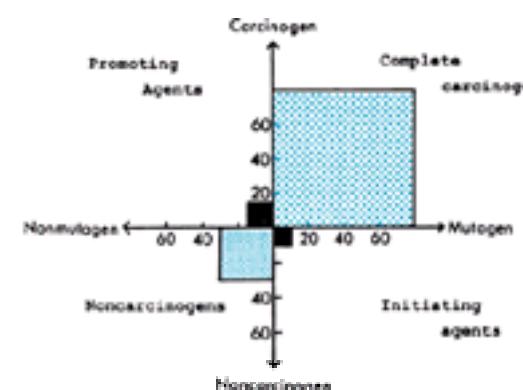
Since bacterial mutagenicity (Fig. 8-25) is the most widely and extensively utilized test for estimating the qualitative carcinogenic potential of an agent, a number of investigations have been directed toward determining the relationship of bacterial mutagenesis and carcinogenesis of the same chemical, usually in rodents. An early graphical relationship of such a series of tests is seen in Fig. 8-32. Obviously, considerable more efforts have been carried out since the publication of this in 1976 (Sugimura et al., 1976). However, the figure does place in rather definitive terms compounds that exhibit either carcinogenic and/or mutagenic activities. The indicated description of complete carcinogen, promoting agent, initiating agent, etc., is an exercise allowing the further classification of such agents in multistage carcinogenesis. In a far more extensive study, Tennant et al. (1987) related the results of bacterial mutagenicity to carcinogenic potential as determined in the chronic 2-year bioassay and found that the short-term assay detected only about half of the carcinogens as mutagens. These studies and a slightly later one by Ashby (1989) pointed again to the importance of using more than a single short-term assay in attempting to relate DNA structural alterations to potential carcinogenicity. Although the prediction of carcinogenic potential by the bacterial mutagenicity tests together with other short-term tests is in the neighborhood of 60 to 70 percent, it is somewhat surprising that interspecies extrapolation of carcinogenesis in rats and mice is not much greater than this. In an analysis by Gold et al. (1989), chronic bioassays for carcinogenic potential in either mice or rats were only about 70 to 75 percent predictive of carcinogenicity in the other species. In a more recent study (Fung et al., 1993) of 379 chemicals tested by the National Cancer Institute/National Toxicology Program for carcinogenic potential, only slightly more than 50 percent of the chemicals tested exhibited carcinogenicity in at least one organ of one sex of one species. Less than half of these exhibited carcinogenic potential in both species tested, a situation most likely to be indicative of a carcinogenic hazard to humans.


Figure 8-32. Graphic representation of mutagens and nonmutagens in relation to their known carcinogenic potential in animal tests.

The labeling of the quadrants using the classification of Table 8-18 is a further potential extrapolation of these data. [After Sugimura et al. (1976), with permission of authors and publishers.]

Several other issues are also relevant to cross-species extrapolation, including differences in metabolism of chemical agents between the species. While metabolic schemes are qualitatively similar across species, significant quantitative differences, especially in metabolic rate, partly owing to elimination kinetics, are the rule. Exposure estimation is frequently based on the daily dose administered or on plasma concentration used as a surrogate for concentrations in the tissue. Using plasma concentrations for extrapolation across species assumes that each species responds in the same manner to any given dose of an agent. In the final analysis, it may be that the best basis for cross-species comparison is serum concentration expressed as milligrams per kilogram body weight, since this better predicts tissue concentration-response effects after chronic administration (Allen et al., 1988; Monro, 1992). Thus, it is clear that the problem of extrapolation of both short- and long-term tests to carcinogenic potential in the human is much less than perfect, suggesting an important need for reevaluation and reinterpretation of the tests currently in use. Needless to say, a program to develop better extrapolative endpoints should be a major priority.

The Dose–Response Problem

Another important component in the analysis of assays for carcinogenic potential, both in vivo and in vitro, is that of the dose–response to a particular test agent. The effectiveness of the induction of neoplasia by a chemical agent is dependent on the dose of that agent administered to the test animal. We have already noted the importance of dose–response curves for the stages of initiation and promotion. The differences in the shapes of the curves for these two processes are of considerable significance in assessing carcinogenic potential and risk.

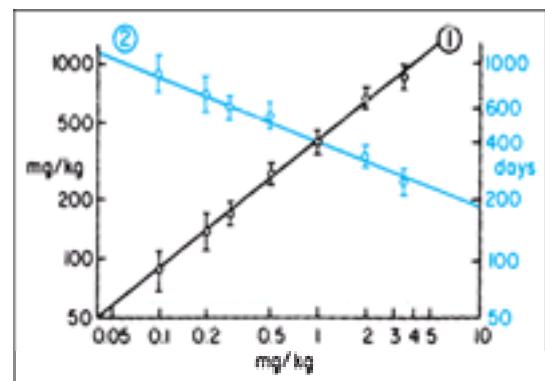
Other factors may also influence a dose–response curve, such as the toxicity of the agent, the bioavailability of the agent, and the metabolic or pharmacokinetic characteristics of the agent within the living organism. A classic dose–response of a complete carcinogen and some of its ramifications are seen in Fig. 8-33 (Druckrey et al., 1963). In this figure, curve 1 shows the relationship between the daily dose administered and the median total dose of animals developing carcinoma. Thus, the left ordinate indicates the sum of all doses administered up to a 50 percent tumor incidence, thus relating the total dose to the tumor incidence. In this way the straight line relationship, if extrapolated, would proceed through the origin. Curve 2 relates the daily dose of carcinogen to the median induction time of the appearance of the first neoplasm. While extrapolation of curve 1 through the origin indicates that there is no dose at which some incidence of neoplasms is not apparent, it should be noted that if the daily dose is less than 0.1 mg/kg, no experimental data points are available. Furthermore, extrapolation of curve 2 to this low-dose region indicates that at doses lower than 0.1 mg/kg, the rats used in this experiment and whose lifetime is approximately 1000 days will not live sufficiently long for carcinomas to appear. In the assay depicted in Fig. 8-33, the animals were administered a carcinogenic agent at a constant rate in the diet. Littlefield and Gaylor (1985) noted that with another complete carcinogen, 2-acetylaminofluorene, both the dose rate and the total dose administered are important in the final analysis. These workers demonstrated that when the total doses of this test agent were similar, the higher dose rates with shorter time periods induced a higher prevalence of neoplasms.


Figure 8-33. Dose – response relation seen in the chronic feeding of 4-dimethylaminostilbene to rats.

1. Relation between the daily dose and the median total dose for animals that developed carcinoma. 2. Relation between daily dose and median induction time. The abscissa shows the daily dose; the ordinate on the left is the total dose administered, and on the right is the time from the beginning of the experiment. All scales are logarithmic. [Modified from Druckrey et al. (1963), with permission.]

The use of the MTD has been criticized because of the toxicity it induces, paralleled by an increase in cell proliferation in a number of susceptible organs (Ames and Gold, 1990). At the other end of the dose–response curve the problem of the presence or absence of a threshold (no-effect level) of a carcinogenic agent is still hotly debated. We have already noted that, on theoretical grounds, agents capable of damaging DNA might not be expected to exhibit a threshold, whereas those exerting their effects through complicated receptor-mediated pathways, as with promoting agents, would be expected to exhibit a threshold of their effects (Aldridge, 1986). In addition, carcinogenic agents, whether DNA damaging or not, may exhibit a lower than control effect at very low doses (Kitchin et al., 1994; Teeguarden et al., 1998). Despite these observations, as well as the data depicted in Fig. 8-33 and our knowledge of the mechanism of action of promoting agents, regulatory agencies have not seen fit in general to alter the philosophy that carcinogenic agents do not have threshold dose levels. As we shall see, this philosophy has permeated much of the regulatory action taken to date with respect to agents shown to be carcinogenic in any form of life.

In most epidemiologic studies it has not been possible to determine the doses of the agents to which humans have been exposed, and only occasional, rather crude retrospective dose–response curves are available. However, a summary was made by the Meselson Committee (1975) of dose levels of several known human carcinogens that appear to be carcinogenic for certain human populations. These estimated levels were compared with levels of these agents known to produce neoplasms in animals (Table 8-32). They show that the cumulative doses required per unit of body weight for tumor induction in the human and experimental animals are of the same order of magnitude for four of the six agents. However, a more detailed comparison would require a correction for the short observation time in many of the studies on humans (as in the case of diethylstilbestrol and vinyl chloride), since many cancers in humans do not appear for 20 to 30 years after exposure. In addition, both vinyl chloride and diethylstilbestrol cause a very rare neoplasm in humans that is not usually seen in experimental animals. Thus, the effective doses of several agents known to be carcinogenic for humans and rodents are not markedly dissimilar in the two species. If this conclusion can be extended to other chemical carcinogens in the human environment, then both the qualitative and quantitative extrapolations of such findings in the animal to the human situation have some degree of validity.

Table 8-32 Approximate Total Doses for Tumor Induction in Humans and Experimental Animals

The Problem of the Potency of Carcinogenic Agents

It should be apparent to the student by now that not all carcinogenic agents are equally effective in inducing neoplasia, i.e., they exhibit differing carcinogenic potencies. The potency of an agent to induce neoplasia has been simply defined as the slope of the dose–response curve for induction of neoplasms (Choy, 1996). However, such a definition has generally not been the basis for estimates of carcinogenic potency based on data from chronic bioassays with continuous administration of the agent. In Table 8-33 may be seen a listing of some methods for the measurement of the potency of carcinogens, beginning with the early study by Iball (1939) resulting in the Iball Index, which was used for a number of years thereafter. The relationship of Meselson and Russell (1977) may also be derived from the results of bacterial mutagenesis assays. The potency relationship developed by Crouch and Wilson (1979) is dependent on a linear, no-threshold extrapolation of the animal bioassay result, giving the slope as b in the equation seen in the table (Barr, 1985). The TD_{50} has been extensively used, and values were recently compiled by Gold and Zeiger (1997) for a large number of chemicals. The range of carcinogenic potencies developed from such a relationship may be seen in Fig. 8-34. Tennant and his associates (Dybing et al., 1997) have modified the TD_{50} potency relationship, using a different fraction of animals that develop neoplasms. The T_{25} is defined by these workers as the chronic dose rate in mg/kg body weight/day that will give 25 percent of the animals neoplasms at a specific tissue site, after correction for spontaneous incidence, within the standard lifetime of the test species. As expected, since the relationship is basically the same as that noted in Table 8-33 except for only half the percentage, the T_{25} values are usually roughly one-half those of the TD_{50} values. Pepelko (1991) has pointed out one of the difficulties of these absolute potency measurements in that differences in solubility, bioavailability, and some other pharmacokinetic parameters do cause considerable variability in some of the potency values reported.

Table 8-33 Some Methods for the Measurement of the Potency of Carcinogens

Figure 8-34. Range of carcinogenic potency as determined by the TD$_{50}$ potency relationship of Peto et al. (1984).

[Adapted from Gold et al. (1998), with permission of authors and publisher.]

While the four relationships noted in the table under "absolute" do analyze carcinogenic potency of a chemical from the data on the bioassay of that chemical alone, Glass and associates (1991) did propose a relative potency relationship that has some degree of flexibility and may have some application in risk assessment different from the absolute analyses. Pitot et al. (1987) have attempted to determine indices relating the stages of initiation and promotion to the potency of the agents inducing such stages. In the case of the initiation index, which is relatively straightforward, the values obtained are absolute. In the case of the promoting index, the value is always given in relation to the nontreated control, which does develop focal lesions from endogenous promotion of spontaneously initiated hepatocytes. However, these measures of initiating and promoting potencies have been applied only to multistage hepatocarcinogenesis in the rat. However, it is quite feasible to extend such analyses to multistage carcinogenesis in a number of other solid organs where the immediate results of initiation can be quantitated and the relative growth of lesions from the initiated cell population can be determined with some degree of accuracy (Pitot et al., 1987).

RELATION (EXTRAPOLATION) OF BIOASSAY DATA TO HUMAN RISK

Campbell (1980) suggested the thesis that the risk (R) of some agent or event can be estimated as a function of the product of the probability (P) of the event and the severity of the harmfulness of the event or agent (H):

$$R = P \times H$$

From the simplest viewpoint, the risk taker may accept harm of greater severity (high value of H) only if the probability of occurrence (P) is very low. Conversely, events that are only modestly harmful (low value of H) may be acceptable at higher levels of frequency or probability. From this argument, safety may be taken as a measure of acceptability of some degree of risk.

Table 8-34, taken from the work of Oser (1978) and Upton (1980), lists the risk of death classified in relation to specific activities. From this table, all of the activities listed exhibit some degree of risk or probability (P) of death or harm (H). The important point to note is that the probability of risk per million persons per year ranges from 0.1 for lightning striking to 20,000 in the case of motorcycling. A careful person presumably compares the risks of any event to his or her health with the benefits that will potentially accrue before making a decision. Relatively few people may actually do this, and even when they do, precisely what index is chosen as the indicator of relative safety is a function of the value judgment of each individual.

Table 8-34 Risk of Death, by Type of Activity

As to the risk of cancer, the harm (H) is considered by most laypersons to be extremely great. In view of this concern by the public, the U.S. government through its regulatory agencies, such as the Environmental Protection Agency (EPA), the Food and Drug Administration (FDA), and others, has assumed a major role in practical considerations of human risk from environmental agents. Two theorems are the basis for the estimations of human risk from carcinogenic agents in the environment.

1. A threshold (no-effect) level for a carcinogenic agent cannot be determined with any degree of accuracy.
2. All carcinogenic agents produce their effects in an irreversible manner, so that the actions of small amounts of carcinogenic agents in our environment are additive—producing a "carcinogenic burden" for the average individual during his or her lifetime.

These bases may be considered as default assumptions that are utilized if there is not sufficient evidence to alter these assumptions. Recent guidelines by the EPA have indicated that at least one regulatory agency is beginning to consider and even include in their final disposition of the regulation of a chemical data that may alter these default assumptions (Page et al., 1997). Since we have already noted the presence of thresholds of promoting agents as well as their reversibility, such data may become useful in consideration of regulation of chemicals in the future. However, the gold standard chronic 2-year bioassay that is utilized as the mainstay in regulation of both industrial and pharmaceutical chemicals does not distinguish between initiating, promoting, and progressor agents; it will require substantial additional studies to give cause to alter the default assumptions. As noted above, scientific risk estimation should be carried out with the full knowledge of the action of the carcinogenic agent as a complete carcinogen, or as having a major action at one or more of the stages of carcinogenesis.

The extrapolation of bioassay data to human risk estimation is one of the most difficult problems that has faced society and will face us for years to come as numerous new chemicals enter the environment. In attempting to predict the behavior of a chemical in the human from data obtained from bioassays, a number of factors should be considered in extrapolation of bioassay data to human risk (Kraybill, 1978). These include:

- Reproducibility of experimental data
- Tumor incidence in experimental animals on a dose–dependent basis
- Relative approximation of experimental dose to that of human exposure
- Acceptable design and statistical evaluation of bioassay
- Consensus on interpretation of histopathologic changes
- Availability of biochemical, metabolic, and pharmacokinetic data to be considered in final decision making

Not included in these factors proposed more than two decades ago is a knowledge of the action of the agent as an initiating, promoting, or progressor agent. Unfortunately, not all of these factors are taken into account when regulatory decisions are made at the governmental level concerning specific compounds in our

environment. Newer requirements for more extensive studies of compounds that would satisfy these factors are a goal to be achieved but as yet not attained.

Another consideration in determination of human risk is whether or not the estimation is qualitative or quantitative. Qualitative risk estimation is much easier to develop based on qualitative analyses of the variety of bioassay procedures utilized. IARC as well as regulatory agencies throughout the world take very seriously the qualitative finding of induction of neoplasia in one or two species of animals as a qualitative indication of risk of carcinogenicity to the human. However, quantitative risk analysis is much more difficult. In fact, a number of epidemiologists have refused to make such quantitative relationships on the basis of animal data and would only use data in the human to carry out such estimates. Still, as we have seen from the utilization of various "safe" doses of carcinogenic agents and a variety of other factors, quantitative risk assessment has been and is being applied to human risk situations of specific chemicals and mixtures. Paramount in such considerations are the use of mathematical models in which, making a variety of assumptions, one may develop quantitative risk estimates for the human. We will consider some of these models below.

STATISTICAL ESTIMATES OF HUMAN RISK FROM BIOASSAY DATA BY USING MATHEMATICAL MODELS

The statistical analyses of whole-animal bioassay data have employed over the years a number of mathematical models in an attempt to relate experimental data to the human situation, especially for the purposes of quantitating human risk inso far as is possible. As Gaylor and Shapiro (1979) have pointed out, "There is no choice but to extrapolate." This means, in essence, that because of the insensitivity of epidemiologic studies and the number and quantity of actual and potential carcinogens in our environment, one must make every attempt possible to relate data from bioassay studies to the human condition, especially the potential risk to the public. Most of these mathematical models have as a basic tenet the assumption that carcinogenic agents lack a threshold, act irreversibly, and have effects that are additive. Equations for some of the more commonly used models are given in Table 8-35. None of these models can prove or disprove the existence of a threshold of response, and none can be completely verified on the basis of biological argument; however, the models have been useful in data evaluation and are presently being used by some federal agencies in extrapolating experimental data to the human risk situation. One of the most commonly used techniques is the log-probit model. In the earlier use of this model, the procedure was to regard every agent as carcinogenic. On this assumption, one must determine some "safe" dosage level at which the risk calculated would not exceed some very small level such as 1 in 100 million or 10^{-8}.

Table 8-35 Mathematical Models Used in the Extrapolation of the Risk of Carcinogenic Agents to the Human

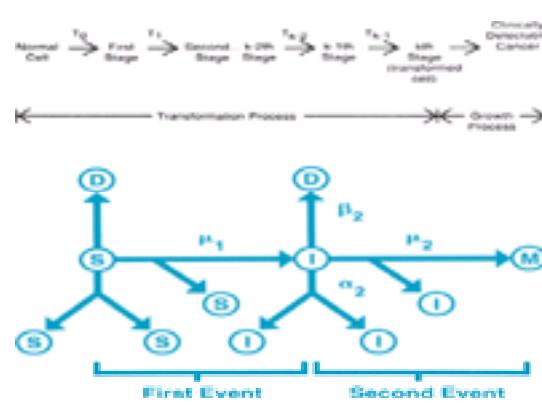
The linear multistage model, first proposed by Armitage and Doll (1954), incorporates the idea of multiple steps into a statistical approach for risk analysis. This multistage model (Fig. 8-35) incorporates one aspect of the pathogenesis of neoplastic development, that of multiple stages, but cell cycle–dependent processes, the dynamics of cell kinetics, birth rate, and death rate are not considered. Furthermore, the transition from one stage to the next is considered irreversible. Despite these deficiencies, the linearized multistage model is one of the most commonly utilized models at the present time. At a low dose the multistage model is used to fit the observed tumor incidence data to a polynomial of the dose as noted in Table 8-35. The linear multistage model is not appropriate for estimating low-dose carcinogenic potency for many chemicals. In most cases, the dose response of high doses of testing differs substantially from the considerably lower doses for exposure. Pharmacokinetic and pharmacodynamic models provide information that can help bridge the gap between the high dose and low dose scenarios (Anderson, 1989). A second problem is associated with extrapolation of lifetime exposure of animals to the MTD of a compound to the less than lifetime exposure common for humans. This problem has been addressed by the EPA through the use of the Weibull model (Hanes and Wedel, 1985), which assumes that risk is greater when encountered at a younger age, and, once exposure occurs, risk continues to accrue despite the cessation of exposure. However, observations in humans and experimental animals have demonstrated that in many cases risk decreases after exposure ceases, as would be true if the agent were a promoting agent.


Figure 8-35. The Armitage and Doll (upper) and MKV (lower) models of multistage carcinogenesis.

In the former, the number of stages is unspecified (T_k), and the transition between them is irreversible. In the MKV model, the fates of stem cells (S) and intermediate (I) cells are death (D) or proliferation. Rarely, I cells undergo (M_2 to malignancy (M). The rates of replication (a_2) and apoptosis (b_2) for I cells are indicated, and similar rates for S cells are implied. μ_1 and μ_2 are the rates of the first genetic event (initiation) and the second genetic event (progression). [Adapted from Pitot and Dragan (1996), with permission of publishers.]

More recently, biomathematical modeling of cancer risk assessment has been used in an attempt to relate such models more closely to the biological characteristics of the pathogenesis of neoplasia. The best known of these biologically based models is that described originally by Moolgavkar, Venzon, and Knudson, termed the MVK model (Moolgavkar, 1986). This model, which is depicted in Fig. 8-35, reproduces quite well the multistage characteristics of neoplastic development with μ_1, the rate at which normal cells are converted to "intermediate" cells (initiated cells), and μ_2, the rate at which intermediate cells are converted to neoplastic (N) cells. These rates model the rates of initiation and progression in multistage carcinogenesis, while the stage of promotion represents the expansion of the intermediate cell population, which is a function of a_2, the rate of division of "intermediate cells," and b_2, the rate of differentiation and/or death of intermediate cells. Other factors in the model that are also true in biology are the rate of replication and cell death of normal or stem cells. While this model originally was developed to explain certain epidemiologic characteristics of breast cancer incidence and mortality in humans (Moolgavkar, 1986), it has found potential application in a variety of multistage models including that of rat liver (Luebeck et al., 1991). Application of the model to risk assessment problems has not found wide use, but this may change in the next few years (Anderson et al., 1992). In addition, integration of biological data, including pharmacokinetic and pharmacodynamic parameters, should aid in the development of a more biologically based risk assessment model.

REGULATION OF CARCINOGENIC RISK AT THE FEDERAL LEVEL

At least four federal agencies have as their primary responsibility the regulation of risk. These agencies include the Consumer Products Safety Commission (CPSC),

the EPA, the FDA, and the Occupational Safety and Health Administration (OSHA). At least two types of regulations affect risk analysis; these include regulations similar to the Clean Water Act, which imposes technology-based standards that are dictated by the best available technology, and the Clean Air Act, which imposes health- or risk-based standards to protect human health by providing an ample margin of safety. A number of laws have been passed that control exposure to carcinogens in food, drugs, and the environment (Table 8-36). Perhaps the most controversial is the Food, Drug, and Cosmetic Act of 1938, including the 1958 amendment known as the Delaney amendment. The Delaney amendment was passed to curtail any possible use of additives in food and drugs that had been demonstrated to induce cancer in humans or animals. This law ignores the presence of endogenous or endogenously produced compounds that have carcinogenic action. For example, nitrites are effective bacteriocidal agents when used at low levels as food additives, but nitrites are produced extensively in vivo during normal metabolism of nitrogenous compounds, especially when nitrates are present in the diet (Rogers, 1982). High doses of nitrites given with secondary amines result in the formation of nitrosamines, which are carcinogenic in rodents (Rogers, 1982). Thus, a number of difficulties are encountered when food and additives are regulated with strict adherence to the Delaney amendment.

Table 8-36 Selected Federal Laws for Regulation of Toxic and Carcinogenic Agents

Besides science, a major driving force in legislative actions concerning the regulation of carcinogenic or potentially carcinogenic chemicals in the environment is the benefit obtained from such regulation. The saccharin-cyclamate debates were an interesting example of this (Kraybill, 1976). Saccharin is carcinogenic at a very high dose in rat uroepithelium (Anderson et al., 1988). After considerable debate, the U.S. Congress passed a law permitting the use of this "carcinogenic" compound as an artificial sweetener because of its low cost and benefit to a variety of individuals, especially diabetics. Recently, the courts rejected the use of two food colorings in drugs and cosmetics on the basis of an interpretation of the Delaney amendment as prohibitive of the use of additives even when only minimal risk can be demonstrated. The EPA faces a difficult situation in the regulation of pesticides when it attempts to balance the requirement of the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA), which requires a balance of risk and benefit in the application of pesticides to raw agricultural products, and the zero tolerance for carcinogens in processed foodstuffs mandated by the Delaney amendment. OSHA is responsible for regulating workers' exposure to potential toxins, including carcinogens. The statutes require that feasibility be considered in concert with lack of effect on workers' health. In the case of *Industrial Union Department v American Petroleum Institute,* the Supreme Court found that the allowable levels of a compound (i.e., benzene) could be established only if a significant risk from exposure could be demonstrated and that this risk could be lessened by a change in practice. In the final analysis, a significant proportion of risk to the average citizen is based on the perception of risk.

International Aspects of Environmental Regulation

Other countries have both preceded and followed legal actions in the United States in regulating noxious and carcinogenic agents that can and do occur in the human environment. The United Kingdom passed a Clean Air Act some three decades ago, well before such legislation appeared in the United States (cf. Hall, 1976). This same nation passed legislation regulating pollution in natural waters within the country at about the same time as similar legislation was enacted in the United States. The European Common Market has also advanced several programs in the area of environmental pollution, especially as related to air and water environments. More generally, they have established an environmental program that concerns itself with the impact of factors involving alterations in the environment, waste disposal, and educational programs (cf. Johnson, 1976). Other countries throughout the world have recognized the importance of controlling potentially damaging agents and have acted accordingly.

RISK-BENEFIT CONSIDERATIONS IN THE REGULATION OF ACTUAL AND POTENTIAL CARCINOGENIC ENVIRONMENTAL HAZARDS

We have briefly reviewed the methods for determining the actual and potential carcinogenic agents in our environment, methods for the estimation of risk to the human population of such agents, and the governmental approach to the regulation of such agents in our environment. An equally important consideration includes somewhat undefined concepts such as benefit-risk analysis, cost-effectiveness, and risk-cost analysis in the regulation of hazardous agents in our environment. These concepts are concerned with such traditional regulatory terms as "safe," "lowest feasible," and "best practicable technology."

Some of the regulatory legislation leaves no latitude for considerations of benefit versus risk. This is the case with the Delaney amendment, a simplistic legal statement that can create major problems when the regulatory agencies are faced with obeying the law. Problems also arose with respect to nitrite, since the benefits of removing nitrites as preservatives in packaged meats were balanced against the risk of bacterial contamination, especially by *Clostridium botulinum,* in nonpreserved packaged products. Federal regulatory agencies decided that these data were insufficient to ban nitrites under the Delaney clause, and thus nitrite continues to be widely used as a preservative, although at lower levels.

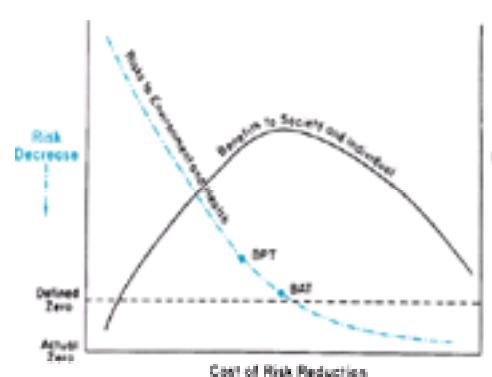
Attempts have been made to quantitate and characterize risks versus benefits. One way is to consider risks to the environment and to health as opposed to risks to society and to general aspects of health. It is evident that reduction in risk from direct exposure to an environmental factor will, at some level of additional cost of control, create new risks to society in terms of increased costs of products, availability of services, personal freedoms, employment, and so on. This relation is shown in Fig. 8-36. In controlling risks to the environment and to health there is a point beyond which the benefits to society and the individual begin to decrease because of the cost, both financial and otherwise, incurred in reducing risk toward actual zero. As was implied previously, there are very rare instances in which actual zero risk is obtained in any circumstance. The points for best practicable technology (BPT) and for best available technology (BAT) are seen on the risk curve. Clearly BPT in risk reduction is less costly than BAT.


Figure 8-36. Risk-cost-benefit relation emphasizing the impact of cost control on all risks and demonstrating the loss of benefit beyond a certain cost of risk reduction.

BPT, best practicable technology; BAT, best available technology. [Modified from Blair and Hoerger (1979), with permission.]

More extensive risk-benefit analyses have been published, such as those of Moll and Tihansky (1977), in which dollar values have been estimated for each life that could potentially be saved by eliminating a specific agent from the environment. They also point out that the risks of specific agents in industrial situations may be far greater than those to society as a whole. An example is asbestos, which, though clearly hazardous to some industrial workers, causes little or no hazard at the levels of exposure of the population in general. In this respect, Samuels (1979) has pointed to the potential fallacy in many benefit-risk determinations unless one takes into consideration the concept of *necessary risk,* especially as related to occupational and industrial hazards. This concept stresses the importance of making every effort to eliminate hazardous agents in our environment that are important to society by replacing them with equally useful but less hazardous or nonhazardous components. If this cannot be done and a necessary risk is present, this consideration must be balanced against the benefits.

GENETIC TOXICOLOGY

R. Julian Preston and George R. Hoffmann

WHAT IS GENETIC TOXICOLOGY?

Genetic toxicology is a branch of the field of toxicology that assesses the effects of chemical and physical agents on the hereditary material (DNA) and on the genetic processes of living cells. Such effects can be assessed directly by measuring the interaction of agents with DNA or more indirectly through the assessment of DNA repair or the production of gene mutations or chromosome alterations. Given the risk assessment framework of this chapter, it is important at the outset to distinguish between genotoxicity and mutagenicity. Genotoxicity covers a broader spectrum of endpoints than mutagenicity. For example, unscheduled DNA synthesis, sister chromatid exchanges, and DNA strand breaks are measures of genotoxicity, not mutagenicity, because they are not themselves transmissible events from cell to cell or generation to generation.

This chapter discusses the history of the development of the field of genetic toxicology, the use of genetic toxicologic data in cancer and genetic risk assessment, the mechanisms underlying genetic toxicology assays, the assays that can be used for detecting genotoxic endpoints, the use of the same assays for better understanding mechanisms of mutagenesis, and new methods for the assessment of genetic alterations. The field is evolving rapidly, and the present snapshot will set the stage for considering this evolution.

HISTORY OF GENETIC TOXICOLOGY

The field of genetic toxicology can be considered to have its roots in the pioneering work of H.J. Muller (1927), who showed that x-rays could induce phenotypically described mutations in the fruit fly, *Drosophila*. In his studies he showed not only that radiation exposures could increase the overall frequencies of mutations but also that the types of mutations induced were exactly the same in effect, or phenotype, as those observed in the absence of radiation exposure. Thus, the induced mutagenic responses must be assessed in relation to background mutations. As a conclusion to this study of radiation-induced mutations, Muller predicted the utility of mutagenesis for gene mapping and for parallel mutagenic responses in germ cells.

Karl Sax (1938) built upon Muller's original studies of radiation-induced mutagenicity by showing that x-rays could also induce structural alterations to chromosomes in *Tradescantia* pollen grains. Sax and his colleagues, notably in the absence of a knowledge of DNA structure and chromosomal organization, showed that at least two critical lesions in a nuclear target are required for the production of an exchange within (intrachromosome) or between (interchromosome) chromosomes. We know now that the lesions identified by Sax are DNA double-strand breaks (dsb), base damages (bd), or multiply damaged sites (mds) (reviewed by Ward, 1988). In addition, Sax and colleagues (Sax, 1939; Sax and Luippold, 1952) showed that the yield of chromosome aberrations was reduced if the total dose of x-rays was delivered over extended periods of time or split into two fractions separated by several hours. These observations led to the concept of restitution of radiation-induced damage, which was later recognized as involving specific DNA repair processes (see below).

Consideration of the genetic effects of exogenous agents on cells was expanded to include chemicals in 1946, when Charlotte Auerbach and colleagues reported that nitrogen mustards could induce mutations in *Drosophila* and that these mutations were phenotypically similar to those induced by x-rays (Auerbach and Robson, 1946). Thus, the field of chemical mutagenesis was initiated to run in parallel with studies of radiation mutagenesis. These original studies of Auerbach (actually conducted in 1941) are placed in a historical and biological perspective by the delightful review of Geoffrey Beale (1993).

While the scientific value of the analysis of mutations in *Drosophila* was clear, there was an impression that the practical application to human populations was too wide a step. Thus, a research effort of great magnitude was initiated to attempt to assess radiation-induced mutations in mice. This effort resulted in the publication by William Russell (1951) of data on x-ray–induced mutations using a mouse specific-locus mutation assay. These data clearly showed that the type of results obtained with *Drosophila* could be replicated in a mammalian system. The mouse tester strain developed for the specific-locus assay has recessive mutations at seven loci coding for visible mutations, such as coat color, eye color, and ear shape. This homozygous recessive tester strain can be used for identifying recessive mutations induced in wild-type genes at the same loci in other mice. It was noteworthy that the mutation rate for x-ray-induced mutations in germ cells was similar in mouse and *Drosophila.* Subsequent studies by Lee Russell (Russell et al., 1981) showed that chemicals could induce mutations at the same seven loci.

Over the next 20 years, genetic toxicologists investigated the induction of mutations and chromosomal alterations in somatic and germ cells largely following exposures to radiations. The ability to grow cells in vitro, either as primary cultures or as transformed cell lines, enhanced these quantitative studies. The in vitro culture of human lymphocytes, stimulated to reenter the cell cycle by phytohemagglutinin, greatly expanded the information on the assessment of chromosomal alterations in human cells [an excellent review by Hsu (1979) is recommended]. It also became feasible to use cytogenetic alterations in human lymphocytes as a biodosimeter for assessing human exposures to ionizing radiations (Bender and Gooch, 1962).

Two events during the 1970s served to expand the utility of mutagenicity data into the realm of risk assessment. The Millers and their colleagues (Miller and Miller, 1977) showed that chemical carcinogens could react to form stable, covalent derivatives with DNA, RNA, and proteins both in vitro and in vivo. In addition, they reported that these derivatives could require the metabolism of the parent chemical to form reactive metabolites. This metabolism is required for some chemicals to become carcinogens. Metabolic capability is endogenous in vivo, but most cell lines in vitro have lost this capacity. To overcome this for in vitro mutagenicity studies, Heinrich Malling and colleagues developed an exogenous metabolizing system based upon a rodent liver homogenate (S9) (Malling and Frantz, 1973). While this

exogenous metabolism system has had utility, it does have drawbacks related to species and tissue specificity. The development of transgenic cell lines containing inducible P450 genes has overcome this drawback to some extent (Crespi and Miller, 1999).

The second development in the 1970s that changed the field of genetic toxicology was the development by Bruce Ames and colleagues (Ames et al., 1975) of a simple, inexpensive mutation assay with the bacterium *Salmonella typhimurium*. This assay can be used to detect chemically induced reverse mutations at the histidine loci and can incorporate the exogenous metabolizing S9 system described above. The Ames assay, as it is generally called, has been expanded and modified to enhance its specificity as discussed below (under "Gene Mutations in Prokaryotes"). The assay has been used extensively, especially for hazard identification, as part of the cancer risk-assessment process. This use was based on the assumption that carcinogens were mutagens, given that cancer required mutation induction. This latter dogma proved to be somewhat inhibitory, in some ways, to the field of genetic toxicology because it provided a framework that was too rigid. Nonetheless, over the decade of the mid-1970s to mid-1980s somewhere on the order of 200 short-term assays were developed for screening potentially carcinogenic chemicals. The screens included mutagenicity, DNA damage, DNA repair, and cell killing or other genotoxic activities. Several international collaborative studies were organized to establish the sensitivity and specificity of a select group of assays as well as to assess interlaboratory variation (IPCS, 1988). In summary, most assays were able to detect carcinogens or noncarcinogens with an efficiency of about 70 percent as compared with the outcome of cancer bioassays. There are a number of possible reasons for the imperfect correspondence, the most likely being that there is a group of chemical carcinogens that do not induce cancer by a direct mutagenic action. The latter point was addressed to some extent by Tennant et al. (1987), who compared the effectiveness of a small standard battery of well-characterized short-term assays to identify carcinogens. Again, this battery predicted about 70 percent of known carcinogens. Subsequently, the lack of a tight correlation between carcinogenicity and mutagenicity (and the converse, noncarcinogenicity and nonmutagenicity) was found to be due to the fact that some chemicals were not directly mutagenic but instead induced the damage necessary for tumor development indirectly by, for example, clonally expanding preexisting mutant cells (i.e., tumor promotion). This class of chemicals has been given the rather unfortunate name of *nongenotoxic* to contrast them with genotoxic ones; the classification as *not directly mutagenic* is more appropriate. In the past 10 years or so, emphasis has been placed on identifying mechanisms whereby non-directly mutagenic chemicals can be involved in tumor production. Those identified include cytotoxicity with regenerative cell proliferation, mitogenicity, receptor-mediated processes, changes in methylation status, and alterations in cell–cell communication.

In the past 10 years or so, the field of genetic toxicology has moved away from the short-term assay approach for assessing carcinogenicity to a much more mechanistic approach, fueled to quite an extent by the advances in molecular biology. The ability to manipulate and characterize DNA, RNA, and proteins and to understand basic cellular processes and how they can be perturbed has advanced enormously over this period. Knowing how to take advantage of these technical developments is paramount. This chapter addresses current genetic toxicology: the assays for qualitative and quantitative assessment of cellular changes induced by chemical and physical agents, the underlying molecular mechanisms for these changes, and how such information can be incorporated in cancer and genetic risk assessments. In addition, the way forward for the field is addressed in the form of an epilogue. Thus, the preceding historical overview sets the stage for the rest of the chapter.

HEALTH IMPACT OF GENETIC ALTERATIONS

The importance of mutations and chromosomal alterations for human health is evident from their roles in genetic disorders and cancer. Therefore, mutations in both germ cells and somatic cells must be considered here.

Somatic Cells

An association between mutation and cancer has long been evident on indirect grounds, such as a correlation between the mutagenicity and carcinogenicity of chemicals, especially in biological systems that have the requisite metabolic activation capabilities. Moreover, human chromosome instability syndromes and DNA repair deficiencies are associated with increased cancer risk (Friedberg, 1985). Cancer cytogenetics has greatly strengthened the association in that specific chromosomal alterations, including deletions, translocations, and inversions, have been implicated in many human leukemias and lymphomas as well as in some solid tumors (Rabbitts, 1994).

Critical evidence that mutation plays a central role in cancer has come from molecular studies of oncogenes and tumor suppressor genes. Oncogenes are genes that stimulate the transformation of normal cells into cancer cells (Bishop, 1991). They originate when genes called proto-oncogenes, involved in normal cellular growth and development, are genetically altered. Normal regulation of cellular proliferation requires a balance between factors that promote growth and those that restrict it. Mutational alteration of proto-oncogenes can lead to overexpression of their growth-stimulating activity, whereas mutations that inactivate tumor suppressor genes, which normally restrain cellular proliferation, free cells from their inhibitory influence (Hanahan and Weinberg, 2000).

The action of oncogenes is genetically dominant in that a single active oncogene is expressed even though its normal allele is present in the same cell. Proto-oncogenes can be converted into active oncogenes by point mutations or chromosomal alterations. Base-pair substitutions in *ras* proto-oncogenes are found in many human tumors (Bishop, 1991; Barrett, 1993). Among chromosomal alterations that activate proto-oncogenes, translocations are especially prevalent (Rabbitts, 1994). For example, Burkitt's lymphoma involves a translocation between the long arm of chromosome 8, which is the site of the *c-MYC* oncogene, and chromosome 14 (about 90 percent of cases), 22, or 2. A translocation can activate a proto-oncogene by moving it to a new chromosomal location, typically the site of a T-cell receptor or immunoglobulin gene, where its expression is enhanced. This mechanism applies to Burkitt's lymphoma and various other hematopoietic cancers. Alternatively, the translocation may join two genes, resulting in a protein fusion that contributes to cancer development. Fusions have been implicated in other hematopoietic cancers and some solid tumors (Rabbitts, 1994). Like translocations, other chromosomal alterations can activate proto-oncogenes, and genetic amplification of oncogenes can magnify their expression (Bishop, 1991).

Mutational inactivation or deletion of tumor suppressor genes has been implicated in many cancers. Unlike oncogenes, the cancer-causing alleles that arise from tumor suppressor genes are typically recessive in that they are not expressed when they are heterozygous (Evans and Prosser, 1992). However, several genetic mechanisms, including mutation, deletion, chromosome loss, and mitotic recombination, can inactivate or eliminate the normal dominant allele, leading to the expression of the recessive cancer gene in a formerly heterozygous cell (Cavenee et al., 1983). The inactivation of tumor suppressor genes has been associated with various cancers, including those of the eye, kidney, colon, brain, breast, lung, and bladder (Fearon and Vogelstein, 1990; Marshall, 1991). Gene mutations in a tumor suppressor gene on, chromosome 17 called *P53* occur in many different human cancers, and molecular characterization of *P53* mutations has linked specific human cancers to mutagen exposures (Harris, 1993; Aguilar et al., 1994).

In the simplest model for the action of tumor suppressor genes, two events are required for the development of the cancer, because both normal alleles must be inactivated or lost (Knudson, 1997). In sporadic forms of the cancer (i.e., no family history), the two genetic events occur independently, but in familial forms (e.g., familial retinoblastoma), the first mutation is inherited, leaving the need for only a single additional event for expression. The strong predisposition to cancer in the inherited disease stems from the high likelihood that a loss of heterozygosity will occur by mutation, recombination, or aneuploidy in at least one or a few cells in the development of the affected organ. The simple model involving two events and a single pair of alleles cannot explain all observations concerning tumor suppressor genes, because many cancers involve more than one tumor suppressor gene. For example, the childhood kidney tumor called Wilms' tumor can be caused by damage in at least three different genes (Marshall, 1991), and colorectal carcinomas are often found to have lost not only the wild-type *P53* tumor suppressor gene but also other tumor suppressor genes (Fearon and Vogelstein, 1990; Stoler et al., 1999). Moreover, a single mutation in a tumor suppressor gene, even though not fully expressed, may contribute to carcinogenesis. For example, a single *P53* mutation in a developing colorectal tumor may confer a growth advantage that contributes to the development of the disease (Venkatachalam et al., 1998). Subsequent loss of heterozygosity will increase the growth advantage as the tumor progresses from benign to malignant (Fearon and Vogelstein, 1990).

Many cancers involve both activation of oncogenes and inactivation of tumor suppressor genes (Bishop, 1991; Fearon and Vogelstein, 1990). The observation of multiple genetic changes supports the view that cancer results from an accumulation of genetic alterations and that carcinogenesis is a multistep process (Stoler et al., 1999; Kinzler et al., 1996; Hahn et al., 1999). At least three stages can be recognized in carcinogenesis: initiation, promotion, and progression (Barrett, 1993). *Initiation* involves the induction of a genetic alteration, such as the mutational activation of a *ras* proto-oncogene by a mutagen. It is an irreversible step that starts the process toward cancer. *Promotion* involves cellular proliferation in an initiated cell population. Promotion can lead to the development of benign tumors such as papillomas. Agents called promoters stimulate this process. Promoters may be mutagenic but are not necessarily so. *Progression* involves the continuation of cell proliferation and the accumulation of additional irreversible genetic changes; it is marked by increasing genetic instability and malignancy. More recent studies are beginning to change this view, leading to the concept of acquired capabilities (Hanahan and Weinberg, 2000).

Gene mutations, chromosome aberrations, and aneuploidy are all implicated in the development of cancer. Mutagens and clastogens contribute to carcinogenesis as initiators. Their role does not have to be restricted to initiation, however, in that mutagens, clastogens, and aneugens may contribute to the multiple genetic alterations that characterize progression or development of acquired capabilities. Other agents that contribute to carcinogenesis, such as promoters, need not be mutagens.

However, the role of mutations is critical, and analyzing mutations and mutagenic effects is essential for understanding and predicting chemical carcinogenesis.

Germ Cells

The relevance of gene mutations to health is evident from the many disorders that are inherited as simple Mendelian characteristics (Mohrenweiser, 1991). About 1.3 percent of newborns suffer from autosomal dominant (1 percent), autosomal recessive (0.25 percent), or sex-linked (0.05 percent) genetic diseases (National Research Council, 1990; Sankaranarayanan, 1998). Molecular analysis of the mutations responsible for Mendelian diseases has revealed that almost half these mutations are base-pair substitutions; of the remainder, most are small deletions (Sankaranarayanan, 1998).

Many genetic disorders (e.g., cystic fibrosis, phenylketonuria, Tay-Sachs disease) are caused by the expression of recessive mutations. These mutations are mainly inherited from previous generations and are expressed when an individual inherits the mutant gene from both parents. New mutations make a larger contribution to the incidence of dominant diseases than to that of recessive diseases because only a single dominant mutation is required for expression. Thus, new dominant mutations are expressed in the first generation. If a dominant disorder is severe, its transmission between generations is unlikely because of reduced fitness. For dominants with a mild effect, reduced penetrance, or a late age of onset, however, the contribution from previous generations is apt to be greater than that from new mutations. Estimating the proportion of all Mendelian genetic disease that can be ascribed to new mutations is not straightforward; a rough estimate is 20 percent (Wyrobek, 1993; Shelby, 1994).

Besides causing diseases that exhibit Mendelian inheritance, gene mutations undoubtedly contribute to human disease through the genetic component of disorders with a complex etiology. Some 3 percent (National Research Council, 1990) or 5 to 6 percent (Sankaranarayanan, 1998) of infants are affected by congenital abnormalities; if one includes multifactorial disorders that often have a late onset, such as heart disease, hypertension, and diabetes, the proportion of the population affected increases to more than 60 percent (National Research Council, 1990; Sankaranarayanan, 1998). Such frequencies are necessarily approximate because of differences among surveys in the reporting and classification of disorders. A higher prevalence would be found if less severe disorders were included in the tabulation. Nevertheless, such estimates provide a sense of the large impact of genetic disease.

Refined cytogenetic methods have led to the discovery of minor variations in chromosome structure that have no apparent effect. Nevertheless, other chromosome aberrations cause fetal death or serious abnormalities. Aneuploidy (gain or loss of one or more chromosomes) also contributes to fetal deaths and causes disorders such as Down's syndrome. About 4 infants per 1000 have syndromes associated with chromosomal abnormalities, including translocations and aneuploidy. The majority of these syndromes (about 85 percent) result from trisomies (National Research Council, 1990). Much of the effect of chromosomal abnormalities occurs prenatally. It has been estimated that 5 percent of all recognized pregnancies involve chromosomal abnormalities, as do about 6 percent of infant deaths and 30 percent of all spontaneous embryonic and fetal deaths (Mohrenweiser, 1991). Among the abnormalities, aneuploidy is the most common, followed by polyploidy. Structural aberrations constitute about 5 percent of the total. Unlike gene mutations, many of which are inherited from the previous generation, about 85 percent of the chromosomal anomalies detected in newborns arise de novo in the germ cells of the parents (Mohrenweiser, 1991). The frequency of aneuploidy assessed directly in human sperm initially by standard karyotyping and more recently by fluorescence in situ hybridization (FISH) is 3 to 4 percent; about 0.4 percent are sex chromosome aneuploidies (Martin et al., 1991; Martin et al., 1996). The frequency of aneuploidy in human oocytes is about 18 percent (Martin et al., 1991).

CANCER AND GENETIC RISK ASSESSMENTS

Cancer Risk Assessment

The formalized process for conducting a cancer risk assessment has many variations based upon national requirements and regulations. A summary of some of the different approaches can be found in Moolenaar (1994). There are ongoing attempts, for example, by the International Program on Chemical Safety (IPCS), to develop a harmonized approach to cancer (and genetic) risk assessments. However, no unified approach is currently available. Thus, for the purpose of this chapter, the formalized approach developed by the U.S. Environmental Protection Agency (EPA) based upon the paradigm presented by the National Research Council (National Research Council, 1983) is described here for depicting the use of genetic toxicology in the risk assessment process.

Genetic toxicology data have been used until recently solely for hazard identification. Namely, if a chemical is directly mutagenic, then tumors are produced by this chemical via direct mutagenicity. This has led, in turn, to the use of the default linear extrapolation from the rodent bioassay tumor data to exposure levels consistent with human environmental or occupational exposures (EPA, 1986). The assessment of risk requires the application of a series of default options—for example, from laboratory animals to humans, from large to small exposures, from intermittent to chronic lifetime exposures, and from route to route of exposure. Default options are "generic approaches, based on general scientific knowledge and policy judgement that are applied to various elements of the risk assessment process when specific scientific information is not available" (National Research Council, 1994). The default options have been in some ways the Achilles' heel of the cancer risk-assessment process, since they have a very significant impact on low exposure risk but are based on an uncertain data base. This concern led the EPA (1996) to develop a very different approach, described in the *Proposed Guidelines for Carcinogen Risk Assessment*. In these proposed guidelines, the emphasis is on using mechanistic data, when available, to inform the risk assessment process, particularly for dose–response assessment. The goal is to develop biologically based dose–response models for estimating cancer risk at low environmental exposures. This does, in general, bring the EPA approach into some harmony with those in other countries (Moolenaar, 1994), where a more narrative approach to risk assessment is preferred to a strictly quantitative one. The outcome of a more mechanistically based cancer risk-assessment process is that there is a greater impetus to developing a database for mechanisms in addition to the yes/no interpretation of genotoxicity assays. The same group of genotoxicity assays can be used for the collection of both types of information. The advent of molecular biology techniques has certainly aided in the pursuit of mechanisms of mutagenicity and carcinogenicity. It is anticipated that the cancer risk-assessment process will evolve as new types of data are obtained.

In this regard, some of the issues that remain to be more firmly elucidated are (1) the relative sensitivities of different species (particularly rodent and human) to the induction of organ-specific mutations and tumors by chemicals and radiation; (2) the shape of the dose response for genetic alterations and tumors at low (environmental) exposure levels, especially for genotoxic chemicals; and (3) the relative sensitivity of susceptible subpopulations of all types. A better understanding of these major issues will greatly reduce the uncertainty in cancer risk assessments by, in part, replacing default options with biological data.

Genetic Risk Assessment

The approach for conducting a genetic risk assessment is less well defined than that for cancer risk. In fact, only a handful of genetic risk assessments have been conducted. An in-depth discussion of the topic can be found in the book *Methods for Genetic Risk Assessment* (Brusick, 1994). The reader is also referred to the genetic risk for ethylene oxide developed by the EPA (Rhomberg et al., 1990) and the discussion of this and a recalculation presented by Preston et al. (1995). These two articles serve to highlight the difficulties with and uncertainties in genetic risk assessments.

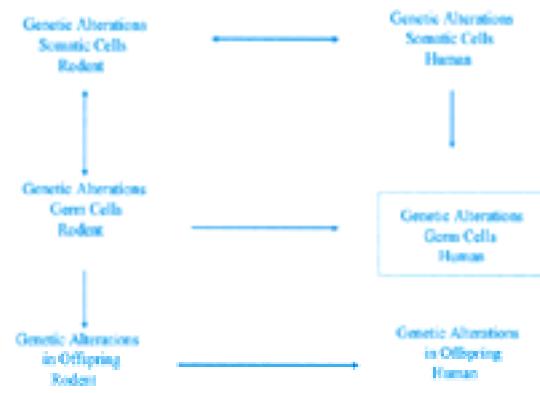
The general approach is to use rodent germ cell and somatic cell data for induced genetic alterations and human data for induced genetic alterations in somatic cells (when available) to estimate the frequency of genetic alterations in human germ cells. This is the "parallelogram approach" (Fig. 9-1) first used by Brewen and Preston (1974) for x-irradiation and subsequently more fully developed for chemical exposures by Sobels (1982). The aim of this approach is to develop two sensitivity factors: (1) somatic to germ cell in the rodent and (2) rodent to human using somatic cells. These factors can then be used to estimate genetic alterations in human germ cells. Of course, for a complete estimate of genetic risk, it is necessary to obtain an estimate of the frequency of genetic alterations transmitted to the offspring. In addition, separate genetic risk assessments need to be conducted for males and females, given the considerable difference in germ cell development and observed and predicted sensitivity differences.


Figure 9-1. Parallelogram approach for genetic risk assessment.

Data obtained for genetic alterations in rodent somatic and germ cells and human somatic cells are used to estimate the frequency of the same genetic alterations in human germ cells. The final step is to estimate the frequency of these genetic alterations that are transmitted to offspring.

MECHANISMS OF INDUCTION OF GENETIC ALTERATIONS

DNA Damage

The types of DNA damage produced by ionizing radiations, nonionizing radiations, and chemicals are many and varied, ranging from single- and double-strand breaks in the DNA backbone to cross-links between DNA bases and between DNA bases and proteins and chemical addition to the DNA bases (adducts) (Fig. 9-2). The aim of this section is to introduce the topic of DNA damage because such damage is the substrate for the formation of genetic alterations and genotoxicity in general. However, much greater detail can be found in recent reviews that are referenced at the appropriate places.

Figure 9-2. Spectrum of DNA damage induced by physical and chemical agents.

Ionizing Radiations Ionizing radiations such as x-rays, gamma rays, and alpha particles produce DNA single- and double-strand breaks and a broad range of base damages (Ward, 1994; Wallace, 1994; Goodhead, 1994). The relative proportions of these different classes of DNA damage vary with type of radiation. For example, single-strand breaks and base damages predominate with x-rays, for which ionization density is sparse, whereas the frequencies of single- and double-strand breaks are more similar with alpha particles, for which ionization density is dense. The frequencies of individual base damages have been assessed using monoclonal antibodies, for example (Le et al., 1998), but only a very few of the total spectrum have so far been studied.

Ultraviolet Light Ultraviolet light (a nonionizing radiation) induces two predominant lesions, cyclobutane pyrimidine dimers and 6,4-photoproducts. These lesions have been studied extensively because they can both be quantitated by chemical and immunological methods (Friedberg et al., 1995).

In part because of this feature, the repair of cyclobutane dimers and 6,4-photoproducts has been extremely well characterized, as discussed below.

Chemicals Chemicals can produce base alterations either directly as adducts or indirectly by intercalation of a chemical between the base pairs (e.g., 9-aminoacridine) (see Heflich, 1991, for a review). Many electrophilic chemicals react with DNA, forming covalent addition products (adducts). The DNA base involved and the positions on DNA bases can be specific for a given chemical. Such specificity of DNA damage can result in a spectrum of mutations that is chemical specific, i.e., a fingerprint of sorts (Dogliotti et al., 1998). Some alkylated bases can mispair, causing mutations when DNA is replicated. Alkylated bases can also lead to secondary alterations in DNA. For example, the alkyl group of an N7-alkylguanine adduct, which is a major adduct formed by many alkylating agents, labilizes the bond that connects the base to deoxyribose, thereby stimulating base loss. Base loss from DNA leaves an apurinic or apyrimidinic site, commonly called an AP site. The insertion of incorrect bases into AP sites causes mutations (Laval et al., 1990).

Bulky DNA adducts formed, for example, by metabolites of benzo(a)pyrene or N-2-acetylaminofluorene are recognized by the cell in a similar way to UV damages and are repaired similarly (see below). Such adducts can also hinder polymerases and cause mutation as a consequence of errors that they trigger in replication.

Endogenous Agents Endogenous agents are responsible for several hundred DNA damages per cell per day (Lindahl, 2000). The majority of these damages are altered DNA bases (e.g., 8-oxoguanine and thymine glycol) and AP sites. The cellular processes that can lead to a DNA damage are oxygen consumption that results in the formation of reactive active oxygen species (e.g., superoxide $\acute{Y}0_2$, hydroxyl free radicals $\acute{Y}OH$, and hydrogen peroxide) and deamination of cytosines and S-methylcytosines leading to uracils and thymines, respectively. The process of DNA replication itself is error-prone, and an incorrect base can be added by the polymerase. The frequencies of these endogenously produced DNA damages can be increased by exogenous (genotoxic) agents.

DNA Repair

The cell is faced with the problem of how to cope with the quite extensive DNA damage that it sustains. In a general sense, two processes are present to achieve this. If the damage is extensive, the cell can undergo apoptosis (programmed cell death), effectively releasing it from becoming a mutant cell (Evan and Littlewood, 1998). If the damage is less severe, cells have developed a range of repair processes that are part of a generalized cellular DNA damage response network that returns the DNA to its undamaged state (error-free repair) or to an improved but still altered state (error-prone repair). The basic principles underlying most repair processes are damage recognition, removal of damage (except for strand breaks or cleavage of pyrimidine dimers), repair DNA synthesis, and ligation. In order to achieve this for different types of DNA lesions, cells have modified the protein complexes used for other housekeeping processes (e.g., transcription, replication, and recombination). The present chapter presents a brief outline of the major classes of DNA repair; much greater detail can be found in the reviews provided for each section and a general review by Van Houten and Albertini (1995).

Base Excision Repair The major pathways by which DNA base damages are repaired involve a glycosylase that removes the damaged base, causing the production of an apurinic or apyrimidinic site that can be filled by the appropriate base or processed further (McCullough et al., 1999; Demple and Harrison, 1994; Seeberg et al., 1995; Wood, 1996). The resulting gap from this further processing can be filled by a DNA polymerase, followed by ligation to the parental DNA. The size of the gap is dependent upon the particular polymerase involved in the repair (i.e., polymerase b for short patches; polymerase d or e for longer patches). Oxidative damages, either background or induced, are important substrates for base excision repair (Lindahl, 2000).

Nucleotide Excision Repair The nucleotide excision repair (NER) system provides the cell's ability to remove bulky lesions from DNA. In the past decade, the NER process has been studied extensively, and a complete characterization of the genes and proteins involved has been obtained (Aboussekhra et al., 1995; Sancar, 1995; Lehmann, 1995; Benhamou and Sarasin, 2000). NER uses about 30 proteins to remove a damage-containing oligonucleotide from DNA. The basic steps are damage recognition, incision, excision, repair synthesis, and ligation. The characterization of these steps has been enhanced by the use of rodent mutant cell lines and cells from individuals with the UV-sensitivity, skin cancer–prone syndrome xeroderma pigmentosum (XP, for which there are at least seven distinct genetic complementation groups). Of particular interest is the link between NER and transcription, for which the DNA damage in actively transcribing genes, and specifically the transcribed strand, is preferentially and thus more rapidly repaired than the DNA damage in the rest of the genome (Lomnel et al., 1995). Thus, the cell protects the integrity of the transcription process. This link between transcription and repair appears to be provided by two factors: (1) when a bulky lesion is located on the transcribed strand of an active gene, RNA polymerase II is blocked, thus providing a signal for recruiting the NER complex, and (2) a major component of the NER complex is the TFII H basal transcription factor. The involvement of TFII H in repair also provides some specificity to the incisions in the DNA required to remove the damaged nucleotide. An incision on the 3' side of the damage is made first by the XPG protein followed by one on the 5' side by the XPF-ERRC1 complex. The lesion is removed in the 27-30 nucleotide segment formed by the two incisions. The gap is filled by polymerase d or e in the presence of replication factor C and proliferating cell nuclear antigen (PCNA). Ligation by DNA ligase I completes the process. This NER process has been reconstituted in vitro, allowing for complete characterization, kinetic studies, and estimates of fidelity (Aboussekhra et al., 1995).

Double-Strand Break Repair Cell survival is seriously compromised by the presence of broken chromosomes. Unrepaired double-strand breaks trigger one or more DNA damage response systems to either check cell-cycle progression or induce apoptosis. In order to reduce the probability of persistent DNA double-strand breaks, cells have developed an array of specific repair pathways. These pathways are largely similar across a broad range of species from yeast to humans, although the most frequently used one is different among species. There are two general pathways for repair of DNA double-strand breaks: homologous recombination and nonhomologous end-joining. These two can be considered as being in competition for the double-strand break substrate (Haber, 2000).

Homologous Recombination Eukaryotes undergo homologous recombination as part of their normal activities both in germ cells (meiotic recombination) and somatic cells (mitotic recombination). The repair of double-strand breaks (and single-strand gaps) basically uses the same process and complex of proteins, although some different protein–protein interactions are involved (Shinohara and Ogawa, 1995). In eukaryotes, the process has been characterized most extensively for yeast, but evidence is accumulating that a very similar process occurs in mammalian cells, including human (Johnson et al., 1999). The basic steps in double-strand break repair are as follows. The initial step is the production of a 3'-ended single-stranded tail by exonucleases or helicase activity. Through a process of strand invasion, whereby the single-stranded tail invades an undamaged homologous DNA molecule, together with DNA synthesis, a so-called Holliday junction DNA complex is formed. By cleavage of this junction, two DNA molecules are produced (with or without a structural crossover), neither of which now contain a strand break. Additional models have been proposed but probably play a minor role in mammalian cells (Haber, 2000). A detailed description of the specific enzymes known to be involved can be found in Shinohara and Ogawa (1995).

Nonhomologous End-Joining (NHEJ) The characterization of NHEJ in mammalian cells was greatly enhanced by the observation that mammalian cell lines that are hypersensitive to ionizing radiation are also defective in the V(D)J recombination process, which is the means by which the huge range of an antibody's antigen-binding sites and T-cell receptor proteins are generated during mammalian lymphoid cell development. V(D)J recombination requires the production of double-strand breaks, recombination of DNA pieces, and subsequent religation. A major component of the NHEJ repair complex is a DNA-dependent protein kinase (DNA-PK). This protein, a serine/threonine kinase, consists of a catalytic subunit (DNA-PK $_{cs}$) and a DNA-end-binding protein consisting of KU70 and KU80 subunits. The specific role of DNA-PK in the repair of double-strand breaks is unclear in mammalian cells; a detailed discussion of what is known and some possible models of NHEJ is presented in the review by Critchlow and Jackson (1998). Perhaps the most viable role of DNA-PK is to align the broken DNA ends to facilitate their ligation. In addition, DNA-PK might serve as a signal molecule for recruiting other repair proteins known to be involved in yeast and to some extent in mammalian cells. The final ligation step is performed by DNA ligase IV in human cells.

Mismatch Repair The study of DNA mismatch repair systems has received considerable attention over the past few years, in part because an association has been demonstrated between genetic defects in mismatch repair genes and the genomic instability associated with cancer susceptibility syndromes and sporadic cancers. In general, DNA mismatch repair systems operate to repair mismatched bases formed during DNA replication, genetic recombination, and as a result of DNA damage induced by chemical and physical agents. Detailed reviews can be found in Kolodner (1995), Jiricny (1998), and Modrich and Lahue (1996).

The principal steps in all cells from prokaryotes to human are damage recognition by a specific protein that binds to the mismatch, stabilizing of the binding by the addition of one or more proteins, cutting the DNA at a distance from the mismatch, excision past the mismatch, resynthesis, and ligation. In some prokaryotes, the cutting of the DNA (for DNA replication mismatches) is directed to the strand that contains the incorrect base by using the fact that recently replicated DNA is unmethylated at *N*6-methyladenine at a GATC sequence. The question of whether or not strand-specific mismatch repair occurs in mammalian cells has not been resolved, although some evidence does point to its occurrence (Modrich, 1997). Strand-specificity for DNA mismatches resulting from induced DNA damage has not been identified.

0^6-**Methylguanine-DNA Methyltransferase Repair** The main role for 0^6-methylguanine-DNA methyltransferase (MGMT) is to protect cells against the toxic effects of simple alkylating agents. The methyl group is transferred from 0^6-methylguanine in DNA to a cysteine residue in MGMT. The adducted base is reverted to a normal one by the enzyme, which is itself inactivated by the reaction. Details of the MGMT enzyme properties and the gene isolation and characterization can be found in Tano et al. (1990) and Grombacher et al. (1996).

The probability that induced DNA damage can be converted into a genetic alteration is influenced by the particular repair pathway(s) recruited, the rate of repair of the damage and the fidelity and completeness of the repair. The mechanisms of induction of gene mutations and chromosome alterations discussed in the following sections build upon the assessment of probability of repair versus misrepair versus nonrepair that can be derived from a knowledge of the mechanism of action of the different DNA repair mechanisms. The preceding sections, together with the references provided, should assist in this assessment.

Formation of Gene Mutations

Somatic Cells Gene mutations are considered to be small DNA-sequence changes confined to a single gene; larger genomic changes are considered below, under "Formation of Chromosomal Alterations." The classes of gene mutations are broadly based substitutions and small additions or deletions. More detailed classifications can be found in the review by Ripley (1991). Base substitutions are the replacement of the correct nucleotide by an incorrect one; they can be further subdivided as transitions where the change is purine for purine or pyrimidine for pyrimidine; and transversions where the change is purine for pyrimidine and vice versa. Frameshift mutations are strictly the addition or deletion of one or a few base pairs (not in multiples of three) in protein coding regions. The definition is more generally extended to include such additions and deletions in any DNA region. For the discussion of the mechanism of induction of gene mutations and chromosomal alterations, it is necessary to distinguish chemicals by their general mode of action. Chemicals that can produce genetic alterations with similar effectiveness in all stages of the cell cycle are called radiomimetic, since they act like radiation in this regard. Chemicals that produce genetic alterations far more effectively in the S phase are described as nonradiomimetic. The great majority of chemicals are nonradiomimetic; the radiomimetic group includes bleomycin, streptonigrin, neocarzinostatin and 8-ethyoxycaffeine.

Gene mutations can arise in the absence of specific exogenous exposures to radiations and chemicals. The great majority of so-called spontaneous (background) mutations arise from *replication* of an altered template. These DNA alterations are either the result of oxidative damage or are produced from the deamination of 5-methyl cytosine to thymine at CpG sites resulting in G:C®A:T transitions. Mutations induced by ionizing radiations tend to be deletions ranging in size from a few bases to multilocus events (Thacker, 1992). The rapid rate of repair of the majority of radiation-induced DNA damages greatly reduces the probability of DNA lesions being present at the time of DNA replication. Thus, mutations induced by ionizing radiations are generally the result of errors of *DNA repair* (Preston, 1992). The low frequency of gene mutations are produced from any unrepaired DNA base damage present during DNA replication.

Gene mutations produced by a majority of chemicals and nonionizing radiations are base substitutions, frameshifts and small deletions. Of these mutations, a very high proportion are produced by errors of DNA *replication* on a damaged template. Thus, the probability of a DNA adduct, for example, being converted into a mutation is determined by the amount of induced DNA adducts that remain in the DNA at the time that it is replicated. Thus, relative mutation frequency will be the outcome of the race between repair and replication, i.e., the more repair that takes place prior to replication the lower the mutation frequency for a given amount of induced DNA damage. Significant regulators of the race are cell cycle checkpoint genes (e.g., *P53*) since, if the cell is checked from entering the S phase at a G $_1$/S checkpoint, then more repair can take place prior to the cell starting to replicate its DNA (Mercer, 1998).

The proportion of chemically-induced gene mutations that result from DNA repair errors is low, given that the DNA repair processes involved are error-free, and that, as a generalization, repair of chemically-induced DNA damage is slower than for ionizing radiation damage, leading to the balance tipping towards replication prior to repair, especially for cells in the S phase at the time of exposure.

Germ Cells The mechanism of production of gene mutations in germ cells is basically the same as in somatic cells. Ionizing radiations produce mainly deletions via errors of DNA repair; the majority of chemicals induce base substitutions, frameshifts and small deletions by errors of DNA replication (Favor, 1999).

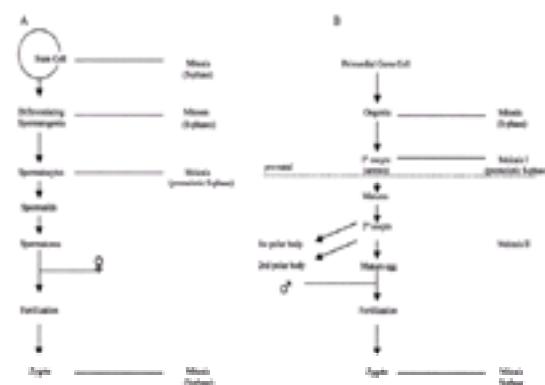
An important consideration for assessing gene mutations induced by chemicals in germ cells is the relationship between exposure and the timing of DNA replication. Figure 9-3 depicts the stages in oogenesis and spermatogenesis when DNA replicates. A few features are worthy of note. The spermatogonial stem cell in humans and rodents has a long cell cycle time, 8 days or longer, with only a small fraction being occupied by the S phase. Thus, the probability of DNA repair taking place prior to DNA replication is high, for both acute and chronic treatments. However, for considerations of genetic risk, it is the spermatogonial stem cell that is the major contributor since it is present, in general, throughout the reproductive lifetime of an individual. Each time a spermatogonial stem cell divides it produces a differentiating spermatogonium and a stem cell. Thus, the stem cell can accumulate genetic damage from chronic exposures. Differentiating spermatogonia, as far as the induction of gene mutation is concerned, are the same as mitotically dividing somatic cells.


Figure 9-3. The stages of spermatogenesis (A) and oogenesis (B) indicating the periods of cell division and DNA replication (S phase).

The next S phase after gametogenesis occurs in the zygote, formed following fertilization. This fact needs to be balanced by the lack of DNA repair in late spermatids and sperm. Thus, DNA damage induced in these stages will remain until the zygote. Post-meiotic germ cells are particularly sensitive to mutation induction by nonradiomimetic chemicals, especially following acute exposures. The fairly short duration of this stage (approximately 21 days in the mouse) means that their contribution to genetic risk following chronic exposures is quite small.

For oogenesis (Fig. 9-3) similar observations on gene mutation induction and timing of S phase can be made. In this case the primary oocyte arrests prior to birth, and there is no further S phase until the zygote. For this reason the oocyte is resistant to the induction of gene mutations by nonradiomimetic chemicals but not to radiation, for which DNA repair is the mode of formation of mutations, and DNA repair occurs in oocytes (Brewen and Preston, 1982).

These mechanistic aspects of the production of gene mutations (and chromosome alterations described in the following two sections) by chemicals and radiations in somatic and germ cells are most important in considerations of the design of genetic toxicology assays, the interpretation of the data generated, and the incorporation of the data into cancer and genetic risk assessments.

Formation of Chromosomal Alterations

Somatic Cells *Structural Chromosome Aberrations* There are components of the formation of chromosome aberrations, sister chromatid exchanges (the apparently reciprocal exchange between the sister chromatids of a single chromosome) and gene mutations that are common. In particular, damaged DNA serves as the substrate leading to all these events. However, chromosome aberrations induced by ionizing radiations are generally formed by errors of DNA repair, whereas those produced by nonradiomimetic chemicals are generally formed by errors of DNA replication on a damaged DNA template.

The DNA repair errors that lead to the formation of chromosome aberrations following ionizing radiation (and radiomimetic chemical) exposure arise from misligation of double-strand breaks or interaction of coincidentally repairing regions during nucleotide excision repair of damaged bases. The details of the DNA damage types and their repair are described above. Thus, the overall kinetics and fidelity of DNA repair influence the sensitivity of cells to the induction of chromosomal aberrations produced by misrepair. The broad outcomes of misrepair are that incorrect rejoining of chromosomal pieces during repair leads to chromosomal exchanges within (e.g., inversions and interstitial deletions) and between (e.g., dicentrics and reciprocal translocations) chromosomes. In fact, using fluorescence in situ hybridization, it can be shown that very complex rearrangements take place (Anderson et al., 2000). Failure to rejoin double-strand breaks or to complete repair of other types of DNA damage leads to terminal deletions.

Acentric fragments arise from interstitial deletions, terminal deletions, and the formation of dicentric chromosomes and rings. The failure to incorporate an acentric fragment into a daughter nucleus at anaphase/telophase, or the failure of a whole chromosome to segregate at anaphase to the cellular poles, can result in the formation of a micronucleus that resides in the cytoplasm.

Errors of DNA replication on a damaged template can lead to a variety of chromosomal alterations. The majority of these involve deletion or exchanges of individual chromatids (chromatid-type aberrations). Thus, nonradiomimetic chemicals induce only chromatid-type aberrations, whereas radiations and radiomimetic chemicals induce chromatid-type aberrations in the S and G_2 phases of the cell cycle, but chromosome-type aberrations affecting both chromatids in G_1. The reason for this latter observation is that the G_1 chromosome behaves as a single DNA molecule and aberrations formed in it will be replicated in the S phase to involve both chromatids. This distinction is important for considerations of outcome of the aberrations and probability of an effect on cells, since for chromatid-type aberrations, one chromatid remains intact and genetically unaltered (Preston et al., 1995).

Numerical Chromosome Changes Numerical changes (e.g., monosomics, trisomics, and ploidy changes) can arise from errors in chromosomal segregation. The complexity of the control and the mechanics of the mitotic process means that alteration of various cellular components can result in failure to segregate the sister chromatids to separate daughter cells or in failure to segregate a chromosome to either pole (Bickel and Orr-Weaver, 1996; Preston, 1996). The mechanisms underlying chromosomal loss are pertinent to those involved in the formation of micronuclei.

A limited set of chemicals has been demonstrated to cause aneuploidy through interaction with components of chromosome movement (Preston, 1996; Aardema et al., 1998). These include benomyl, griseofulvin, nocodazole, colchicine, colecemid, vinblastine, and paclitaxel. These chemicals affect tubulin polymerization or spindle microtubule stability. To date, other mechanisms of aneuploidy induction by chemicals have not been firmly identified.

Sister Chromatid Exchange Sister chromatid exchanges (SCE) are produced during the S phase and are presumed to be a consequence of errors in the replication process, perhaps at the sites of stalled replication complexes (Painter, 1980; Heartlein et al., 1983; Preston, 1991). It is, in fact, this mode of action that makes assays for SCE less than ideal for detecting effects due directly to a chemical exposure. The creation of intracellular conditions that slow the progress of DNA replication, for example, could lead to the formation of SCE.

Germ Cells The formation of chromosomal alterations in germ cells is basically the same as that for somatic cells, namely via misrepair for ionizing radiations and radiomimetic chemicals for treatments in G_1 and G_2, and by errors of replication for all radiations and chemicals for DNA damage present during the S phase. Also, the restrictions on the timing of formation of chromosomal alterations induced by nonradiomimetic chemicals in germ cells is as described above for gene mutations,

namely at the specific stages where DNA synthesis occurs, as depicted in Fig. 9-3.

The types of aberrations formed in germ cells are the same as those formed in somatic cells (e.g., deletions, inversions, translocations), although their appearance in diplotene/diakinesis of meiosis I, where analysis is frequently conducted, is rather different because of the homologous chromosome pairing that takes place in meiotic cells (see the review by Leonard, 1973). The specific segregation of chromosomes during meiosis influences the probability of recovery of an aberration, particularly a reciprocal translocation, in the offspring of a treated parent. This is discussed in detail in Preston et al. (1991).

ASSAYS FOR DETECTING GENETIC ALTERATIONS

Introduction to Assay Design

Genetic toxicology assays are used to identify germ cell mutagens, somatic cell mutagens, and potential carcinogens. They detect diverse kinds of genetic alterations that are relevant for human health, including gene mutations, chromosome aberrations, and aneuploidy. Over the last three decades, hundreds of chemicals have been evaluated for genotoxic effects. Genetic toxicology assays serve two interrelated but distinct purposes in the toxicologic evaluation of chemicals: (1) identifying mutagens for purposes of hazard identification, and (2) characterizing dose –response relationships and mutagenic mechanisms, both of which contribute to an understanding of genetic and carcinogenic risks.

A common experience in surveying the mutagenicity literature is encountering a bewildering array of assays in viruses, bacteria, fungi, cultured mammalian cells, plants, insects, and mammals. More than 200 assays for mutagens have been proposed, and useful information has been obtained from many of them. Fortunately, however, most genetic toxicology testing and evaluation relies on relatively few assays.

Table 9-1 lists key assays that have a prominent place in genetic toxicology and for regulatory considerations. Table 9-2 is a more comprehensive list that provides literature citations to many of the assays that one might encounter in the genetic toxicology literature. Even this extensive table is not exhaustive, in that it emphasizes methods of applied genetic toxicology and not those whose use has been restricted largely to studies of mutational mechanisms. The commonly used assays have relied on phenotypic effects as indicators of gene mutations or small deletions and on cytologic methods for observing gross chromosomal damage. Detailed information on assay design, testing data, controls, sample sizes, and other factors in effective testing is found in the references cited.

Table 9-1 Principal Assays in Genetic Toxicology

Table 9-2 Overview of Genetic Toxicology Assays

Some assays for gene mutations detect forward mutations whereas others detect reversion. Forward mutations are genetic alterations in a wild-type gene and are detected by a change in phenotype caused by the alteration or loss of gene function. In contrast, a back mutation or reversion is a mutation that restores gene function in a mutant and thereby brings about a return to the wild-type phenotype. In principle, forward-mutation assays should respond to a broad spectrum of mutagens because any mutation that interferes with gene expression should confer the detectable phenotype. In contrast, a reversion assay might be expected to have a more restricted mutational response because only mutations that correct or compensate for the specific mutation in a particular mutant will be detected. In fact, some reversion assays respond to a broader spectrum of mutational changes than one might expect because mutations at a site other than that of the original mutation (i.e., a suppressor mutation) can sometimes confer the detected phenotype. Both forward mutation assays and reversion assays are used extensively in genetic toxicology.

The simplest gene mutation assays rely on selection techniques to detect mutations. A selection technique is a means of imposing experimental conditions under which only cells or organisms that have undergone mutation can grow. Selection techniques greatly facilitate the identification of rare cells that have experienced mutation among the many cells that have not. Forward mutations and reversions can both be detected by selection techniques in microorganisms and cultured mammalian cells. Because of their speed, low cost, and ease of detecting events that occur at low frequency (i.e., mutation), assays in microorganisms and cell cultures have figured prominently in genetic toxicology.

Studying mutagenesis in intact animals requires assays of more complex design than the simple selection methods used in microorganisms and cultured cells. Genetic toxicology assays therefore range from inexpensive short-term tests that can be performed in a few days to complicated assays for mutations in mammalian germ cells. Even in complex multicellular organisms, however, there has been an emphasis on designing assays that detect mutations with great efficiency. Nevertheless, there remains a gradation in which an increase in relevance for human risk entails more elaborate and costly tests. The most expensive mammalian tests are typically reserved for agents of special importance in basic research or risk assessment, whereas the simpler assays can be applied more broadly.

Because of their reliance on cytologic rather than genetic methods, cytogenetic assays differ in design from typical gene mutation assays. The goal in cytogenetic assays is to apply methodology that permits the unequivocal visual recognition of cells that have experienced genetic damage. The alterations measured include chromosome aberrations, micronuclei, SCE and changes in chromosome numbers. Cytogenetic assays are listed in Table 9-1 and Table 9-2 and discussed later in this chapter.

In all mutagenicity testing, one must be aware of possible sources of error. Factors to consider in the application of mutagenicity assays are the choice of suitable organisms and growth conditions, appropriate monitoring of genotypes and phenotypes, effective experimental design and treatment conditions, inclusion of proper positive and negative controls, and sound methods of data analysis (Kirkland et al., 1990).

Many compounds that are not themselves mutagenic or carcinogenic can be activated into mutagens and carcinogens by mammalian metabolism. Such compounds

are called promutagens and procarcinogens. Because microorganisms and mammalian cell cultures lack many of the metabolic capabilities of intact mammals, provision must be made for metabolic activation in order to detect promutagens in many genetic assays. The most common means of doing so is to include an in vitro metabolic activation system derived from a mammalian tissue homogenate in the microbial or cell culture assay. For example, the promutagens dimethylnitrosamine and benzo[a]pyrene are not themselves mutagenic in bacteria, but they are mutagenic in bacterial assays if the bacteria are treated with the promutagen in the presence of a homogenate from mammalian liver.

The most widely used metabolic activation system in microbial and cell culture assays is a postmitochondrial supernatant from a rat liver homogenate, along with appropriate buffers and cofactors (Kirkland et al., 1990; Maron and Ames, 1983). The standard liver metabolic activation system is called an S9 mixture, designating a supernatant from centrifugation at 9000 ´ g. Most of the short-term assays in Table 9-2 require exogenous metabolic activation to detect promutagens. Exceptions are those in intact mammals and a few simpler assays, such as the detection of unscheduled DNA synthesis (UDS) in cultured hepatocytes (Madle et al., 1994), that have a high level of endogenous cytochrome P450 metabolism.

Rat liver S9 should be thought of as providing a broad assemblage of metabolic reactions, but not necessarily the same as those of hepatic metabolism in an intact rat. Alternative metabolic activation systems based on homogenates from other species or organs have found some use, but such variations may similarly differ from the species or organs of their origin. Therefore, alternative metabolic activation systems tend to be more useful if chosen for mechanistic reasons rather than simply testing another species or organ. For example, metabolism by intact hepatocytes (Langenbach and Oglesby, 1983) can preserve elements of cellular compartmentalization of reactions altered in tissue homogenation. Likewise, a system that includes a reductive reaction not encompassed by standard S9 is required for detecting the mutagenicity of some azo dyes and nitro compounds (Dellarco and Prival, 1989). Despite their usefulness, in vitro metabolic activation systems, however well refined, cannot mimic mammalian metabolism perfectly. There are differences among tissues in reactions that activate or inactivate foreign compounds, and organisms of the normal flora of the gut can contribute to metabolism in intact mammals. Agents that induce enzyme systems or otherwise alter the physiologic state can also modify the metabolism of toxicants, and the balance between activation and detoxication reactions in vitro may differ from that in vivo.

An interesting development with respect to metabolic activation is the expression of human enzymes in microorganisms or cell cultures. The incorporation of human genes into Salmonella tester strains derived from the Ames assay permits the activation of promutagens (e.g., 2-aminoanthracene or 2-aminofluorene) by human cytochrome P4501A2 without an S9 mixture (Josephy et al., 1995). Mammalian cell lines have also been genetically engineered to express human enzymes of metabolic activation (Sawada and Kamataki, 1998). Many cell lines stably expressing a single form of P450 have been established. Mutagenesis can be measured through such endpoints as *HPRT* mutations and cytogenetic alterations, and the cells are well suited to analyzing the contribution of different enzymes to the activation of promutagens. Cell lines that express various combinations of phase I and phase II enzymes are being developed (Sawada and Kamataki, 1998).

DNA Damage and Repair Assays

Some assays measure DNA damage itself rather than mutational consequences of DNA damage. They may do so directly, through such indicators as chemical adducts or strand breaks in DNA, or indirectly, through measurement of biological repair processes. Adducts in DNA can be detected by ^{32}P-postlabeling, immunologic methods using antibodies against specific adducts, or fluorometric methods in the case of such fluorescent compounds as polynuclear aromatic hydrocarbons and aflatoxin (Chang et al., 1994; Kriek et al., 1998; Phillips et al., 2000). The ^{32}P-postlabeling technique is highly sensitive and applicable to diverse mutagens. The measurement of adducts is useful in human monitoring and molecular dosimetry in that DNA adducts have been quantified after human exposure to various chemicals (Chang et al., 1994; Kriek et al., 1998; Phillips et al., 2000). DNA strand breakage can be measured by alkaline elution and electrophoretic methods (Elia et al., 1994). The applicability of DNA damage assays to rodent testes (Bentley et al., 1994) makes these methods helpful in interpreting risks to germ cells.

A rapid method of measuring DNA damage that has grown in importance over the last decade is the single-cell gel electrophoresis assay, also called the comet assay (Fairbairn et al., 1995; Tice et al., 2000). In this assay cells are incorporated into agarose on slides, lysed so as to liberate their DNA, and subjected to electrophoresis. The DNA is stained with a fluorescent dye for observation and image analysis. Because broken DNA fragments migrate more quickly than larger pieces of DNA, a blur of fragments (a "comet") is observed when the DNA is extensively damaged. The extent of DNA damage can be estimated from the length and other attributes of the comet tail. Variations in the procedure permit the assay's use for the general detection of DNA strand breakage under alkaline conditions (Fairbairn et al., 1995; Tice et al., 2000) or the preferential detection of double-strand breaks under neutral conditions (Fairbairn et al., 1995). Although the comet assay is relatively new and needs further study before its ultimate utility is clear, it appears to be a rapid and sensitive indicator of DNA damage with broad applicability. Though it has most commonly been used with human lymphocytes (Fairbairn et al., 1995) and other mammalian cells (Tice et al., 2000), it can be adapted to diverse species, including plants, worms, mollusks, fish, and amphibians (Cotelle and Férard, 1999). This adaptability suggests that it will find diverse uses in environmental genetic toxicology.

The occurrence of DNA repair can serve as a readily measured indicator of DNA damage. Repair assays have been developed in microorganisms, cultured mammalian cells, and intact mammals (Table 9-2), and some of these assays remain in use. Greater toxicity of a chemical in DNA repair–deficient strains than in their repair-proficient counterparts has served as an indicator of DNA damage in bacteria (e.g., *polA*⁻ and *polA*⁺ in *Escherichia coli*, or *rec*⁻ and *rec*⁺ in *Bacillus subtilis*) (Hamasaki et al., 1992). The induction of bacterial SOS functions, indicated by phage induction or by colorimetry in the SOS chromotest, can similarly serve as a general indicator of genetic damage (Quillardet and Hofnung, 1993). The most common repair assay in mammalian cells is an assay for UDS, which is a measure of excision repair. The occurrence of UDS indicates that the DNA had been damaged (Madle et al., 1994). However, it is to be stressed that the absence of UDS does not denote an absence of DNA damage, because of low sensitivity of the assay and the occurrence of classes of damage that are not actively excised. Though bacterial repair assays have declined in usage over the years, UDS assays continue to be used because of their applicability to cultured hepatocytes with endogenous cytochrome P450 enzyme activities and to tissues of intact animals, including hepatocytes (Madle et al., 1994) and germinal tissue (Bentley et al., 1994).

Gene Mutations in Prokaryotes

The most common means of detecting mutations in microorganisms is selecting for reversion in strains that have a specific nutritional requirement differing from wild-type members of the species; such strains are called auxotrophs. For example, the widely used assay developed by Bruce Ames and his colleagues is based on measuring reversion in a series of histidine auxotrophs in *Salmonella typhimurium*. In the Ames assay one measures the frequency of histidine-independent bacteria that arise in a histidine-requiring strain in the presence or absence of the chemical being tested. Auxotrophic (nutrient deficient) bacteria are treated with the chemical of interest by one of several procedures (e.g., a plate-incorporation assay or a preincubation test) and plated on medium that is deficient in histidine (Kirkland et al., 1990; Maron and Ames, 1983). The assay is conducted using several genetically different strains so that reversion by base-pair substitutions and frameshift mutations in several DNA sequence contexts can be detected and distinguished. Besides the histidine alleles that provide the target for measuring mutagenesis, the Ames tester strains contain other genes and plasmids that enhance the assay. The principal strains of the Ames test and their characteristics are summarized in Table 9-3. Since *S. typhimurium* does not have a capacity for metabolism of promutagens comparable to mammalian tissues, the assay is generally performed in the presence and absence of a rat liver S9 metabolic activation system. Hence, the Ames assay is also commonly called the *Salmonella*/microsome assay.

Table 9-3 The Ames Assay: Tester Strains and Their Characteristics

Though simplicity is a great merit of microbial assays, it can also be deceptive. Even assays that are simple in design and application can be performed incorrectly. For example, in the Ames assay one may see very small colonies in the Petri dishes at highly toxic doses (Kirkland et al., 1990; Maron and Ames, 1983). Counting such colonies as revertants would be an error because they may actually be nonrevertant survivors that grew on the low concentration of histidine in the plates. Were there millions of survivors, the amount of histidine would have been insufficient to allow any of them (except real revertants) to form colonies. This artifact is easily avoided by checking that there is a faint lawn of bacterial growth in the plates; one can also confirm that colonies are revertants by streaking them on medium without histidine to be sure that they grow in its absence. Such pitfalls exist in all mutagenicity tests. Anyone performing mutagenicity tests must, therefore, have detailed familiarity with the laboratory application and literature of the assay and be observant about the responsiveness of the assay.

Though most frequently used as a testing assay, the *Salmonella*/microsome system also provides information on molecular mechanisms of mutagenesis. The primary reversion mechanisms, summarized in Table 9-3, were initially determined by genetic and biochemical means (Maron and Ames, 1983). An ingenious method called allele-specific colony hybridization has greatly facilitated the molecular analysis of revertants in the Ames assay (Koch et al., 1994), and many spontaneous and induced revertants have been cloned or amplified by polymerase chain reaction (PCR) and sequenced (Levine et al., 1994; DeMarini, 2000).

The development of *Salmonella* strains that revert only by a single class of point mutation has made the identification of specific base-pair substitutions more straightforward. These strains (TA7001-TA7006) each revert from *his*⁻ to *his*⁺ by a single kind of mutation (e.g., G:C to T:A), and collectively they permit the specific detection of all six possible base pair substitutions (Gee et al., 1994; Gee et al., 1998). Specific reversion assays are also available in *E. coli*. A versatile system based on reversion of *lacZ* mutations in *E. coli* permits the specific detection of all six possible base-pair substitutions (Cupples and Miller, 1989) and frameshift mutations in which one or two bases have been added or deleted in various sequence contexts (Cupples et al., 1990). The broader understanding of mutational mechanisms that comes from refined genetic assays and molecular analysis of mutations can contribute to the interpretation of mutational hazards.

Though information from the Ames assay has become a standard in genetic toxicology testing, equivalent information can be obtained from other bacterial assays. Like the Ames assay, the WP2 tryptophan reversion assay in *E. coli* (Kirkland et al., 1990; Gatehouse et al., 1994) incorporates genetic features that enhance assay sensitivity, can accommodate S9 metabolic activation, and performs well in many laboratories. Mutations are detected by selecting for reversion from *trp*⁻ to *trp*⁺.

Bacterial forward mutation assays, such as a selection for arabinose resistance in *Salmonella* (Jurado et al., 1994), are also used in research and testing, though less extensively than the reversion assays. A versatile forward mutation assay that has contributed greatly to an understanding of mutagenic mechanisms is the *lacI* system in *E. coli* (Calos and Miller, 1981; Halliday and Glickman, 1991). Mutations in the *lacI* gene, which encodes the repressor of the lactose operon, are easily identified by phenotype, cloned or amplified by the polymerase chain reaction, and sequenced. The *lacI* gene is widely used as a target for mutagenesis in *E. coli* and in transgenic mice, and more than 30,000 *lacI* mutants have been sequenced (Mirsalis et al., 1994).

Gene Mutations in Nonmammalian Eukaryotes

Many early studies of mutagenesis used yeasts, mycelial fungi, plants, and insects as experimental organisms. Though well-characterized genetic systems permit the detection of a diverse array of genetic alterations in these organisms (Table 9-2), assays in nonmammalian eukaryotes have been largely supplanted in genetic toxicology by bacterial and mammalian systems. Exceptions are to be found where the nonmammalian eukaryotes permit the study of genetic endpoints that are not readily analyzed in mammals or where the organism has special attributes that fit a particular application.

The fruit fly, *Drosophila*, has long occupied a prominent place in genetic research. In fact, the first unequivocal evidence of chemical mutagenesis was obtained in Scotland in 1941 when Charlotte Auerbach and J.M. Robson demonstrated that mustard gas is mutagenic in *Drosophila*. *Drosophila* continues to be used in modern mutation research (Potter and Turenchalk, 2000) but its role in genetic toxicology is now more limited. The *Drosophila* assay of greatest historical importance is the sex-linked recessive lethal (SLRL) test. A strength of the SLRL test is that it permits the detection of recessive lethal mutations at 600 to 800 different loci on the X chromosome by screening for the presence or absence of wild-type males in the offspring of specifically designed crosses (Mason et al., 1987). The genetic alterations include gene mutations and small deletions. The spontaneous frequency of SLRLs is about 0.2 percent, and a significant increase over this frequency in the lineages derived from treated males indicates mutagenesis. Though it requires screening large numbers of fruit fly vials, the SLRL test yields information about mutagenesis in germ cells, which is lacking in all microbial and cell culture systems. However, means of exposure, measurement of doses, metabolism, and gametogenesis in *Drosophila* differ from those in mammalian toxicology, therefore potentially limiting their relevance to human genetic risk. *Drosophila* assays are also available for studying the induction of chromosome abnormalities in germ cells, specifically heritable translocations (Mason et al., 1987) and sex-chromosome loss (Osgood and Cyr, 1998).

Genetic and cytogenetic assays in plants (Grant, 1994) also occupy a more restricted niche in modern genetic toxicology than they did years ago. However, plant assays continue to find use in special applications, such as in situ monitoring for mutagens (Lewtas, 1991) and exploration of the metabolism of promutagens by agricultural plants. In in situ monitoring, one looks for evidence of mutagenic effects in organisms that are grown in the environment of interest. Natural populations of organisms can also be examined for evidence of genetic damage. For example, frequencies of chlorophyll mutations in red mangroves have been correlated with concentrations of polycyclic hydrocarbons in the sediments in which they were growing (Klekowski et al., 1994). While studies of natural populations are of obvious interest, they require utmost precaution when characterizing the environments and defining appropriate control populations.

Assays in nonmammalian eukaryotes continue to be important in the study of induced recombination. Recombinagenic effects in yeast have long been used as a general indicator of genetic damage (Zimmermann et al., 1984), and interest in the induction of recombination has increased as recombinational events have been implicated in the etiology of cancer (Sengstag, 1994). The best characterized assays for recombinagens are those that detect mitotic crossing over and mitotic gene conversion in the yeast *Saccharomyces cerevisiae* (Zimmermann, 1992; Howlett and Schiestl, 2000). Hundreds of chemicals have been tested for recombinagenic effects in straightforward yeast assays. In yeast strain D7, for example, mitotic crossing over involving the *ade2* locus is detected on the basis of pink and red colony color, and mitotic gene conversion at the *trp5* locus is detected by selection for growth without tryptophan. Strategies have also been devised to detect recombinagenic effects in mycelial fungi, cultured mammalian cells, plants, and mice (Hoffmann, 1994), and at least 350 chemicals have been evaluated in *Drosophila* somatic cell assays in which recombinagenic effects are detected by examining wings or eyes for regions in which recessive alleles are expressed in heterozygotes (Vogel et al., 1999).

Gene Mutations in Mammals

Gene Mutations in Vitro Mutagenicity assays in cultured mammalian cells have some of the same advantages as microbial assays with respect to speed and cost, and they follow quite similar approaches. The most widely used assays for gene mutations in mammalian cells detect forward mutations that confer resistance to a toxic chemical (DeMarini et al., 1989). For example, mutations in the gene encoding hypoxanthine-guanine phosphoribosyltransferase (HPRT enzyme; *HPRT* gene) confer resistance to the purine analog 6-thioguanine (Walker et al., 1999), and thymidine kinase mutations (TK enzyme; *TK* gene) confer resistance to the pyrimidine analog trifluorothymidine (Moore et al., 2000). *HPRT* and *TK* mutations may therefore be detected in cultured cells by attempting to grow cells in the presence of purine analogs and pyrimidine analogues, respectively. For historical reasons, *HPRT* assays have most commonly been conducted in Chinese hamster or human cells and *TK* assays in mouse lymphoma cells or human cells. Although forward-mutation assays typically respond to diverse mechanisms of mutagenesis, there are exceptions. For example, resistance to ouabain results from a specific alteration in the target gene, and alterations that eliminate the gene function are lethal (DeMarini et al., 1989); therefore, ouabain resistance is not useful for general mutagenicity testing.

Gene Mutations in Vivo In vivo assays involve treating intact animals and analyzing genetic effects in appropriate tissues. The choice of suitable doses, treatment procedures, controls, and sample sizes is critical in the conduct of in vivo tests. Mutations may be detected either in somatic cells or in germ cells. Germ cell mutagenesis is of special interest with respect to risk for future generations and is discussed later in the chapter.

The mouse spot test is a traditional genetic assay for gene mutations in somatic cells (Styles and Penman, 1985). Visible spots of altered phenotype in mice heterozygous for coat color genes indicate mutations in the progenitor cells of the altered regions. The spot test is less used today than other somatic cell assays or than its germ cell counterpart, the mouse specific-locus test. Cells from intact animals that are amenable to positive selection for mutants form the basis for efficient in vivo mutation detection in assays analogous to those used in mammalian cell cultures. Lymphocytes with mutations in the *HPRT* gene are readily detected by selection for resistance to 6-thioguanine. The *HPRT* assay in mice, rats, and monkeys (Walker et al., 1999; Casciano et al., 1999) is of special interest because it permits comparisons to the measurement of *HPRT* mutations in humans, an important assay in human mutational monitoring (Cole and Skopek, 1994; Albertini and Hayes, 1997).

Besides determining whether agents are mutagenic, mutation assays provide information on mechanisms of mutagenesis that contribute to an understanding of mutational hazards. Base substitutions and large deletions, which may be indistinguishable on the basis of phenotype, can be differentiated through the use of probes for the target gene and Southern blotting, in that base substitutions are too subtle to be detectable on the blots, whereas gross structural alterations are visible (Cole and Skopek, 1994; Albertini and Hayes, 1997). Molecular analysis has been used to determine proportions of mutations ascribable to deletions and other structural alterations in several assays, including the specific-locus test for germ cell mutations in mice (Favor, 1999) and the human *HPRT* assay (Cole and Skopek, 1994). Gene mutations have been characterized at the molecular level by DNA sequence analysis both in transgenic rodents (Mirsalis et al., 1994) and in endogenous mammalian genes (Cariello and Skopek, 1993). Many *HPRT* mutations from human cells in vitro and in vivo have been analyzed at the molecular level and classified with respect to base-pair substitutions, frameshifts, small deletions, large deletions, and other alterations (Cole and Skopek, 1994).

Transgenic Assays Transgenic animals are products of DNA technology in which the animal contains foreign DNA sequences that have been added to the genome and are transmitted through the germ line. The foreign DNA is therefore represented in all the somatic cells of the animal. Mutagenicity assays in transgenic animals show promise of combining in vivo metabolic activation and pharmacodynamics with simple microbial detection systems, permitting refined analyses of mutations induced in diverse mammalian tissues (Mirsalis et al., 1994; Heddle et al., 2000).

The transgenic animals that have figured most heavily in genetic toxicology are mice that carry *lac* genes from *E. coli.* The bacterial genes were introduced into mice by injecting a vector carrying the genes into zygotes, described in Mirsalis et al. (1994). The strains are commonly referred to by their commercial names— the "Big Blue Mouse" and "MutaMouse." The former uses *lacI* as a target for mutagenesis, and the latter uses *lacZ.* After mutagenic treatment of the transgenic animals, the *lac* genes are recovered from the animal, packaged in phage l, and transferred to *E. coli* for mutational analysis. Mutant plaques are identified on the basis of phenotype, and mutant frequencies can be calculated for different tissues of the treated animals (Mirsalis et al., 1994). The *cII* locus may be used as a second target gene in both the *lacZ* and *lacI* assays (Swiger et al., 1999). Its use offers technical advantages as a small, easily sequenced target in which independent mutations may be detected readily by positive selection, and it permits interesting comparisons both within and between assays (Swiger et al., 1999). Other transgenic assays are under development and offer the prospect of expanding the versatility of transgenic assays. The *gpt* delta mouse, for example, offers the prospect of detecting large deletions that are induced by many mutagens and clastogens but not readily detected in the *lacI* and *lacZ* transgenic systems (Okada et al., 1999).

Various mutagens, including alkylating agents, nitrosamines, procarbazine, cyclophosphamide, and polycyclic aromatic hydrocarbons have been studied in transgenic mouse assays, and mutant frequencies have been analyzed in such diverse tissues as liver, skin, spleen, kidney, bladder, small intestine, bone marrow, and testis (Morrison and Ashby, 1994). Tissue-specific mutant frequencies can be compared to the distribution of adducts among tissues and to the site-specificity of carcinogenesis (Mirsalis et al., 1994). An important issue that remains to be unequivocally resolved is the extent to which transgenes resemble endogenous genes. Though their mutational responses tend to be comparable (Swiger et al., 1999), some differences have been noted (Burkhart and Malling, 1993; Vijg and van Steeg, 1998), and questions have been raised about the relevance of mutations that might be recovered from dying or dead animal tissues (Burkhart and Malling, 1994). Therefore, transgenic animals offer promising models for the study of chemical mutagenesis, but they must be further characterized before their ultimate place in hazard assessment is clear.

Mammalian Cytogenetic Assays

Chromosome Aberrations Genetic assays as generally conducted (i.e., in the absence of DNA sequencing) are indirect, in that one observes a phenotype and reaches conclusions about genes. In contrast, cytogenetic assays use microscopy for direct observation of the effect of interest. In conventional cytogenetics, metaphase analysis is used to detect chromosomal anomalies, especially unstable chromosome and chromatid aberrations. A key factor in the design of cytogenetic assays is obtaining appropriate cell populations for treatment and analysis (Kirkland et al., 1990; Preston et al., 1981; Ishidate et al., 1988; Galloway et al., 1994). Cells with a stable, well-defined karyotype, short generation time, low chromosome number, and large chromosomes are ideal for cytogenetic analysis. For this reason, Chinese hamster cells have been used widely in cytogenetic testing. Other cells are also suitable, and human cells, especially peripheral lymphocytes, have been used extensively. Cells should be treated during a sensitive period of the cell cycle (typically S), and aberrations should be analyzed at the first mitotic division after treatment so that the sensitivity of the assay is not reduced by unstable aberrations being lost during cell division. Examples of chromosome aberrations are shown in Fig. 9-4.

Figure 9-4. Chromosome aberrations induced by x-rays in Chinese hamster ovary (CHO) cells.

A. A chromatid deletion (➤). *B.* A chromatid exchange called a triradial (➤). *C.* A small interstitial deletion (➤) that resulted from chromosome breakage. *D.* A metaphase with more than one aberration: a centric ring plus an acentric fragment (➤) and a dicentric chromosome plus an acentric fragment (®).

Cytogenetic assays require careful attention to growth conditions, controls, doses, treatment conditions, and time intervals between treatment and the sampling of cells for analysis (Kirkland et al., 1990). Data collection is a critical step in cytogenetic analysis. It is essential that sufficient cells be analyzed because a negative result in a small sample is equivocal. Results should be recorded for specific classes of aberrations, not just as an overall index of aberrations per cell. The need for detailed data is all the more important because of nonuniformity in the classification of aberrations and disagreement on whether small achromatic (i.e., unstained) gaps in chromosomes are true chromosomal aberrations. Gaps should be quantified but not pooled with other aberrations.

In interpreting results on the induction of chromosome aberrations in cell cultures, one must be alert to the possibility of artifacts associated with extreme assay conditions because aberrations induced under such circumstances may not be a reflection of a chemical-specific genotoxicity (Scott et al., 1991; Galloway, 2000). Questionable positive results have been found at highly cytotoxic doses (Galloway, 2000), high osmolality, and pH extremes (Scott et al., 1991). The possibility that metabolic activation systems may be genotoxic also warrants scrutiny (Scott et al., 1991). While excessively high doses may lead to artifactual positive responses, the failure to test to sufficiently high doses also undermines the utility of a test; therefore, testing should be extended to a dose at which some cytotoxicity is observed, such as a reduction in the mitotic index (the proportion of cells in division), or to an arbitrary limit of about 10 mM if the chemical is nontoxic (Kirkland et al., 1990).

In vivo assays for chromosome aberrations involve treating intact animals and later collecting cells for cytogenetic analysis (Kirkland et al., 1990; Preston et al., 1981; Tice et al., 1994). The main advantage of in vivo assays is that they include mammalian metabolism, DNA repair, and pharmacodynamics. The target is a tissue from which large numbers of dividing cells are easily prepared for analysis, so bone marrow from rats, mice, or Chinese hamsters is most commonly used. An exception is the analysis of interphase cells by FISH, described below. Lymphocytes are another suitable target when stimulated to divide with a mitogen such as phytohemagglutinin. In any case, effective testing requires dosages and routes of administration that ensure adequate exposure of the target cells, proper intervals between treatment and collecting cells, and sufficient numbers of animals and cells analyzed (Kirkland et al., 1990).

FISH is a recent development in cytogenetic analysis; in this procedure, a nucleic acid probe is hybridized to complementary sequences in chromosomal DNA. The probe is labeled with a fluorescent dye so that the chromosomal location to which it binds is visible by fluorescence microscopy. Composite probes have been developed from sequences unique to specific human chromosomes, giving a uniform fluorescent label over the entire chromosome. Slides prepared for standard metaphase analysis are suitable for FISH after they have undergone a simple denaturation procedure. The use of whole-chromosome probes is commonly called

"chromosome painting."

Chromosome painting facilitates cytogenetic analysis, because aberrations are easily detected by the number of fluorescent regions in a painted metaphase. For example, if chromosome 4 were painted with a probe while the other chromosomes were counterstained in a different color, one would see only the two homologs of chromosome 4 in the color of the probe in a normal cell. However, if there were a translocation or a dicentric chromosome and fragment involving chromosome 4, one would see three areas of fluorescence—one normal chromosome 4 and the two pieces involved in the chromosome rearrangement. Aberrations are detected only in the painted portion of the genome, but this disadvantage may be offset by painting a few chromosomes simultaneously with probes of different colors (Tucker et al., 1993). FISH reduces the time and technical skill required to detect chromosome aberrations, and it permits the scoring of stable aberrations, such as translocations and insertions, that are not readily detected in traditional metaphase analysis of unbanded chromosomes. Additionally, some chromosome analysis can be conducted using FISH in interphase cells. Though not routinely used in genotoxicity testing, FISH is a valuable research tool for studying clastogens and is having a substantial impact in monitoring human populations for chromosomal damage.

Micronuclei Metaphase analysis is time-consuming and requires considerable skill, so there is interest in the development of simpler cytogenetic assays, of which micronucleus assays have become increasingly important. Micronuclei are chromatin-containing bodies that represent chromosomal fragments or sometimes whole chromosomes that were not incorporated into a daughter nucleus at mitosis. Since micronuclei usually represent acentric chromosomal fragments, they are most commonly used as simple indicators of chromosomal damage. However, the ability to detect micronuclei containing whole chromosomes has led to their use for detecting aneuploidy as well. Micronucleus assays may be conducted in primary cultures of human lymphocytes (Fenech, 1993; Fenech, 1997), mammalian cell lines (Miller et al., 1998; Kirsch-Volders et al., 2000), or in mammals in vivo (Heddle et al., 1991; Hayashi et al., 1994; Hayashi et al., 2000).

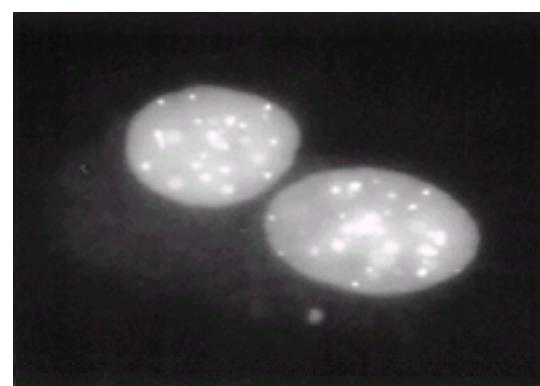
Micronucleus assays in lymphocytes have been greatly improved by the cytokinesis-block technique in which cell division is inhibited with cytochalasin B, resulting in binucleate and multi-nucleate cells (Fenech, 1993; Fenech, 1997; Kirsch-Volders et al., 2000). In the cytokinesis-block assay in human lymphocytes, nondividing (G_0) cells are treated with ionizing radiation or a radiomimetic chemical and then stimulated to divide with the mitogen phytohemagglutinin. Alternatively, the lymphocytes may be exposed to the mitogen first, so that the subsequent mutagenic treatment with radiations, or radiomimetic and nonradiomimetic chemicals, includes the S period of the cell cycle. In either case, cytochalasin B is added for the last part of the culture period, and micronuclei are counted only in binucleate cells so as to ensure that the cells have undergone a single nuclear division that is essential for micronucleus development. The assay thereby avoids confusion owing to differences in cellular proliferation kinetics. Micronuclei in a binucleate human lymphocyte are shown in Fig. 9-5.


Figure 9-5. Micronucleus in a human lymphocyte.

The cytochalasin B method was used to inhibit cytokinesis that resulted in a binucleate nucleus. The micronucleus resulted from failure of an acentric chromosome fragment or a whole chromosome being included in a daughter nucleus following cell division. (Kindly provided by James Allen, Jill Barnes, and Barbara Collins.)

The in vivo micronucleus assay is most often performed by counting micronuclei in immature (polychromatic) erythrocytes in the bone marrow of treated mice, but it may also be based on peripheral blood (Heddle et al., 1991; Hayashi et al., 1994; Hayashi et al., 2000). Micronuclei remain in the cell when the nucleus is extruded in the maturation of erythroblasts. In vivo micronucleus assays are increasingly used in genotoxicity testing as a substitute for bone marrow metaphase chromosome analysis. Micronucleus assays in mammalian tissues other than bone marrow and blood are useful for mechanistic studies and research but are less often applied to genotoxicity testing (Hayashi et al., 2000).

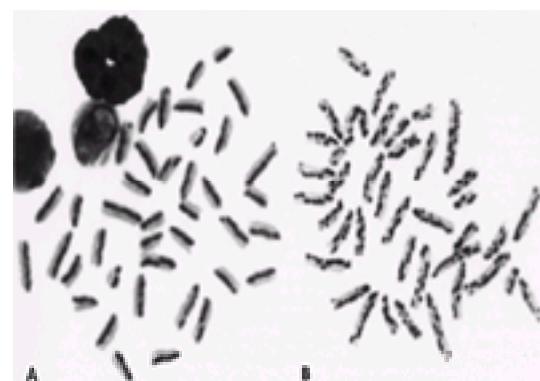
Sister Chromatid Exchange SCE, in which apparently reciprocal segments have been exchanged between the two chromatids of a chromosome, is visible cytologically through differential staining of chromatids. Figure 9-6 shows SCE in human cells. Many mutagens induce SCE in cultured cells and in mammals in vivo (Tucker et al., 1993). Despite the convenience and responsiveness of SCE assays, data on SCE are less informative than data on chromosome aberrations. There is uncertainty about the underlying mechanisms by which SCEs are formed and how DNA damage or perturbations of DNA synthesis stimulate their formation. SCE assays are therefore best regarded as general indicators of mutagen exposure, analogous to DNA damage and repair assays, rather than measures of a mutagenic effect.


Figure 9-6. Sister chromatid exchanges (SCE) in human lymphocytes.

A. SCE in untreated cell. *B.* SCE in cell exposed to ethyl carbamate. The treatment results in a very large increase in the number of SCE. (Kindly provided by James Allen and Barbara Collins.)

Aneuploidy Although assays for aneuploidy are not yet as refined as those for gene mutations and chromosome aberrations, they are being developed (Aardema et al., 1998). Some of the methods are restricted to specific targets, such as the mitotic spindle in an assay for effects on the polymerization of tubulin in vitro (Parry, 1993). Most, however, measure aneuploidy itself and should therefore encompass all relevant cellular targets. Assays include chromosome counting (Aardema et al., 1998), the detection of micronuclei that contain kinetochores (Aardema et al., 1998; Natarajan, 1993), and the observation of abnormal spindles or spindle-chromosome associations in cells in which spindles and chromosomes have been differentially stained (Parry, 1998). Recently, FISH-based assays have been developed for the assessment of aneuploidy in interphase somatic cells (Rupa et al., 1997) and in sperm (Baumgarthner et al., 1999).

A complication in chromosome counting is that a metaphase may lack chromosomes because they were lost during cell preparation for analysis, rather than having been absent from the living cell. To avoid this artifact, cytogeneticists generally use extra chromosomes (i.e., hyperploidy) rather than missing chromosomes (i.e., hypoploidy) as an indicator of aneuploidy in chromosome preparations from mammalian cell cultures (Aardema et al., 1998; Galloway and Ivett, 1986) or mouse bone marrow (Adler, 1993). A promising means of circumventing this difficulty is growing and treating cells on a glass surface and then making chromosome preparations in

situ, rather than dropping cells onto slides from a cell suspension. By counting chromosomes in intact cells, one can collect data for both hyperploidy and hypoploidy (Natarajan, 1993). It has been suggested that counting polyploid cells, which is technically straightforward, may be an efficient way to detect aneugens (Aardema et al., 1998), but there remains some disagreement on the point (Parry, 1998).

Micronucleus assays can detect aneugens as well as clastogens. Micronuclei that contain whole chromosomes are not readily distinguished from those containing chromosome fragments in typically stained preparations, though chromosome-containing ones tend to be somewhat larger (Natarajan, 1993). However, the presence of the spindle attachment region of a chromosome (kinetochore) in a micronucleus can indicate that it contains a whole chromosome. Aneuploidy may therefore be detected by means of antikinetochore antibodies with a fluorescent label or FISH with a probe for centromere-specific DNA (Natarajan, 1993; Lynch and Parry, 1993). Micronuclei containing kinetochores or centromeric DNA may be detected both in cell culture assays (Aardema et al., 1998; Lynch and Parry, 1993) and mouse bone marrow in vivo (Heddle et al., 1991; Adler, 1993). Frequencies of micronuclei ascribable to aneuploidy and to clastogenic effects may therefore be determined concurrently by tabulating micronuclei with and without kinetochores.

Germ Cell Mutagenesis

Gene Mutations Germ cell mutagenesis is of special interest as an indicator of genetic damage that enters the gene pool and is transmitted through generations. Mammalian germ cell assays provide the best basis for assessing risks to human germ cells and therefore hold a central place in genetic toxicology despite their relative complexity and expense. The design of the test must compensate for the fact that mutation occurs at low frequency, and even the simplest animal systems face a problem of there being a sufficiently large sample size. One can easily screen millions of bacteria or cultured cells by selection techniques, but screening large numbers of mice poses practical limitations. Therefore, germ cell studies must offer a straightforward, unequivocal identification of mutants with minimal labor.

The mouse specific-locus test detects recessive mutations that produce easily analyzed, visible phenotypes (coat pigmentation and ear size) conferred by seven genes (Favor, 1999; Russell and Shelby, 1985; Ehling, 1991; Russell and Russell, 1992). Mutants may be classified as having point mutations or chromosomal alterations on the basis of genetic and molecular analysis (Favor, 1999). The assay has been important in assessing genetic risks of ionizing radiation and has been used to study various chemical mutagens. Other gene mutation assays in mouse germ cells detect, for example, recessive mutations that cause electrophoretic changes in proteins (Lewis, 1991) and dominant mutations that cause skeletal abnormalities or cataracts (Ehling, 1991).

Mammalian assays permit the measurement of mutagenesis at different germ cell stages (Favor, 1999). Late stages of spermatogenesis are often found to be sensitive to mutagenesis, but spermatocytes, spermatids, and spermatozoa are transitory. Mutagenesis in stem cell spermatogonia and resting oocytes is of special interest in genetic risk assessment because of the persistence of these stages throughout reproductive life (discussed above, with mechanisms of induction of mutations and chromosome alterations in germ cells). Chemical mutagens show specificity with respect to germ cell stages. For example, ethylnitrosourea and chlorambucil are both potent mutagens in the mouse specific-locus test, but the former induces primarily point mutations in spermatogonia, whereas the latter mostly induces deletions in spermatids (Russell and Russell, 1992). The ratio of deletions to point mutations is not only a function of the nature of the mutagen but depends on germ-cell stage, as some mutagens induce higher proportions of gross alterations in late stages of spermatogenesis than in spermatogonia (Favor, 1999; Lewis, 1991).

Chromosomal Alterations Knowledge of the induction of chromosome aberrations in germ cells is important for assessing risks to future generations. Although metaphase analysis of germ cells is not widely used in mutagenicity testing, it is feasible in rodent spermatogonia, spermatocytes, or oocytes (Kirkland et al., 1990; Tease, 1992). A germ cell micronucleus assay, in which chromosomal damage induced in meiosis is measured by observation of rodent spermatids, has been developed (Hayashi et al., 2000; Lähdetie et al., 1994). Aneuploidy originating in mammalian germ cells may be detected cytologically through chromosome counting for hyperploidy (Aardema et al., 1998; Adler, 1993; Allen et al., 1986) or genetically in the mouse sex-chromosome loss test (Russell and Shelby, 1985; Allen et al., 1986), though these methods are not widely used in toxicological testing.

Besides cytologic observation, indirect evidence for chromosome aberrations is obtained in the mouse heritable translocation assay, which measures reduced fertility in the offspring of treated males (Russell and Shelby, 1985). This presumptive evidence of chromosomal rearrangements can be confirmed through cytogenetic analysis. Data from the mouse heritable translocation test in postmeiotic male germ cells have been used in an attempt to quantify human germ cell risk for ethylene oxide, a mutagen used as a fumigant, sterilizing agent, and reactant in chemical syntheses (Rhomberg et al., 1990; Preston et al., 1995).

Dominant Lethal Mutations The mouse or rat dominant lethal assay (Adler et al., 1994) offers an extensive data base on the induction of genetic damage in mammalian germ cells. In the most commonly used version of the assay, males are treated on an acute or subchronic basis with the agent of interest and then mated with virgin females at appropriate intervals. The females are killed and necropsied during pregnancy so that embryonic mortality may be characterized and quantified. Most dominant lethal mutations, manifested as intrauterine deaths, are thought to arise from chromosomal anomalies.

Development of Testing Strategies

Concern about adverse effects of mutation on human health, principally carcinogenesis and the induction of transmissible damage in germ cells, has provided the impetus to identify environmental mutagens. Priorities must be set for testing, because it is not feasible to conduct multiple tests of all chemicals to which people are exposed. Such factors as production volumes, intended uses, the extent of human exposure, environmental distribution, and effects that may be anticipated on the basis of chemical structure or previous testing must be considered in order to ensure that compounds with the greatest potential for adverse effects receive the most comprehensive study. The most obvious use of genetic toxicology assays is screening chemicals to detect mutagens, but they are also used to obtain information on mutagenic mechanisms and dose responses that contribute to an evaluation of hazards. Besides testing pure chemicals, environmental samples are tested (DeMarini, 1991; DeMarini, 1998) because many mutagens exist in complex mixtures.

The first indication that a chemical is a mutagen often lies in chemical structure. Potential electrophilic sites in a molecule serve as an alert to possible mutagenicity and carcinogenicity, because such sites confer reactivity with nucleophilic sites in DNA (Tennant and Ashby, 1991). Attempts to formalize the structural prediction through automated computer programs have not yet led to an ability to make exact predictions of mutagenicity and carcinogenicity of new chemicals (Parry, 1994; Richard, 1998), but structural alerts in combination with critical interpretation are a valuable adjunct to mutagenicity testing Tennant and Ashby, 1991; Parry, 1994; Ashby and Paton, 1993). Though informative, structural alerts cannot eliminate the need for biological data, and they must be used with cognizance of other factors that can influence the effects of a chemical. Factors that may reduce the likelihood of mutagenicity or carcinogenicity of a structurally alerting compound are steric hindrance of reactive or potentially reactive substituents, metabolism, toxicity, and substituents that enhance the chemical's excretion (Ashby, 1994). Moreover, some agents that lack structural alerts may stimulate mutagenesis indirectly by such mechanisms as the generation of radicals that cause oxidative DNA damage (Clayson et al., 1994).

Assessment of a chemical's genotoxicity requires data from well-characterized genetic assays. Assays are said to be validated when they have been shown to perform reproducibly and reliably with many compounds from diverse chemical classes in several laboratories. To explore test performance, we shall consider the use of mutagenicity assays in attempting to predict whether chemicals are carcinogens. Mutagenicity testing, combined with an evaluation of chemical structure, has been found to identify a large proportion of trans-species, multiple-site carcinogens (Tennant and Ashby, 1991; Gold et al., 1993). In contrast, some carcinogens are not detected as mutagens. Putatively nongenotoxic carcinogens often give responses that are more specific with respect to species, sites, and conditions (Ashby and Paton, 1993; Gold et al., 1993). In predicting carcinogenicity, one should consider both the sensitivity and the specificity of an assay. Sensitivity refers to the proportion of carcinogens that are positive in the assay, whereas specificity is the proportion of noncarcinogens that are negative (Tennant et al., 1987; McGregor et al., 1999). Sensitivity and specificity both contribute to the predictive reliability of an assay. The commonly held view that deficiencies in the sensitivity or specificity of individual assays may be circumvented by using assays in complementary combinations called tiers or batteries has fallen into disfavor because, rather than offsetting each other's strengths and weaknesses, genetic toxicology assays are often consistent with one another (Tennant et al., 1987; Ashby and Tennant, 1991; Kim and Margolin, 1999).

Rather than trying to assemble batteries of complementary assays, it is prudent to emphasize mechanistic considerations in choosing assays. Such an approach makes a sensitive assay for gene mutations (e.g., the Ames assay) and an assay for clastogenic effects in mammals pivotal in the evaluation of genotoxicity, and this is the basis for our highlighting these assays in Table 9-1. The Ames assay has performed reliably with hundreds of compounds in laboratories throughout the world. Other bacterial assays and mammalian cell assays also provide useful information on gene mutations. Beyond gene mutations, one should evaluate damage at the chromosomal level with a mammalian in vitro or in vivo cytogenetic assay. Cytogenetic assays in rodents are especially useful for this purpose because they combine a well-validated genetic assay with mammalian pharmacodynamics and metabolism. The other assays in Table 9-1 offer an extensive data base on chemical mutagenesis (*Drosophila* SLRL), a unique genetic endpoint (i.e., aneuploidy; mitotic recombination), applicability to diverse organisms and tissues (i.e., DNA damage assays, such as the comet assay), or special importance in the assessment of genetic risk (i.e., germ cell assays). The more extensive listing of assays in Table 9-2

provides references that can be helpful in interpreting genetic toxicology data in the scientific literature.

HUMAN POPULATION MONITORING

For cancer risk assessment considerations, the human data utilized most frequently, absent epidemiologic data, are those collected from genotoxicity assessment in human populations. The studies conducted most frequently are for chromosome aberrations, micronuclei, and sister chromatid exchanges (SCE) in peripheral lymphocytes. Cytogenetic alterations have also been assessed in a small number of bone marrow samples. Mutations at the *HPRT* locus have been assessed in peripheral lymphocytes, and glycophorin A variants have been studied in red blood cells.

An important component of any population monitoring study is the selection of the study groups, namely, those individuals who are potentially exposed and the unexposed controls. The size of each study group should be sufficiently large to avoid any confounder having undue influence. Certain characteristics should be matched among exposed and unexposed groups. These include age, sex, smoking status, and general dietary features. Certain characteristics are exclusionary, namely, current or recent medication, radiation exposure, and certain illnesses. It is possible to develop a lengthy list of additional possible confounders of response that would make the selection of suitable study groups very difficult indeed. Study groups of 20 or more individuals can be used as a reasonable substitute for exact matching because confounders will be less influential on chromosome alteration or mutation frequency in larger groups, as mentioned above (discussed in Au et al., 1998). In some instances, it might be informative to compare exposed groups with a historical control, as well as to a concurrent control.

The magnitude of different known confounders varies quite considerably among studies, based in part on the size of the study populations. Some general indication of the magnitude of the effects of age and smoking status on the frequencies of chromosome aberrations and SCE is presented to illustrate the importance of accounting for confounders in the design of a population monitoring study. The comparisons presented are for large studies only. For chromosome aberrations, the frequency of aberrations has been reported in one large study to be about 50 percent higher in smokers (l.5 aberrations per 100 cells in smokers versus 1.0 per 100 cells in the nonsmokers) (Galloway et al., 1986) and in another no difference between smokers and nonsmokers (Bender et al., 1988). The complete data set has been reviewed recently by Au et al. (1998). In general, the frequency of SCE is increased by about one SCE per cell in smokers compared with nonsmokers (Bender et al., 1988; Barale et al., 1998). The study by Barale et al. (1998) also reported a dose response association between SCE frequency and smoking level. The frequency of aberrations, particularly chromosome-type exchanges, has been shown to increase with age of subject. Galloway et al. (1986) reported an increase from 0.8 per 100 cells at about 25 years of age to about 1.5 at 60. Bender et al. (1988) reported an increase with age only for chromosome-type dicentric aberrations, but the increase over a broad age range was small and just statistically significant. Ramsey et al. (1995), using chromosome painting techniques reported that individuals 50 years and older had frequencies of stable aberrations, dicentrics, and acentric fragments that were 10.6-fold, 3.3-fold, and 2.9-fold, respectively, greater than the frequency in cord bloods. Bender et al. (1998) did not find an increase in SCE frequency with the increasing age of the subject. The differences among the results from these large control studies emphasize the difficulty of adequately accounting for confounders (age and smoking presented here) when only a small control group is used, as is frequently the case.

Similar sources of variation have been identified for the monitoring of individuals for *HPRT* mutations. The data are reviewed in detail by Albertini and Hayes (1997). There is less information on sources of variation of glycophorin A variants although quite considerable interindividual variation exists (reviewed in Cole and Skopek, 1994).

For cytogenetic assays (chromosome aberrations, sister chromatid exchanges, and micronuclei) the alterations are produced as a consequence of errors of DNA replication, as discussed in previous sections. From the nature of the alterations, assessed in traditional cytogenetic assays, in which nontransmissible alterations are analyzed, it can be established that these alterations were produced at the first in vitro S phase. Irrespective of the duration of exposure, the frequency of cytogenetic alterations will be proportional to that fraction of the DNA damage that remains at the time of in vitro DNA replication. All the DNA damage induced by potent clastogens that results in chromosome alterations is repaired within a relatively short time after exposure for G_0 human lymphocytes. Thus, for chronic exposures the lymphocyte cytogenetic assay as typically conducted is insensitive.

It is now possible to analyze reciprocal translocations using FISH methods (reviewed in Tucker et al., 1997), and because this aberration type is transmissible from cell generation to generation, its frequency can be representative of an accumulation over time of exposure. The importance of this is that stable chromosome aberrations observed in peripheral lymphocytes exposed in vivo, but assessed following in vitro culture, are produced in vivo in hematopoietic stem cells or other precursor cells of the peripheral lymphocytes pool. To date, population cytogenetic monitoring studies involving the analysis of reciprocal translocations in chemically exposed individuals or radiation-exposed individuals have been conducted quite rarely (Smith et al., 1998; Lucas et al., 1992). To date, the overall sensitivity of the FISH analysis of reciprocal translocations for assessing effects of chronic, low level of exposure to chemical clastogens has not been established. However, a cautionary note is provided by the recent study by Director et al. (1998), who showed that there was no increase in reciprocal translocations assessed by FISH following exposure to cyclophosphamide (0, 32, 64, or 96 ppm) or urethane (0, 5000, 10,000, or 15,000 ppm) for up to 12 weeks. In contrast, recent data from the present author's laboratory (Preston et al., unpublished) have shown that exposure of male mice to ethylene oxide at concentrations of 0, 25, 50, 100, 200 ppm for 6, 12, 24, or 48 weeks resulted in a time and concentration-dependent increase in reciprocal translocations assessed by FISH.

Another factor that certainly affects the utility of population monitoring data on reciprocal translocations using FISH is that the frequency of reciprocal translocations increases significantly with increasing age (Ramsey et al., 1995), but to a lesser extent for nontransmissible aberrations (Bender et al., 1988). Ramsey et al. (1995) provided data on the influence of other confounders on the frequency of reciprocal translocations in human groups. These confounders include smoking, consumption of diet drinks and/or diet sweeteners, exposure to asbestos or coal products, and having a previous major illness. This reemphasizes the point that the selection of study groups and accounting for confounders is essential for a human population cytogenetic monitoring study to be of utility.

Thus, very few of the published studies of cytogenetic population monitoring for individuals have analyzed the appropriate endpoint for detecting the genetic effects of long-term exposure to chemicals. It is quite surprising that positive responses have been reported for increases in unstable, chromatid aberrations because these are nontransmissible, and as noted above are induced at the first in vitro S phase.

The *HPRT* mutation assay can assess the frequency of induced mutations in stem cells or other procursor cells, since a proportion of the mutations are induced as nonlethal events. The transmissible proportion will be greater for agents that do not induce large deletions; this will include the majority of nonradiomimetic chemicals. Induction of mutations in lymphocyte precursor cells will lead to clonal expansion of the mutation in the peripheral pool. However, assessment of the T-cell antigen receptor status of the mutant clones permits a correction for clonal expansion. The population of cells derived from any particular stem cell has a unique antigen receptor status (Albertini and Hayes, 1997). The GPA assay can similarly be used for the assessment of chronic exposures or for estimating exposures at some long time after exposure (Albertini and Hayes, 1997). The predictive value of the assay for adverse health outcome appears to be limited, but it can provide an estimate of exposure.

The potential for cytogenetic endpoints being predictive of relative cancer risk has been addressed in recent reports from the European Study Group on Cytogenetic Biomarkers and Health (Hagmar et al., 1998a; Hagmar et al., 1998b). A study group selected for cytogenetic studies consisted of individuals with reported occupational exposure and unexposed controls. The association between cancer and the frequency of unstable chromosome aberrations in the study groups was not based on exposure status, but rather on the relative frequency of chromosome aberrations, namely, low (1 to 33 percentiles), medium (34 to 66 percentiles), and high (67 to 100 percentiles). In general, the higher the relative frequency of unstable aberrations, the greater the risk of cancer death for all tumors combined. The authors make it clear that there is insufficient information on exposure for it to be used as a predictor of cancer development. In fact, the data indicate that individuals with higher frequencies of chromosome aberrations for whatever reason (genetic or environmental) are *as a group* at greater risk of dying from cancer. This is very different from concluding that exposures to mutagens that result in a higher frequency of chromosome aberrations in peripheral lymphocytes leads to an increased risk of cancer, especially for specific tumor types. The relevance of exposure to mutagenic chemicals in these studies by Hagmar et al. (1998a; 1998b) is uncertain because there was no association between increased SCE frequencies and increased cancer mortality.

This latter concern was addressed by the same group (Bonassi et al., 2000) in a more recent study. The study again showed that there was a significantly increased risk for subjects with a high level of chromosome aberrations compared to those with a low level in both a Nordic and Italian cohort. Of particular relevance to risk assessment, the relationships were not affected by the inclusion of occupational exposure level or smoking. The risk for high versus low levels of chromosome aberrations was similar in individuals heavily exposed to carcinogens and in those who had never, to their knowledge, been exposed to any specific environmental carcinogen. These data highlight the need to use caution when considering the relevance of chromosome aberration data in cancer risk assessment.

NEW APPROACHES FOR GENETIC TOXICOLOGY

In the past 15 years, the field of genetic toxicology has moved into the molecular era. The potential for advances in our understanding of basic cellular processes and how they can be perturbed is enormous. The ability to manipulate and characterize DNA, RNA, and proteins has been at the root of this advance in knowledge. However, the development of sophisticated molecular biology does not in itself imply a corresponding advance in the utility of genetic toxicology and its application to risk assessment. Knowing the types of studies to conduct and knowing how to interpret the data remain as fundamental as always. Measuring finer and finer detail can perhaps complicate the utility of the various mutagenicity assays. There is a need for genetic toxicology to avoid the temptation to use more and more sophisticated techniques to address the same questions and in the end make the same mistakes as have been made previously. How successful we are in designing informative studies perhaps cannot be judged at this time. However, the following examples of recent approaches to obtaining data for enhancing our ability to use noncancer (genotoxicity) data in a mechanistically based cancer (and genetic) risk assessment process provide some encouragement. Several recent developments (e.g., the use of transgenic animals, the comet assay for assessing DNA damages) have already been described in the appropriate assay section above since they are currently in general use.

Advances in Cytogenetics

Until quite recently, the analysis of chromosome alterations relied on conventional chromosome staining with DNA stains such as Giemsa or on the process of chromosome banding. Both approaches require considerable expenditure of time and a rather high level of expertise. However, chromosome banding does allow for the assessment of transmissible aberrations such as reciprocal translocations and inversions with a fairly high degree of accuracy. Knowing the induction frequency of such aberrations is very important, given that they are not lethal to the cell and constitute by far the major class observed in inherited genetic defects and a significant fraction of the alterations observed in tumors. In addition, since stable aberrations are transmissible from parent to daughter cell, they represent effects of chronic exposures. The more readily analyzed but cell lethal, nontransmissible aberrations such as dicentrics and deletions reflect only recent exposures and then only when analyzed at the first division after exposure. (For a more detailed explanation, see Preston, 1998.)

The relative ease with which specific chromosomes, specific genes, and chromosome alterations can be detected has been radically enhanced by the development of FISH (Trask et al., 1993). In principle, the technique relies on amplification of DNA from particular genomic regions such as whole chromosomes or gene regions and the hybridization of these amplified DNAs to metaphase chromosome preparations or interphase nuclei. Regions of hybridization can be determined by the use of fluorescent antibodies that detect modified DNA bases incorporated during amplification or by incorporating fluorescent bases during amplification. The fluorescently labeled, hybridized regions are detected by fluorescence microscopy, and the signal can be increased in strength by computer-enhanced processes. The level of sophistication has increased so much that all 24 different human chromosomes (22 autosomes, X and Y) can be individually detected (Macville et al., 1997), as can all mouse chromosomes (Liyanage et al., 1996). Alterations in tumors can also be detected on a whole-genome basis (Coleman et al., 1997; Veldman et al., 1997).

There is an extensive literature on the use of FISH for karyotyping tumors and in gene mapping but less on its utility for genetic toxicology studies, especially the assessment of stable chromosome aberrations at long periods after exposure or after long-term exposures. Three particular studies do, however, serve to exemplify the use of FISH in genetic toxicology.

Lucas et al. (1992) demonstrated that stable chromosomal aberrations could be detected in individuals decades after exposure to atomic bombs in Japan. How these frequencies relate to frequencies at the time of exposure is not known with any certainty, given the fact that induced frequencies were not measured since appropriate techniques were not available at that time.

A recent study by Tucker et al. (1997) provided some assessment of the utility of FISH for the analysis of radiation-induced, stable chromosome alterations at various times after exposure. The frequency of reciprocal translocations induced by gamma rays in rat peripheral lymphocytes decreased with time after exposure, reaching a plateau of four days that was 55 to 65 percent of the induced frequency and with a dose dependency. This result suggests that reciprocal translocations fall into two classes, stable and unstable (cell-lethal). Additional work is required to clarify this conclusion and to extend the studies to effects of chemicals.

FISH methods have also allowed for an accurate and sensitive assessment of chromosomal alterations present in tumors. The particular advance that makes this assessment feasible is known as comparative genomic hybridization (CGH) (Kallioniemi et al., 1992). CGH results in the ability to identify the role of chromosomal structural and numerical alterations in tumor development. The genomic instability present in all tumor types appears to have a specific genetic basis, as shown elegantly for colon cancer by Vogelstein and colleagues (Cahill et al., 1998). For CGH, tumor and control DNAs are differentially labeled with fluorescence probes and cohybridized to normal metaphase chromosome preparations. The ratio of the fluorescence intensities of hybridized tumor and control DNA indicates regions of normal genomic content as well as those regions that are over- or underrepresented in tumors. The CGH method is being adapted for automated screening approaches using biochips (Solinas-Tolado et al., 1997). Assessing genetic alterations such as specific gene deletions in single metastatic tumor cells is feasible with a slightly different approach (Pack et al., 1997).

The types of FISH approaches described here undoubtedly indicate the direction in which cytogenetic analysis will proceed. The types of data collected will affect our understanding of how tumors develop. Data on the dose-response characteristics for a specific chromosomal alteration as a proximate marker of cancer can enhance the cancer risk assessment process by describing effects of low exposures that are below those for which tumor incidence can be reliably assessed. Cytogenetic data of the types described above can also improve extrapolation from data generated with laboratory animals to humans.

Molecular Analysis of Mutations and Gene Expression

With the advent of molecular biology techniques, the exact basis of a mutation at the level of the DNA sequence can be established. In many cases, the genetic basis of human disease can be determined even though human genes have long DNA sequences and a complex genomic arrangement. Molecular biology techniques have also enabled a distinction to be made between background mutations and those induced by specific agents. The latter observations are addressed by analyzing the mutational spectra in target genes in laboratory animals and in humans (DeMarini, 2000). For reasons of inherent sensitivity of available methods, the genes analyzed for mutations are ones for which mutated forms can be selected. The confounding factor of many normal cells, which far outnumber a few mutant cells in an exposed cellular population, can be removed. Methods to overcome this drawback are currently being developed, and particular methods such as ligation-mediated polymerase chain reaction (PCR) are close to the required sensitivity level (Albertini and Hayes, 1998).

A giant step forward in the ability to detect and characterize mutations at both the DNA and RNA level has been provided by the development of chip technology (Southern, 1996) and array-based assay systems (Woldicka et al., 1997). With hybridization of test DNAs to oligonucleotide arrays, specific genetic alterations or their cellular consequences can be determined rapidly and automatically. Cost remains a limiting factor, but the potential for assessing specific cellular changes following chemical exposure is enormous.

Until recently, alterations in gene expression following specific exposures or for specific genotypes were analyzed gene by gene. Such an approach makes it difficult to assess changes in gene expression that occur in a concerted fashion. Recent advances using cDNA microarray technologies have allowed the measurement of changes in expression of hundreds or even thousands of genes at one time (Harrington et al., 2000). The level of expression at the mRNA level is measured by amount of hybridization of isolated cDNA's to oligonucleotide fragments from known genes or expressed sequence tags (EST) on a specifically laid out grid. Although this technique holds great promise for establishing a cell's response to exposure to chemical or physical agents in the context of normal cellular patterns of gene expression, it remains to be established how to analyze the vast amounts of data that can and are being obtained and what magnitude of change in gene expression constitutes an adverse effect as far as cellular phenotype is concerned. Extrapolating the responses to organs and whole animals represents a challenge still to be addressed.

CONCLUSIONS

The field of genetic toxicology has had an overall life of about seventy years and has undergone several rebirths during this period. Genetic toxicology began as a basic research field with demonstrations that ionizing radiations and chemicals could induce mutations and chromosome alterations in plant, insect, and mammalian cells. The development of a broad range of short-term assays for genetic toxicology served to identify many mutagens and address the relationship between mutagens and cancer-causing agents, or carcinogens. The inevitable failure of the assays to be completely predictive resulted in the identification of nongenotoxic carcinogens. In 1980, genetic toxicology moved toward gaining a better understanding of the mutagenic mechanisms underlying carcinogenicity and heritable effects. With this improved understanding, genetic toxicology studies began to turn away from hazard identification alone and move toward quantitative risk assessment. Major advances in our knowledge of mechanisms of cancer formation have been fueled by truly amazing progress in molecular biology. Genetic toxicology has begun to take advantage of the knowledge that cancer is a genetic disease with multiple steps, many of which require a mutation. The identification of chromosome

alterations involved in tumor formation has been facilitated greatly by the use of FISH. The ability to distinguish between background and induced mutations can in some cases be achieved by mutation analysis at the level of DNA sequence. Key cellular processes related to mutagenesis have been identified, including multiple pathways of DNA repair, cell cycle controls, and the role of checkpoints in ensuring that the cell cycle does not proceed until the DNA and specific cellular structures are checked for fidelity. These observations have enhanced our knowledge of the importance of genotype in susceptibility to cancer. Recent developments in genetic toxicology have greatly improved our understanding of basic cellular processes and alterations that can affect the integrity of the genetic material and its functions. The ability to detect and analyze mutations in mammalian germ cells continues to improve and can contribute to a better appreciation for the long-term consequences of mutagenesis in human populations. Improvements in the qualitative assessment of mutation in somatic cells and germ cells have been paralleled by advances in the ability to assess genetic alterations quantitatively, especially in ways that enhance the cancer and genetic risk assessment process.

DEVELOPMENTAL TOXICOLOGY

John M. Rogers and Robert J. Kavlock

HISTORY

Developmental toxicology encompasses the study of pharmacokinetics, mechanisms, pathogenesis, and outcome following exposure to agents or conditions leading to abnormal development. Manifestations of developmental toxicity include structural malformations, growth retardation, functional impairment, and/or death of the organism. Developmental toxicology so defined is a relatively new science, but teratology, or the study of structural birth defects, as a descriptive science precedes written language. For example, a marble sculpture from southern Turkey, dating back to 6500 B.C., depicts conjoined twins (Warkany, 1983), and Egyptian wall paintings of human conditions such as cleft palate and achondroplasia have been dated as early as 5000 years ago. It is believed that mythologic figures such as the cyclops and sirens took their origin in the birth of severely malformed infants (Thompson, 1930; Warkany, 1977). The Babylonians, Greeks, and Romans believed that abnormal infants were reflections of stellar events and as such were considered to be portents of the future. Indeed, the Latin word *monstrum,* from *monstrare* (to show) or *monere* (to warn), is derived from this perceived ability of malformed infants to foretell the future. In turn, derivation of the word *teratology* is from the Greek word for monster, *teras.*

Hippocrates and Aristotle considered that abnormal development could originate in physical causes such as uterine trauma or pressure, but Aristotle also shared a widespread belief that maternal impressions and emotions could influence the development of the child. He advised pregnant women to gaze at beautiful statuary to increase their child's beauty. Though this theory may sound fanciful, it is present in diverse cultures throughout recorded history; indeed, we now know that maternal stress can be deleterious to the developing conceptus (Chernoff et al., 1989).

Another belief, the hybrid theory, held that interbreeding between humans and animals was a cause of congenital malformations (Ballantyne, 1904). Again, such hybrid creatures abound in mythology, including centaurs, minotaurs, and satyrs. Into the seventeenth century, cohabitation of humans with demons and witches was blamed for the production of birth defects. Birth defects were also viewed to represent God's retribution on the parents of the malformed infant and on society.

In 1649, the French surgeon Ambrois Paré expounded the theory of Aristotle and Hippocrates by writing that birth defects could result from narrowness of the uterus, faulty posture of the pregnant woman, or physical trauma, such as a fall. Amputations were thought to result from amniotic bands, adhesions, or twisting of the umbilical cord. This conjecture has proven to be true. With the blossoming of the biological sciences in the sixteenth and seventeenth centuries, theories of the causation of birth defects with basis in scientific fact began to emerge. In 1651, William Harvey put forth the theory of developmental arrest, which stated that malformations resulted from incomplete development of an organ or structure. One example given by Harvey was harelip in humans, a condition that represents a normal early developmental stage. Much later, the theory of developmental arrest was solidified by the experiments of Stockard (1921) using eggs of the minnow, *Fundulus heteroclitus.* By manipulating the chemical constituents and temperature of the growth medium, he produced malformations in the embryos, the nature of which depended on the stage of the insult. He concluded that developmental arrest explained all malformations except those of hereditary origin (Barrow, 1971).

With the advent of the germplasm theory elucidated by Weissmann in the 1880s and the rediscovery of Mendel's laws in 1900, genetics as the basis for some birth defects was accepted. In 1894, Bateson published his treatise on the study of variations in animals as a tool for understanding evolution, inferring that inheritance of such variations could be a basis for speciation (Bateson, 1894). His study contains detailed descriptions and illustrations of such human birth defects as polydactyly and syndactyly, supernumerary cervical and thoracic ribs, duplicated appendages, and horseshoe (fused) kidneys. In this volume, Bateson coined the term *homeosis* to denote morphologic alterations in which one structure has taken on the likeness of another. Study of such alterations in mutants of the fruit fly *Drosophila* and, more recently, the mouse have served as the basis for much of the recent knowledge of the genetic control of development. *Homeobox genes* are found throughout the animal and plant kingdoms and direct embryonic pattern formation (Graham et al., 1989). Acceptance of a genetic basis of birth defects was furthered with studies of human inborn errors of metabolism in the first decade of the twentieth century.

Modern experimental teratology began in the early nineteenth century with the work of Etienne Geoffrey Saint-Hilaire. Saint-Hilaire produced malformed chick embryos by subjecting eggs to various environmental conditions including physical trauma (jarring, inversion, pricking) and toxic exposures. In the latter part of the nineteenth century, Camille Dareste experimented extensively with chick embryos, producing a wide variety of malformations by administering noxious stimuli, physical trauma, or heat shock at various times after fertilization. He found that timing was more important than the nature of the insult in determining the type of malformation produced. Among the malformations described and beautifully illustrated by Dareste (1877), (1891) were the neural tube defects anencephaly and spina bifida, cyclopia, heart defects, situs inversus, and conjoined twins. Many of the great embryologists of the nineteenth and twentieth centuries, including Loeb, Morgan, Driesch, Wilson, Spemann and Hertwig, performed teratological manipulations using various physical and chemical probes to deduce principles of normal development.

In the early twentieth century, a variety of environmental conditions (temperature, microbial toxins, drugs) were found to perturb development in avian, reptilian, fish, and amphibian species. However, despite the already rich literature of nonmammalian teratologic experiments, mammalian embryos were thought to be resistant to induction of malformations and to be either killed outright or protected by the maternal system from adverse environmental conditions. The first reports of induced birth

defects in mammalian species were published in the 1930s and were the result of experimental maternal nutritional deficiencies. Hale (1935) produced malformations including anophthalmia and cleft palate in offspring of sows fed a diet deficient in vitamin A. Beginning in 1940, Josef Warkany and coworkers began a series of experiments in which they demonstrated that maternal dietary deficiencies and other environmental factors could affect intrauterine development in rats (Warkany and Nelson, 1940; Warkany, 1945; Warkany and Schraffenberger, 1944; Wilson et al., 1953). These experiments were followed by many other studies in which chemical and physical agents—e.g., nitrogen mustard, trypan blue, hormones, antimetabolites, alkylating agents, hypoxia, and x-rays, to name a few—were clearly shown to cause malformations in mammalian species (Warkany, 1965).

The first human epidemic of malformations induced by an environmental agent was reported by Gregg (1941), who linked an epidemic of rubella virus infection in Austria to an elevation in the incidence of eye, heart, and ear defects as well as to mental retardation. Heart and eye defects predominated with infection in the first or second months of pregnancy, whereas hearing and speech defects and mental retardation were most commonly associated with infection in the third month. Later, the risk of congenital anomalies associated with rubella infection in the first four weeks of pregnancy was estimated to be 61 percent; in weeks five to eight, 26 percent; and in weeks nine to twelve, 8 percent (Sever, 1967). It has been estimated that in the United States alone approximately 20,000 children have been impaired as a consequence of prenatal rubella infections (Cooper and Krugman, 1966).

Although embryos of mammals, including humans, were found to be susceptible to common external influences such as nutritional deficiencies and intrauterine infections, the impact of these findings was not great at the time (Wilson, 1973). That changed, however, in 1961, when the association between thalidomide ingestion by pregnant women and the birth of severely malformed infants was established (see "Scope of the Problem," below).

SCOPE OF PROBLEM—THE HUMAN EXPERIENCE

Successful pregnancy outcome in the general population occurs at a surprisingly low frequency. Estimates of adverse outcomes include postimplantation pregnancy loss, 31 percent; major birth defects, 2 to 3 percent at birth and increasing to 6 to 7 percent at 1 year as more manifestations are diagnosed; minor birth defects, 14 percent; low birth weight, 7 percent; infant mortality (prior to 1 year of age), 1.4 percent; and abnormal neurologic function, 16 to 17 percent (Schardein, 1993). Thus, less than half of all human conceptions result in the birth of a completely normal, healthy infant. Reasons for the adverse outcomes are largely unknown. Brent and Beckman (1990) attributed 15 to 25 percent of human birth defects to genetic causes, 4 percent to maternal conditions, 3 percent to maternal infections, 1 to 2 percent to deformations (e.g., mechanical problems such as umbilical cord limb amputations), <1 percent to chemicals and other environmental influences, and 65 percent to unknown etiologies. These estimates are not dramatically different from those suggested by Wilson (1977). Regardless of the etiology, the sum total represents a significant health burden in light of the 2 million annual births in the United States.

It has been estimated that more that 4100 chemicals have been tested for teratogenicity, with approximately 66 percent shown to be nonteratogenic, 7 percent teratogenic in more than one species, 18 percent teratogenic in most species tested and 9 percent producing equivocal experimental results (Schardein, 2000). In contrast, only about 35 to 40 chemicals, chemical classes, or conditions (Table 10-1) have been documented to alter prenatal development in humans (Schardein and Keller, 1989; Shepard, 1998). Review of several human developmental toxicants provides both a historical view of the field of developmental toxicology and an illustration of some of key principles presented below.

Table 10-1 Human Developmental Toxicants

Thalidomide

In 1960, a large increase in newborns with rare limb malformations was recorded in West Germany. The affected individuals had amelia (absence of the limbs) or various degrees of phocomelia (reduction of the long bones of the limbs), usually affecting the arms more than the legs and usually involving both left and right sides, although to differing degrees. Congenital heart disease; ocular, intestinal, and renal anomalies; and malformations of the external and inner ears were also involved. However, the limb defects were characteristic. Limb reduction anomalies of this nature are exceedingly rare. At the university clinic in Hamburg, for example, no cases of phocomelia were reported between 1940 and 1959. In 1959 there was a single case; in 1960, there were 30 cases; and in 1961, a total of 154 cases (Taussig, 1962). The unusual nature of the malformations was key in unraveling the epidemic. In 1961, Lenz and McBride, working independently in Germany and Australia, identified the sedative thalidomide as the causative agent (McBride, 1961; Lenz, 1961; 1963). Thalidomide had been introduced in 1956 by Chemie Grunenthal as a sedative/hypnotic and was used throughout much of the world as a sleep aid and to ameliorate nausea and vomiting in pregnancy. It had no apparent toxicity or addictive properties in humans or adult animals at therapeutic exposure levels. The drug was widely prescribed at an oral dose of 50 to 200 mg/day. There were a few reports of peripheral neuritis attributable to thalidomide, but only in patients with long-term use for up to 18 months (Fullerton and Kermer, 1961). Following the association with birth defects, thalidomide was withdrawn from the market by Grunenthal in November 1961 and case reports ended in mid-1962 as exposed pregnancies were completed. All told, an estimated 5850 malformed infants were born worldwide (Lenz, 1988). Quantitative estimates of malformation risks from exposure have been difficult to compile but are believed to be in the range of one in two to one in ten (Newman, 1985). Due to concerns regarding the severity of the peripheral neuritis and subsequent questions with regard to safety in pregnancy, thalidomide did not receive marketing approval by the U.S. Food and Drug Administration (FDA) prior to its removal from the world market following the epidemic.

As a result of this catastrophe, regulatory agencies in many countries began developing animal testing requirements, separate from chronic toxicity studies, for evaluating the effects of drugs on pregnancy outcomes (Stirling et al., 1997). In the United States, the discussions ultimately led to the development of the Segment I, II, and III testing protocols (Kelsey, 1988). Details and evolution of safety testing requirements for assessment of pregnancy outcomes are found later in this chapter.

It is both ironic and telling that the chemical largely responsible for the advent of modern regulation of potential developmental toxicants presents a very complex pattern of effects in various animal species. It has been tested for prenatal toxicity in at least 19 laboratory species. Malformations and increased resorptions have been observed in some studies in rats, while generally no effects were reported in studies with hamsters or most mouse strains. Effects similar to those observed in humans have been reported for several rabbit strains and in eight of nine primate species. The potency of thalidomide ranges from approximately 1 to 100 mg/kg among sensitive species. In this ranking the human sensitivity was estimated to be 1 mg/kg (Schardein, 1993).

Studies of the relationship between periods of drug use and type of malformation induced established that thalidomide was teratogenic between 20 and 36 days after fertilization (Lenz and Knapp, 1962). Because of its short half-life, teratogenic potency, and good records/recall of drug use, fairly concise timetables of susceptibility can be constructed (Lenz and Knapp, 1962; Nowack, 1965; Neubert and Neubert, 1997; Miller and Stromland, 1999). During the susceptible period of 20 to 36 days postfertilization, anotia (missing ear) was the defect induced earliest, followed by thumb, upper extremity, lower extremity, and triphalangeal thumb (Miller and Stromland, 1999).

Research to understand the species and strain differences in response to thalidomide has met with limited success. Extensive structure-activity studies involving analogs of thalidomide found strict structural requirements (e.g., an intact phthalimide or phthalimidine group) but shed little light on potential mechanisms (Jonsson, 1972; Schumacher, 1975; Helm, 1981). Stephens (1988) reviewed 24 proposed mechanisms, including biochemical alterations involving vitamin B, glutamic acid, acylation, nucleic acids, and oxidative phosphorylation; cellular mechanisms including cell death and cell-cell interactions; and tissue level mechanisms including inhibition of nerve and blood vessel outgrowth. None was considered sufficient by that reviewer. More recent hypotheses concerning the mechanism of thalidomide

teratogenesis include effects on angiogenesis (D'Amato et al., 1994; Joussen et al., 1999; Sauer et al., 2000), integrin regulation (Neubert et al., 1996), oxidative DNA damage (Parman et al., 1999), TNF-a inhibition (Argiles et al., 1998), growth factor antagonism (Stephens et al., 1998; Stephens and Fillmore, 2000), and effects on glutathione and redox status (Hansen et al., 1999).

Research on alterations in immune function and angiogenesis has opened the possibility of expanded use of thalidomide in diseases including HIV infection, arthritis, myeloma, diabetic retinopathy, and macular degeneration (Adler, 1994; Calabrese and Fleischer, 2000). Thalidomide has recently been approved by the FDA for oral ulcers associated with AIDS and for erythema nodosum leprosum, an inflammatory complication of Hansen's disease (leprosy). An unprecedented level of safeguards, embodied in the STEPS program (System of Thalidomide Education and Prescribing Safety), surrounds thalidomide use to prevent accidental exposure during pregnancy, including required registration of all prescribers, pharmacies, and patients, required use of contraception, and periodic pregnancy testing for patients of childbearing ability (Lary et al., 1999).

Diethylstilbestrol

Diethylstilbestrol (DES) is a synthetic nonsteroidal estrogen widely used from the 1940s to the 1970s in the United States to prevent threatened miscarriage by stimulating synthesis of estrogen and progesterone in the placenta. Between 1966 and 1969, seven young women between the ages of 15 and 22 were seen at Massachusetts General Hospital with clear cell adenocarcinoma of the vagina. This tumor had never before been seen in patients younger than 30. An epidemiologic case-control study subsequently found an association with first-trimester DES exposure (reviewed in Poskranzer and Herbst, 1977). The Registry of Clear Cell Adenocarcinoma of the Genital Tract of Young Females was established in 1971 to track affected offspring. Maternal use of DES prior to the 18th week of gestation appeared to be necessary for induction of the genital tract anomalies in offspring. The incidence of genital tract tumors peaked at age 19 and declined through age 22, with absolute risk of clear cell adenocarcinoma of the vagina and cervix estimated to be 0.14 to 1.4 per 1000 exposed pregnancies (Herbst et al. 1977). However, the overall incidence of noncancerous alterations in the vagina and cervix was estimated to be as high as 75 percent (Poskranzer and Herbst, 1977). In male offspring of exposed pregnancies, a high incidence of epididymal cysts, hypotrophic testes, and capsular induration along with low ejaculated semen volume and poor semen quality were observed (Bibbo et al., 1977). The realization of the latent and devastating manifestations of prenatal DES exposure has broadened our concept of the magnitude and scope of potential adverse outcomes of intrauterine exposures and foreshadowed today's interest in "endocrine disruptors" (Colburn et al., 1993).

Ethanol

The developmental toxicity of ethanol has been a recurrent concern throughout history and can be traced to biblical times (e.g., Judges 13:3-4), yet only since the description of the Fetal Alcohol Syndrome (FAS) by Jones and Smith in the early 1970s (Jones and Smith, 1973; Jones et al., 1973) has a clear recognition and acceptance of alcohol's developmental toxicity occurred. Since that time, there have been hundreds of clinical, epidemiologic, and experimental studies of the effects of ethanol exposure during gestation.

The FAS comprises craniofacial dysmorphism, intrauterine and postnatal growth retardation, retarded psychomotor and intellectual development, and other nonspecific major and minor abnormalities (Abel, 1982). The average IQ of FAS children has been reported to be 68 (Streissguth et al., 1991a) and changes little over time (Streissguth et al., 1991b). Full-blown FAS has been observed only in children born to alcoholic mothers, and among alcoholics the incidence of FAS has been estimated at 25 per 1000 (Abel, 1984). Numerous methodologic difficulties are involved in attempting to estimate the level of maternal ethanol consumption associated with FAS, but estimates of a minimum of 3 to 4 oz of alcohol per day have been made (Clarren et al., 1987; Ernhart et al., 1987).

In utero exposure to lower levels of ethanol has been associated with a wide range of effects, including isolated components of FAS and milder forms of neurologic and behavioral disorders. These more subtle expressions of the toxicity of prenatal ethanol exposure have been termed Fetal Alcohol Effects (FAE) (Clarren, 1982). Alcohol consumption can affect birth weight in a dose-related fashion even if the mother is not alcoholic. Little (1977) studied prospectively 800 women to evaluate the effects of drinking on birth weight. After adjusting for smoking, gestational age, maternal height, age, parity, and sex of the child, it was found that for each ounce of absolute ethanol consumed per day during late pregnancy there was a 160-g decrease in birth weight. Effects of maternal alcohol consumption during pregnancy on attention, short-term memory, and performance on standardized tests have been noted in a longitudinal prospective study of 462 children (Streissguth et al., 1994a,1994b). Alcohol intake was related to these effects, the number of drinks per drinking occasion being the strongest predictor.

One animal model of FAS in which pathogenesis of the craniofacial effects has been extensively studied involves intraperitoneal injection of ethanol to pregnant C57Bl/6J mice in early pregnancy when embryos are undergoing gastrulation (Sulik et al., 1981; Sulik and Johnston, 1983). Following such exposures, term fetuses exhibit many of the features of FAS, including microcephaly, microphthalmia, short palpebral fissures, deficiencies of the philtral region, and a long upper lip. The specific set of craniofacial malformations produced in offspring depends on the time of exposure. The mechanisms by which ethanol exerts its teratogenic effects are not understood but probably involve a complex combination of maternal factors and biochemical/cellular effects in the embryo (Rogers and Daston, 1997). Excess cell death in sensitive cell populations appears to be a common finding (Kotch and Sulik, 1992).

Tobacco Smoke

Prenatal and early postnatal exposure to tobacco smoke or its constituents may well represent the leading cause of environmentally induced developmental disease and morbidity today. Approximately 25 percent of women in the United States continue to smoke during pregnancy, despite public health programs aimed at curbing this behavior. Because of the high number of pregnant smokers and the relative accuracy of assessing smoking during pregnancy, results of epidemiologic studies provide a well-characterized picture of the consequences of developmental tobacco smoke exposure. These include spontaneous abortions; perinatal deaths; increased risk of sudden infant death syndrome (SIDS); increased risk of learning, behavioral, and attention disorders; and lower birth weight (Slotkin, 1998; Fried et al., 1998; Tuthill et al., 1999; Haug et al., 2000). One component of tobacco smoke, nicotine, is a known neuroteratogen in experimental animals and can by itself produce many of the adverse developmental outcomes associated with tobacco smoke (Slotkin, 1998). Perinatal exposure to tobacco smoke can also affect branching morphogenesis and maturation of the lung, leading to altered physiologic function (Pinkerton and Joad, 2000; Gilliland et al., 2000). Dempsey and coworkers (2000) found that hypertonia among cocaine-exposed infants was associated not with maternal cocaine usage (as determined by fetal meconium analyses for the cocaine metabolite benzoylecgonine) but rather with maternal urine cotinine levels (a nicotine metabolite). It is important to keep in mind that environmental (passive) tobacco smoke also represents a significant risk to the pregnant nonsmoker (e.g., Windham et al., 2000), as inhaled doses in some situations are similar to those for light smokers.

Cocaine

Cocaine, a plant alkaloid derived from coca, is a local anesthetic with vasoconstrictor properties. During the 1980s, as more potent forms became widely available, cocaine abuse became an epidemic health problem. It has been estimated that up to 45 percent of pregnancies at an urban teaching hospital and 6 percent in a suburban hospital had recent cocaine exposure. Effects on the fetus are complicated and controversial and demonstrate the difficulty of monitoring the human population for adverse reproductive outcomes (reviewed in Scanlon, 1991; Volfe, 1993). Accurate exposure ascertainment is difficult, as many confounding factors—including socioeconomic status and concurrent use of cigarettes, alcohol, and other drugs of abuse—may be involved. In addition, reported effects on the fetus and infant (neurologic and behavioral changes) are difficult to identify and quantify. Nevertheless, a plethora of adverse effects appear to be reliably associated with cocaine exposure in humans, including abruptio placentae; premature labor and delivery; microcephaly; altered prosencephalic development; decreased birth weight; a neonatal neurologic syndrome of abnormal sleep, tremor, poor feeding, irritability, and occasional seizures; and SIDS. Congenital malformations of the genitourinary tract have also been reported (Lutiger et al., 1991), and kidney and bladder function is diminished in fetuses of pregnant women using cocaine (Mitra, 1999). Moreover, fetal cocaine exposure has been associated with impaired neonatal auditory processing (Potter et al., 2000). Fetal cocaine exposure was estimated by chemical analysis of fetal meconium, which can provide a measure of developmental exposure to xenobiotic agents ranging from food additives to over-the-counter medications to drugs of abuse (Ostrea et al., 1998).

Retinoids

The ability of excess vitamin A (retinol) to induce malformations has been known for at least forty years (Cohlan, 1954). Effects on the developing embryo include malformations of the face, limbs, heart, central nervous system, and skeleton. Similar malformations were later shown to be induced by retinoic acid administration in the mouse (Kochhar, 1967) and hamster (Shenefelt, 1972). Since those observations, knowledge relating to the effects of retinol, retinoic acid, and structurally related chemicals that bind to and activate specific nuclear receptors that then regulate a variety of transcriptional events has been expanding rapidly (Chambon, 1994; Lohnes et al., 1994; Mendelsohn et al., 1994; Collins and Mao, 1999; Arafa et al., 2000). The RXR-alpha receptor appears to play an important role in cleft palate induced by retinoic acid (Nugent et al., 1999). The teratogenic effects of vitamin A and retinoids have been reviewed (Nau et al., 1994; Collins and Mao, 1999).

Recently, a link between retinoids and schizophrenia has been proposed, supported by three lines of evidence (Goodman, 1998). First, congenital anomalies similar to those caused by retinoid dysfunction are found in schizophrenics and their relatives; second, genetic loci that are putatively involved in schizophrenia are also the loci of genes in the retinoid cascade; and third, transcriptional activation of candidate schizophrenia genes as well as that of the dopamine D2 receptor is regulated by retinoic acid.

Beginning in 1982, one retinoid, 13- *cis*-retinoic acid (isotretinoin or Accutane), was marketed as an effective treatment of recalcitrant cystic acne. Despite clear warnings against use in pregnancy on the label of this prescription drug (FDA pregnancy category X), an extensive physician and patient education program, and restrictive requirements for prescription to women of childbearing potential, infants with pathognomonic malformations involving the ears, heart, brain, and thymus began to be reported as early as 1983 (Rosa, 1983; Lammer et al., 1985). Among 115 exposed pregnancies not electively terminated, 18 percent ended in spontaneous abortion and 28 percent of the live-born infants had at least one major malformation (Dai et al., 1992). In another prospective study, there was nearly a doubling of the risk for premature delivery after first-trimester exposure, and about 50 percent of the exposed children had full-scale IQ scores below 85 at age 5 (Lammer, 1992).

Valproic Acid

Valproic acid, or 2-propylpentanoic acid, is an anticonvulsant first marketed in Europe in 1967 and in the United States in 1978. In 1982, Elizabeth Robert reported that of 146 cases of spina bifida aperta contained in a birth defects surveillance system in Lyon, France, nine of the mothers had taken valproate during the first trimester. The odds ratio for this finding in a case-control study was 20.6, and the estimated risk of a valproate-exposed woman having a child with spina bifida was 1.2 percent, a risk similar to that for women with a previous child with a neural tube defect (Centers for Disease Control, 1982). The report was quickly confirmed in other areas of the world through the efforts of the International Clearinghouse of Birth Defect Registries (Centers for Disease Control, 1983). Because of the relatively low risk, the fact that epileptic women are already at elevated risk for birth defects, and that the majority of pregnant epileptics are on drug therapy (including several known teratogens), it was fortunate that several events came together that allowed the determination of valproate as a human teratogen. These included the active birth defects registry, an interest by Robert in the genetics of spina bifida, a question on epilepsy and anticonvulsant use in Robert's survey, and the prevalence of valproate monotherapy for epilepsy in that region (Lammer et al., 1987). While these findings spurred a great deal of research on the effects of valproate in multiple species, including interesting results on the effects of enantiomers of valproate analogs, the mechanism of action, as for most developmental toxicants, remains elusive (Nau et al., 1991; Ehlers et al., 1992; Hauck and Nau, 1992). Use of inbred mouse strains differing in their sensitivity to valproate-induced teratogenesis has revealed several candidate genes conferring sensitivity in that species (Finnell et al., 1997; Craig et al., 2000; Bennett et al., 2000; Faiella et al., 2000).

PRINCIPLES OF DEVELOPMENTAL TOXICOLOGY

Principles of teratology were put forth by Jim Wilson in 1959 and in his watershed monograph *Environment and Birth Defects* (Wilson, 1973) (Table 10-2). Although much progress has been made in the ensuing decades, these basic principles have withstood the test of time and remain basic to developmental toxicology.

Table 10-2 Wilson's General Principles of Teratology

Critical Periods of Susceptibility and Endpoints of Toxicity

Basic familiarity with principles of normal development is prerequisite to understanding abnormal development. Development is characterized by change: change in size, changes in biochemistry and physiology, changes in form and functionality. These changes are orchestrated by a cascade of factors regulating gene transcription, the first of which are maternally inherited and present in the egg prior to fertilization. In turn, these factors activate regulatory genes in the embryonic genome, and sequential gene activation continues throughout development. Intercellular and intracellular signaling pathways essential for normal development have been elucidated and rely on transcriptional, translational, and posttranslational controls (e.g., phosphorylation).

Because of the rapid changes occurring during development, the nature of the embryo/fetus as a target for toxicity is also changing. While the basic tenets of toxicology discussed elsewhere in this text also apply during development, the principle of critical periods of sensitivity based on developmental stage of the conceptus is a primary and somewhat unique consideration. In this section we discuss normal developmental stages in the context of their known and potential susceptibility to toxicants. It should be made clear, however, that development is a continuum. Therefore, these stages are used for descriptive purposes and do not necessarily represent discrete developmental events. Timing of some key developmental events in humans and experimental animal species is presented in Table 10-3.

Table 10-3 Timing of Key Developmental Events in Some Mammalian Species

As a logical starting point, *gametogenesis* is the process of forming the haploid germ cells, the egg and sperm. These gametes fuse in the process of *fertilization* to form the diploid *zygote,* or one-celled embryo. Gametogenesis and fertilization are vulnerable to toxicants, but this is the topic of another chapter in this text. It is now known that the maternal and paternal genomes are not equivalent in their contributions to the zygotic genome. The process of *imprinting* occurs during gametogenesis, conferring to certain allelic genes a differential expressivity depending on whether they are of maternal or paternal origin (Latham, 1999). Because imprinting involves cytosine methylation and changes in chromatin conformation, this process may be susceptible to toxicants that affect these targets (Murphy and Jirtle, 2000). Although a plausible target for toxicity, imprinting is not well understood and at present there are no documented examples of toxicant effects on this process. Toxic effects on imprinting could conceivably play a role in paternally mediated developmental toxicity, a topic that is not discussed here but which has received increased attention in the recent literature (Olshan and Mattison, 1995).

Exposure to toxicants during a brief period (~6 h) immediately following fertilization has been demonstrated to result in malformed fetuses for a number of chemicals including ethylene oxide (Generoso et al., 1987), ethylmethane sulfonate, ethylnitrosourea, and triethylene melamine (Generoso et al., 1988). The mechanisms underlying these unexpected findings have not been elucidated but probably do not involve point mutations.

Following fertilization, the embryo moves down the fallopian tube and implants in the wall of the uterus. The *preimplantation* period comprises mainly an increase in cell number through a rapid series of cell divisions with little growth in size (*cleavage* of the zygote) and cavitation of the embryo to form a fluid-filled blastocoele. This stage, termed the *blastocyst,* consisting of about a thousand cells, may contain as few as three cells destined to give rise to the embryo proper (Markert and Petters, 1978), and these cells are within a region called the *inner cell mass.* The remainder of the blastocyst cells give rise to extraembryonic membranes and support structures (e.g., trophoblast and placenta). However, the fates of the cells in the early embryo are not completely determined at this stage. The relatively undifferentiated preimplantation embryo has great restorative (regulative) growth potential (Snow and Tam, 1979). Experiments of Moore et al. (1968) demonstrated that single cells from eight-celled rabbit embryos are capable of producing normal offspring.

Toxicity during preimplantation is generally thought to result in no or slight effect on growth (because of regulative growth) or in death (through overwhelming damage or failure to implant). Preimplantation exposure to DDT, nicotine, or methylmethane sulfonate results in body and/or brain weight deficits and embryo lethality, but not malformations (Fabro, 1973; Fabro et al., 1984). However, there are also examples of toxicant exposure during the preimplantation period leading to fetal malformations. Treatment of pregnant mice with methylnitrosourea on days 2.5, 3.5, and 4.5 of gestation resulted in neural tube defects and cleft palate (Takeuchi, 1984). Cyproterone acetate and medroxyprogesterone acetate are capable of producing malformations when administered on day 2 of gestation (Eibs et al., 1982). Rutledge and coworkers (Rutledge et al., 1994) produced hind-limb and lower body duplications by treating pregnant mice with all-*trans* retinoic acid on gestation day 4.5 to 5.5, at which time the embryos are at the late blastocyst and proamniotic stages. This finding suggests that patterning of the limbs and lower body may begin prior to gastrulation. Because of the rapid mitoses occurring during the preimplantation period, chemicals affecting DNA synthesis or integrity or those affecting microtubule assembly would be expected to be particularly toxic if given access to the embryo.

Following implantation the embryo undergoes *gastrulation.* Gastrulation is the process of formation of the three primary germ layers—the *ectoderm, mesoderm,* and *endoderm.* During gastrulation, cells migrate through a structure called the *primitive streak,* and their movements set up basic morphogenetic fields in the embryo (Smith et al., 1994). As it is a prelude to organogenesis, the period of gastrulation is quite susceptible to teratogenesis. A number of toxicants administered during gastrulation produce malformations of the eye, brain and face. These malformations are indicative of damage to the anterior neural plate, one of the regions defined by the cellular movements of gastrulation.

The formation of the neural plate in the ectoderm marks the onset of *organogenesis,* during which the rudiments of most bodily structures are established. This is a period of heightened susceptibility to malformations and extends from approximately the third to the eighth weeks of gestation in humans. Within this short period, the embryo undergoes rapid and dramatic changes. At 3 weeks of gestation, the human conceptus is in most ways indistinguishable from other mammalian and indeed other vertebrate embryos, consisting of only a few cell types in a trilaminar arrangement. By 8 weeks, the conceptus, which can now be termed a fetus, has a form clearly recognizable as human. The rapid changes of organogenesis require cell proliferation, cell migration, cell-cell interactions, and morphogenetic tissue remodeling. These processes are exemplified by the *neural crest* cells. These cells originate at the border of the *neural plate* and migrate to form a wide variety of structures throughout the embryo. Neural crest cells derived from segments of the hindbrain (*rhombomeres*) migrate to form bone and connective tissues in the head (Krumlauf, 1993; Vaglia and Hall, 1999).

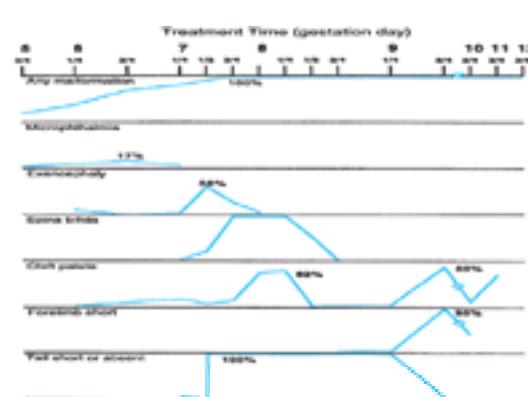
Within organogenesis, there are periods of peak susceptibility for each forming structure. This is nicely illustrated by the work of Shenefelt (1972), who studied the developmental toxicity of carefully timed exposures to retinoic acid in the hamster. The incidence of some of the defects seen after retinoic acid administration at different times in development are shown in Fig. 10-1. The peak incidence of each malformation coincides with the timing of key developmental events in the affected structure. Thus, the specification of developmental fields for the eyes is established quite early, and microphthalmia has an early critical period. Establishment of rudiments of the long bones of the limbs occurs later, as does susceptibility to shortened limbs. The palate has two separate peaks of susceptibility, the first corresponding to the early establishment of the palatal folds and the second to the later events leading to palatal closure. Notice also that the total incidence of malformations is lower prior to organogenesis but increases to 100 percent by gestation day 7¾. The processes underlying the development of normal structures are poorly understood but involve a number of key events. A given toxicant may affect one or several developmental events, so the pattern of sensitivity of a structure can change depending on the nature of the toxic insult. Cleft palate is induced in mouse fetuses following maternal exposure to methanol as early as day 5 of gestation, with a peak sensitivity at day 7 and little or no sensitivity after day 9 (Rogers et al., 1994). In contrast, the typical peak critical period for induction of cleft palate for most agents is between gestation days 11 and 13. In a large series of experiments in NMRI mice, Neubert's group found that the day of peak sensitivity to the induction of cleft palate was day 11 for TCDD, day 12 for 2,4,5-trichlorophenoxyacetic acid, and day 13 for dexamethasone (Neubert et al., 1973). Detection of unexpected critical periods like that for induction of cleft palate by methanol may provide clues to normal developmental processes not presently understood.


Figure 10-1. Critical periods of sensitivity for induction of various defects by retinoic acid in the hamster.

Incidence of defects are estimates for the embryo/fetal LD$_{50}$ maternal dosage. Note in the top panel that fewer malformations are induced on days 5 to 6, prior to organogenesis, indicating that during this period embryos for the most part either die or recover. Likelihood of malformation increases rapidly during gastrulation and reaches 100 percent during organogenesis. Peak incidence for each defect are enumerated and reflect timing of critical events in the development of each structure. [Modified from Shenefelt (1972), with permission.]

The end of organogenesis marks the beginning of the *fetal period* (from days 56 to 58 to birth in humans), characterized primarily by tissue differentiation, growth, and physiologic maturation. This is not to say that formation of the organs is complete but that almost all organs are present and grossly recognizable. Further development of organs proceeds during the fetal period to attain requisite functionality prior to birth, including fine structural morphogenesis (e.g., neural outgrowth and synaptogenesis, branching morphogenesis of the bronchial tree and renal cortical tubules) as well as biochemical maturation (e.g., induction of tissue-specific enzymes and structural proteins). One of the latest organogenetic events is closure of the urethral groove in the male, which occurs at about gestation day 90. Failure of this event produces hypospadias, a ventral clefting of the penis.

Exposure during the fetal period is most likely to result in effects on growth and functional maturation. Functional anomalies of the central nervous system and reproductive organs—including behavioral, mental, and motor deficits as well as decreases in fertility—are among the possible adverse outcomes. These manifestations are not apparent prenatally and require careful postnatal observation and testing of offspring. Such postnatal functional manifestations can be sensitive indicators of in utero toxicity, and reviews of postnatal functional deficits of the central nervous system (Rodier et al., 1994), immune system (Holladay and Luster, 1994) and heart, lung, and kidneys (Lau and Kavlock, 1994) are available. Major structural alterations can occur during the fetal period, but these generally result from *deformations* (disruption of previously normal structures) rather than malformations. The extremities may be affected by amniotic bands, wrapping of the umbilical cord, or vascular disruptions, leading to loss of distal structures.

There is a paucity of data concerning the long-term effects of toxic exposure during the fetal period. Some effects could require years to become apparent (such as those noted for DES in above), and others may even result in the onset of senescence and/or organ failure late in life. In rats, prenatal exposure to high dosages of

ethanol during the second half of pregnancy shortens life span of the offspring, by about 20 weeks in females and 2.5 to 7 weeks in males (Abel et al., 1987).

Dose–Response Patterns and the Threshold Concept

The major effects of prenatal exposure, observed at the time of birth in developmental toxicity studies, are embryo lethality, malformations, and growth retardation. The relationship between these effects is complex and varies with the type of agent, the time of exposure, and the dose. For some agents these endpoints may represent a continuum of increasing toxicity, with low dosages producing growth retardation and increasing dosages producing malformations and then lethality. Malformations and/or death can occur in the absence of any effect on intrauterine growth, but this is unusual. Likewise, growth retardation and embryo lethality can occur without malformations. Agents producing the latter pattern of response would be considered embryotoxic or embryolethal but not teratogenic (unless it were subsequently established that death was due to a structural malformation).

Another key element of the dose–response relationship is the shape of the dose–response curve at low exposure levels. Because of the high restorative growth potential of the mammalian embryo, cellular homeostatic mechanisms, and maternal metabolic defenses, mammalian developmental toxicity has generally been considered a threshold phenomenon. Assumption of a threshold means that there is a maternal dosage below which an adverse response is not elicited. Daston (1993) summarized two approaches for establishing the existence of a threshold. The first, exemplified by a large teratology study on 2,4,5-T (Nelson and Holson, 1978), suggests that no study is capable of evaluating the dose–response at low response rates (e.g., 805 litters per dose would be necessary to detect the relatively high rate of a 5 percent increase in resorptions). The second approach is to determine whether a threshold exists for the mechanism responsible for the observed effect. While relatively few mechanisms are known, it is clear that cellular and embryonic repair mechanisms and dose-dependent kinetics both support the plausibility of a mechanistic threshold. Lack of a threshold implies that exposure to any amount of a toxic chemical, even one molecule, has the potential to cause developmental toxicity. One mechanism of abnormal development for which this might be the case is gene mutation. A point mutation in a critical gene could theoretically be induced by a single hit or single molecule, leading to a deleterious change in a gene product and consequent abnormal development. This, of course, carries the large assumption that the molecule could traverse the maternal system and the placenta and enter a critical progenitor cell in the embryo. An effect on a single cell might result in abnormal development at the zygote (one-cell) stage, the blastocyst stage (when only a few cells in the inner cell mass are embryo progenitors), or during organogenesis, when organ rudiments may consist of only a few cells.

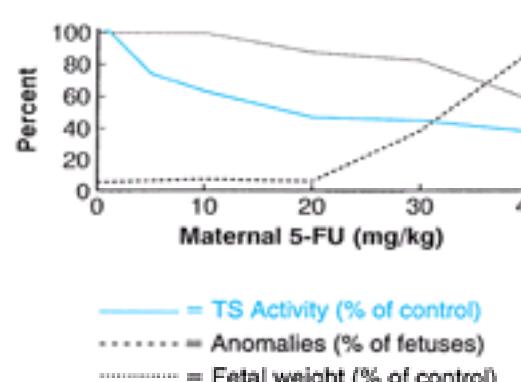
An apparent threshold for developmental toxicity based at least in part on cellular homeostatic mechanisms is demonstrated in studies of biological mechanisms underlying the developmental dose–response for 5-fluorouracil (Shuey et al, 1994; see also "Safety Assessment," further on). This agent inhibits the enzyme thymidylate synthetase (TS), thus interfering with DNA synthesis and cell proliferation. Significant embryonal TS inhibition can be measured at maternal dosages an order of magnitude below those required to produce malformations and about fivefold below those affecting fetal growth (Figure 10-2). The lack of developmental toxicity despite significant TS inhibition probably reflects ability of the embryo to compensate for imbalances in cellular nucleotide pool sizes.


Figure 10-2. Relationship between inhibition of embryonal thymidylate synthetase (TS) and adverse fetal outcome following maternal 5-fluorouracil (5-FU) administration on gestation day 14 in the rat.

5-FU inhibits embryonal TS activity at low dosages, with most of the inhibition occurring below 20 mg/kg. Fetal weight is affected at 20 mg/kg and above, while incidence of anomalies increases only at 30 mg/kg and above. Anomalies include edema, skull dysmorphology, orbital hemorrhage, wavy ribs, cleft palate, brachygnathia and hindlimb defects. [Based on Shuey et al. (1994) and Lau et al. (1992) and unpublished observations.]

In the context of human health risk assessment, it is also important to consider the distinction between individual thresholds and population thresholds. There is wide variability in the human population, and a threshold for a population is defined by the threshold of the most sensitive individual in the population (Gaylor et al., 1988). Indeed, even though the biological target of a developmental toxicant may be thresholded, background factors such as health status or concomitant exposures may render an individual at or even beyond the threshold for failure of that biological process. Any further toxic impact on that process, even one molecule, would theoretically increase risk.

MECHANISMS AND PATHOGENESIS OF DEVELOPMENTAL TOXICITY

The term *mechanisms* is used here to refer to cellular-level events that initiate the process leading to abnormal development. *Pathogenesis* comprises the cell-, tissue-, and organ-level sequelae that are ultimately manifest in abnormality. Mechanisms of teratogenesis listed by Wilson (1977) include mutations, chromosomal breaks, altered mitosis, altered nucleic acid integrity or function, diminished supplies of precursors or substrates, decreased energy supplies, altered membrane characteristics, osmolar imbalance, and enzyme inhibition. While these cellular insults are not unique to development, they may relatively quickly trigger unique pathogenetic responses in the embryo, such as reduced cell proliferation, cell death, altered cell-cell interactions, reduced biosynthesis, inhibition of morphogenetic movements, or mechanical disruption of developing structures.

Experimental studies of cyclophosphamide (CP), a teratogenic chemotherapeutic agent, provide an example of current approaches to understanding teratogenic mechanisms and pathogenesis. Much of this and other mechanistic work was made possible by the advent of whole rodent embryo culture techniques, which involve removing rodent embryos from the uterus at the beginning of organogenesis and growing them in serum-containing culture media (New, 1978; Sadler and Warner, 1984). Embryos will grow normally for about 48 h, completing most of organogenesis. The ability to grow embryos in isolation allows direct exposure, manipulation, and observation of the organogenesis-stage embryo.

Using the embryo culture system, Fantel et al. (1979) and Sanyal et al. (1979) showed that hepatic S9 fractions and cofactors were needed to elicit abnormal development by CP, demonstrating that it must be metabolically activated to be teratogenic. Activation of CP was inhibited by metyrapone or carbon monoxide, indicating involvement of P450 monooxygenases. Of the CP metabolites (Fig. 10-3), 4-hydroxycyclophosphamide (4OHCP) and aldophosphamide (AP) are unstable. A stable derivative of 4OHCP, 4-hydroperoxy-cyclophosphamide (4OOHCP) was tested in vivo (Hales, 1982) and in whole embryo culture (Mirkes, 1987). In the latter study, the morphology of the treated embryos was indistinguishable from that of embryos cultured with CP and an activating system. Spontaneous conversion of 4OOHCP to 4OHCP and then to phosphoramide mustard and acrolein occurs rapidly, and these further metabolites, as well as 4-ketocyclophosphamide (4-ketoCP) and carboxyphosphamide (CaP), have also been studied for their teratogenicity. It appears that 4OHCP is not teratogenic (Hales, 1983) and toxicity elicited by 4-ketoCP is dissimilar to that of activated CP (Mirkes et al., 1981). Subsequent work centered on the two remaining metabolites, PM and AC. Mirkes et al. (1981) demonstrated that the effects of PM on cultured rat embryos were indistinguishable from those of activated CP. Hales (1982) administered CP, PM, or AC to gestation day 13 rat embryos by intraamniotic injection. CP and AC caused hydrocephaly, open eyes, cleft palate, micrognathia, omphalocele and tail and limb defects, while PM produced only hydrocephaly and tail and limb defects. Thus, both PM and AC appear to be teratogenic metabolites of CP.

Figure 10-3. Metabolic pathway for cyclophosphamide. [From Mirkes (1985b), with permission.]

What are the cell and molecular targets of activated CP, and what is the nature of the interaction? Experiments with (^{3}H)CP show that approximately 87 percent of bound radioactivity is associated with protein, 5 percent with DNA, and 8 percent with RNA (Mirkes, 1985a). Using alkaline elution, it was demonstrated that CP and PM produce single-strand DNA breaks and DNA-DNA and DNA-protein cross-linking. To determine whether DNA cross-linking is essential for teratogenicity, a monofunctional derivative of PM, capable of producing single-strand breaks but not cross-links in DNA, was tested. Although higher concentrations were needed, this derivative produced the same spectrum of effects as PM (Mirkes et al., 1985). Later, Little and Mirkes (1990) showed that 4-hydroperoxydechlorocyclophosphamide, a CP analog that yields AC and a nonalkylating derivative of PM, did not produce DNA damage when embryos were exposed in serum-containing medium. Using radiolabeled CP, they further found that AC preferentially binds to protein and shows high incorporation into the yolk sac, while PM binds preferentially to DNA. Hales (1989) showed that PM and AC have strikingly different effects on limb buds in culture. These results indicate that PM and AC have different targets in the embryo and that PM is responsible for CP-induced DNA damage.

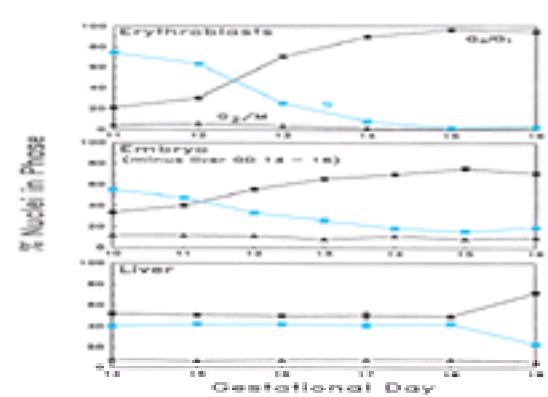
How do chemical insults at the cell and molecular level translate to a birth defect? To illustrate pathogenesis, we will consider inhibition of cell cycle perturbations and cell death, and continue with our example of cyclophosphamide. Cell death plays a critical role in normal morphogenesis. The term *programmed cell death* (pcd) refers to a specific type of cell death, *apoptosis,* under genetic control in the embryo (Lavin and Watters, 1993). Apoptosis is necessary for sculpting the digits from the hand plate, for instance, and for assuring appropriate functional connectivity between the central nervous system and distal structures. Cell proliferation is obviously essential for development. Cells within the primitive streak of the gastrula-stage rat embryo have the shortest known cell cycle time of any mammalian cell, 3 to 3.5 h (MacAuley et al., 1993). Cell proliferation rates change both spatially and temporally during ontogenesis, as can be demonstrated by examining the proportion of cells in S phase over time in different tissues during mid- to late gestation (Fig. 10-4). There is a delicate balance between cell proliferation, cell differentiation, and apoptosis in the embryo, and one molecular mechanism discussed above (DNA damage) might lead to the cell cycle perturbations and cell death induced by CP in specific cell populations.


Figure 10-4. Normal developmental changes in cell cycle distributions in erythroblasts, embryo (minus the liver after GD 13), and fetal liver.

Percentages of cells in: ● G_c/G_1; ■ S; and ▲ G_2/M are shown for rat embryos between gestation days 10 and 19 (note changing x-axis range).

The proportion of cells in S phase generally reflects proliferation rate, which decreases with developmental stage in the embryo and erythroblasts. The percentage of S-phase cells in the fetal liver remains fairly high and constant until near term, when a growth spurt occurs. [From Elstein et al. (1993), with permission.]

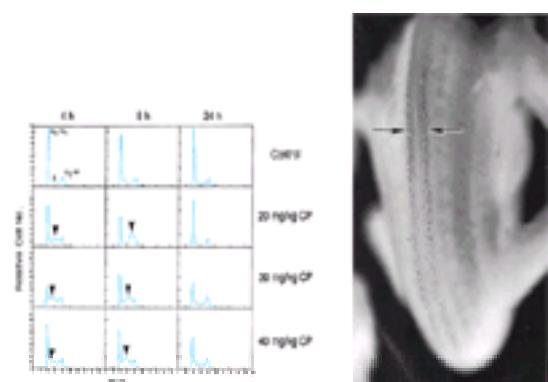
Maternal cyclophosphamide treatment on gestation day 10 in the rat causes an S-phase cell cycle block as well as widespread cell death in the embryo (Fig. 10-5). In agreement with the S-phase cell cycle block, cell death is observed in areas of rapid cell proliferation (Chernoff et al., 1989; Francis et al., 1990). Similar blockage of the embryonal cell cycle and cell death were observed using activated CP in whole embryo culture (Little and Mirkes, 1992). The embryonal neuroepithelium is quite sensitive to CP-induced cell death, while the heart is resistant. Differences in cell cycle length may, in part, underlie this differential sensitivity. The neuroepithelium of the day 10 rat embryo has a cell cycle time of approximately 9.5 h, while the cell cycle length in the heart was estimated to be 13.4 h. This difference is due to a longer G_0/G_1 phase in the heart cells compared to the neuroepithelium (Mirkes et al, 1989). Damage to DNA by PM occurs predominately in S phase (Little and Mirkes, 1992), which constitutes a relatively greater proportion of the cell cycle in the heart than in the neuroepithelium.


Figure 10-5. Maternal cyclophosphamide (CP) administration on gestation day 10 in CD-1 mice produces perturbations of the embryonal cell cycle and cell death in areas of rapid proliferation.

Left: Cells are inhibited from progressing through the S (DNA synthetic) phase of the cell cycle, indicated by the abnormal population of cells (*arrowheads*) accumulating at progressively earlier stages of S phase 4 and 8 h after increasing maternal CP dosages. The upper panels show the normal GD 10-11 distributions, with the G_0/G_1, S, and G_2/M peaks identified in the upper left panel. By 24 h postdosing, cell cycle distributions have returned to normal at 20 mg/kg, but remain abnormal at higher dosages. *Right:* Nile blue sulfate staining of a mouse embryo 24 h after maternal CP dosing shows cell death (*stippling along either side of the midline, arrows*) in the neural tube, one of the most sensitive target sites for CP. [Adapted from Chernoff et al. (1989), with permission.]

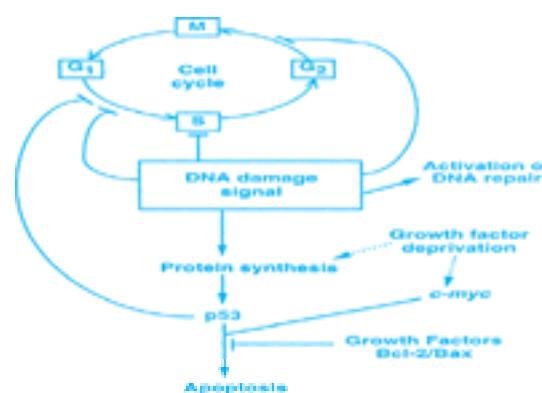
Damage to DNA can inhibit cell cycle progression at the G_1-S transition, through the S phase, and at the G_2-M transition. If DNA damage is repaired, the cell cycle can return to normal, but if damage is too extensive or cell cycle arrest too long, apoptosis may be triggered. The relationship between DNA damage and repair, cell cycle progression, and apoptosis is depicted in Fig. 10-6. An increasing number of genes are being identified that play a role in apoptosis (White, 1993). The p53 gene, which may function as a tumor suppressor, can promote apoptosis or growth arrest. Apoptosis occurring during normal development does not require this gene, as p53-deficient embryos develop normally. However, p53 may be critical for induction of growth arrest or apoptosis in response to DNA damage. The incidence of benzo[a]pyrene-induced fetal resorptions and postpartum death were increased 3-fold and over 10-fold, respectively, in offspring of heterozygous p53-deficient (p/+) pregnant mice compared to normal homozygous (+/+) controls (Harrison et al., 1994). Growth factors and some cytokines (IL-3, IL-6) can prevent p53-dependent apoptosis. Expression of c-myc produces continued DNA synthesis, which may precipitate apoptosis in the face of DNA damage. Bcl-2 functions as a repressor of apoptosis and functions in conjunction with Bax, a homolog that dimerizes with itself or with Bcl-2. Bax homodimers favor cell death while Bcl-2/Bax heterodimers inhibit cell death (Oltvai and Korsmeyer, 1994).


Figure 10-6. Relationships between DNA damage and the induction of cell cycle arrest or apoptosis.

DNA damage can signal inhibition of the cell cycle between G_1 and S, in S phase or between G_2 and mitosis. The signal(s) can also activate DNA repair mechanisms and synthesis of proteins, including p53, that can initiate apoptosis. Growth factors and products of the proto-oncogene *c-myc* and the Bcl-2/Bax gene family, as well as differentiation state and cell cycle phase, are important determinants of the ultimate outcome of embryonal DNA damage.

From the multiple checkpoints and factors present to regulate the cell cycle and apoptosis, it is clear that different cell populations may respond differently to a similar stimulus, in part because cellular predisposition to apoptosis can vary. In regard to the induction of cell death in the neuroepithelium but not the heart by CP, it may be relevant that a portion of the cells from the neuroepithelium undergoes apoptosis normally during this stage of development, indicating competence to respond to an appropriate signal. Conversely, although diverse environmental agents including ethanol, 13-*cis* retinoic acid, ionizing radiation, and hyperthermia are able to induce characteristic patterns of cell death in the embryo (Sulik, et al., 1988), none of them effect cell death in the heart. Recently, Mirkes and Little (1998) have shown that treatment of postimplantation mouse embryos with hyperthermia, cyclophosphamide or sodium arsenate induced DNA fragmentation, activation of caspase-3, and cleavage of poly (ADP-ribose) polymerase (PARP) along with apoptosis in some embryonal tissues, but none of these events occurred in the heart. Subsequently, these investigators demonstrated that these agents can induce changes in embryonal mitochondria resulting in release of cytochrome *c* and activation of caspase-9, the upstream activator of caspase-3. In agreement with the observed lack of apoptosis in the heart, this tissue was also refractory to teratogen-induced cytochrome *c* release from mitochondria (Mirkes and Little, 2000).

In addition to affecting proliferation and cell viability, molecular and cellular insults can affect essential processes such as cell migration, cell-cell interactions, differentiation, morphogenesis, and energy metabolism. Although the embryo has compensatory mechanisms to offset such effects, production of a normal or malformed offspring will depend on the balance between damage and repair at each step in the pathogenetic pathway.

Advances in the Molecular Basis of Dysmorphogenesis

Our still fragmentary understanding of normal development, combined with the small size and inaccessibility of the mammalian embryo, have made the elucidation of mechanisms of abnormal development a daunting task. Now, rapid advances in molecular biology and related technologies are bringing new understanding of mechanisms of normal and abnormal development. Targeted gene disruption by homologous recombination (gene "knockout") has been used to study the function of members of the retinoic acid receptor (RAR) family of nuclear ligand-inducible transcription factors. Chambon and colleagues have produced mice lacking several of these receptors either singly or as double knockouts. Single-receptor isoform mutants were often unaffected, suggesting functional redundancy. Double mutants were invariably nonviable and presented widespread malformations of the skeleton and viscera (Lohnes et al., 1994; Mendelsohn et al., 1994). The compound RARg-RARb null mouse exhibits syndactyly, indicating that retinoic acid plays a role in interdigital cell death (Dupe et al., 1999).

The use of synthetic antisense oligonucleotides allows temporal and spatial restriction of gene ablation. In this technique, 15-25-mer oligonucleotides are synthesized that are complimentary to the mRNA to be disrupted (Helene et al., 1990). These probes can enter embryonal cells, and hybridization with cellular mRNA causes disruption of native message. In this way, gene function can be turned off at specific times. Added advantages of the antisense approach are the ability to ablate multiple gene family members (by making the antisense probes to regions of sequence homology) and the much shorter-time frame for the experiments (Sadler and Hunter, 1994). The proto-oncogenes Wnt-1 and Wnt-3a have been implicated in the development of the midbrain and hindbrain. Augustine et al. (1993) attenuated Wnt-1 expression using antisense oligonucleotide inhibition in mouse embryos developing in culture. Exposure during neurulation produced mid- and hindbrain malformations similar to those seen in Wnt-1 null mutant mice, as well as cardiac anomalies not observed in Wnt-1 knockouts created by homologous recombination. Antisense attenuation of Wnt-3a caused anomalies of the forebrain, midbrain, and spinal cord. Simultaneously attenuating both Wnt-1 and Wnt-3a targeted all brain regions and worsened the effect on the spinal cord, suggesting that these genes may serve a complementary function in the development of the central nervous system.

Gain of gene function can also be studied by engineering genetic constructs with an inducible promoter attached to the gene of interest. Ectopic gene expression can be made ubiquitous or site-specific depending on the choice of promoter to drive expression. Ectopic expression of the Hoxa-7 gene induced in mouse embryos by attaching it to the chicken b-actin promoter resulted in a phenotype exhibiting multiple craniofacial and cervical vertebral malformations (Balling et al., 1989; Kessel et al., 1990). Transient overexpression of specific genes can be accomplished by adding extra copies using adenoviral transduction. In proof-of-concept, Hartig and Hunter (1998) injected the adenoviral vector containing either the bacterial beta-galactosidase or green fluorescent protein reporter gene under the control of the human cytomegalovirus early gene promoter into the intraamniotic space of neurulation-stage mouse embryos and achieved intense gene expression in the neuroepithelium.

Reporter transgenes contain a gene with a readily detectable product fused downstream of a selected regulatory region. The *Escherichia coli lacZ* (b-galactosidase) gene is commonly used for this purpose. Cell lineage studies can be carried out by fusing *lacZ* to a constitutive regulatory sequence and introducing the construct into a somatic cell early in ontogenesis. The reporter gene will then be expressed in and mark all progeny of the transfected cell. This method has been used to study postimplantation development in the mouse embryo (Sanes et al., 1986), although intracellular injection of fluorescent dyes has also proven highly reliable for cell lineage studies (e.g., Smith et al., 1994). The pattern of expression of a particular gene of interest can be discriminated by fusing upstream regulatory elements of the gene to *lacZ,* which will then be transcribed under control of those upstream elements (Zakany et al., 1990).

Retinoic acid (RA) can activate hox genes in vitro, and the 3' hox genes have multiple RA response elements (RAREs). Evidence that RA-induced malformations in mouse embryos are related to changes in hox expression was first provided by staining of hox-*lacZ* transgenic embryos (Marshall, 1992). Within a few hours of RA treatment, hoxb-1 expression extends anteriorly, suggesting that hox genes could be direct targets of RA induction. Regions of altered hox expression could be manifest as abnormal cell fate and morphogenesis (Marshall, 1996; Collins and Mao, 1999). One of the best examples of hox-mediated retinoid teratogenicity is the effect on the developing hindbrain. Identity of the hindbrain segments (rhombomeres) is in part conferred by anterior expression boundaries of specific hox genes, and these boundaries are altered in distinct ways by retinoid treatment. Alterations in expression boundaries for the genes correlate with phenotypic changes seen in the

hindbrain at later developmental stages, including transformation of rhombomeres to a phenotype usually associated with a more caudal rhombomere.

PHARMACOKINETICS AND METABOLISM IN PREGNANCY

The manner in which chemicals are absorbed during pregnancy and the extent to and form in which they reach the conceptus are important determinants of whether the agent can impact development. The maternal, placental, and embryonic compartments comprise independent yet interacting systems that undergo profound changes throughout the course of pregnancy. Changes in maternal physiology during pregnancy involve hepatic metabolism, the gastrointestinal tract, cardiovascular system, excretory system, and the respiratory system (Hytten, 1984; Krauer, 1987; Mattison et al., 1991). While these physiologic changes are necessary to support the growing needs of the conceptus in terms of energy supply and waste elimination, the alterations can have significant impact on the uptake, distribution, metabolism, and elimination of xenobiotics. For example, decreases in intestinal motility and increases in gastric emptying time result in longer retention time of ingested chemicals in the upper gastrointestinal tract. Cardiac output increases by 50 percent during the first trimester in humans and remains elevated throughout pregnancy, while blood volume increases and plasma proteins and peripheral vascular resistance decrease. The relative increase in blood volume over red cell volume leads to borderline anemia and a generalized edema with a 70 percent elevation of extracellular space. Thus, the volume of distribution of a chemical and the amount bound by plasma proteins may change considerably during pregnancy. Renal blood flow and glomerular filtration are also increased in many species during pregnancy. Increases in tidal volume, minute ventilation, and minute O_2 uptake can result in increased pulmonary distribution of gases and decreases in time to reach alveolar steady state.

In addition to changes in maternal physiology, limited available evidence suggests that relative rates of drug metabolizing enzymes also change during pregnancy (Juchau, 1981; Juchau and Faustman-Watts, 1983). Decreased hepatic monooxygenase activity has been observed during pregnancy in rats and has been attributed to decreased enzyme levels and to competitive inhibition by circulating steroids (Neims, 1976). Another factor that contributes to lower monooxygenase activity is that pregnant rats appear to be less responsive to induction of hepatic monooxygenases by phenobarbital (but not 3-methylcholanthrene) than are non-pregnant females (Guenther and Mannering, 1977). Despite the absence of a comprehensive literature on this subject, there appears to be an overall decrease in hepatic xenobiotic biotransformation during pregnancy. Clearly, maternal handling of a chemical bears considerable weight in determining the extent of embryotoxicity. In one of the few studies of its type, a linear combination of the 45-min and the 24-h maternal blood concentrations was able to predict the litter response rate for pregnant rats dosed with 500 mg/kg sodium salicylate on gestation day 11 (Kimmel and Young, 1983). These two kinetic parameters probably reflect the influence of the peak drug concentration as well as the cumulative area under the concentration-time curve in inducing developmental disturbances.

The placenta plays a central role in influencing embryonic exposure by helping to regulate blood flow, by offering a transport barrier, and by metabolizing chemicals (Slikker and Miller, 1994). Functionally, the placenta acts as a lipid membrane that permits bidirectional transfer of substances between maternal and fetal compartments. The transfer depends on three major elements: the type of placentation, the physicochemical properties of the chemical, and rates of placental metabolism. Although there are marked species differences in types of placentas, orientation of blood vessels, and numbers of exchanging layers, these do not seem to play a dominant role in placental transfer of most chemicals. It is important to note that virtually any substance present in the maternal plasma will be transported to some extent by the placenta. The passage of most drugs across the placenta seems to occur by simple passive diffusion, the rate of which is proportional to the diffusion constant of the drug, the concentration gradient across the maternal and embryonic plasma, the area of exchange, and the inverse of the membrane thickness (Nau, 1992). Important modifying factors to the rate and extent of transfer include lipid solubility, molecular weight, protein binding, the type of transfer (passive diffusion, facilitated or active transport), the degree of ionization, and placental metabolism. Weak acids appear to be rapidly transferred across the placenta, due in part to the pH gradient between the maternal and embryonic plasma which can trap ionized forms of the drug in the slightly more acidic embryonic compartment (Nau and Scott, 1986). Blood flow probably constitutes the major rate-limiting step for more lipid-soluble compounds.

Quantitating the form, amount, and timing of chemical delivery to the embryonic compartment relative to concurrent developmental processes is an important component of understanding mechanisms of embryotoxicity and species differences in embryonic sensitivity (Nau, 1986). The small size of the conceptus during organogenesis and the fact that the embryo is changing at a rapid rate during this period makes assessment of toxicokinetics difficult. Nevertheless, there has been considerable progress in this area (Nau and Scott, 1987; Clark, 1993). Increasingly sensitive analytical methods are now providing evidence to challenge the historical view, particularly for cytochrome P450–dependent monooxygenases, that the early embryo has low metabolic capabilities (Juchau et al., 1992). Using an embryo culture system, Juchau and coworkers demonstrated that the rat conceptus was able to generate sufficient amounts of metabolites of the proteratogen 2-acetylaminofluorene (2-AAF) to induce dysmorphogenesis, and that the proximate toxicant, the 7-hydroxy metabolite, was different from the metabolite responsible for 2-AAF mutagenesis and carcinogenesis. Prior exposure of the dams to 3-methylcholanthrene increased the sensitivity of the cultured embryos to 2-AAF, thus demonstrating the inducibility of at least some cytochromes in the conceptus. These investigators later showed that embryos could further metabolize the 7-hydroxy metabolite to an even more toxic catechol. No previous induction was necessary for this activation step, demonstrating the presence of constitutive metabolizing enzymes in the embryo. Although the rates of metabolism for these activation steps may be low relative to the maternal liver, they occur close to the target site of the embryo or even within it and thus are significant in terms of inducing embryotoxicity.

The advent of physiologically based pharmacokinetic models has provided the framework to integrate what is known about physiologic changes during pregnancy, both within and between species, with aspects of drug metabolism and embryonic development into a quantitative description of the events. Gabrielson and coworkers (Gabrielson and Paalkow, 1983; Gabrielson and Larsson, 1990) were among the first investigators to develop physiologically based models of pregnancy, and others (Fisher et al., 1989; O'Flaherty et al., 1992; Clark et al., 1993; Luecke et al., 1994, 1997; Young, 1998) have added to their comprehensiveness. The pregnancy model of O'Flaherty and coworkers describes the entire period of gestation, and consists of the uterus, mammary tissue, maternal fat, kidney, liver, other well-perfused maternal tissues, embryo/fetal tissues and yolk sac, and chorioallantoic placentas. It takes into account the growth of various compartments during pregnancy (including the embryo itself), as well as changes in blood flow and the stage-dependent pH gradients between maternal and embryonic plasma. Transfer across the placenta in the model is diffusion limited. The utility of the model was evaluated using 5,5'-dimethyloxazolidine-2,4-dione (DMO), a weak acid that is not appreciably bound to plasma proteins and is eliminated by excretion in the urine. The model demonstrated that the whole body disposition of DMO, including distribution to the embryo, can be accounted for solely on the basis of its pK_a and of the pH and volumes of body fluid spaces. Differences between the disposition of DMO by the pregnant mouse and rat are consistent simply with differences in fluid pH.

The solvent 2-methoxyethanol is embryotoxic and teratogenic in all species tested to date. The proximate teratogen appears to be the metabolite 2-methoxyacetic acid (2-MAA). A physiologically based pharmacokinetic model has been developed for the pregnant mouse (Terry et al., 1995). Pharmacokinetics and tissue partition coefficients for 2-MAA were determined at different stages of embryonal development, and various models were tested based on the alternative hypotheses involving (1) blood-flow limited delivery of 2-MAA to model compartments, (2) pH trapping of ionized 2-MAA within compartments, (3) active transport of 2-MAA into compartments, and (4) reversible binding of 2-MAA within compartments. While the blood-flow limited model best predicted gestation day 8 dosimetry, the active transport models better described dosimetry on gestation days 11 and 13. Using published data on biotransformation of 2-methoxyethanol to ethylene glycol and 2-MAA in rats, Hays et al. (2000) have adapted the pregnant mouse PBPK model to the pregnant rat and successfully predicted tissue levels of 2-MAA following oral or intravenous administration of 2-methoxyethanol. The next step was to extrapolate this model to the inhalation route of exposure, and to model both rats and humans (Gargas et al., 2000). The extrapolation of the model enabled predictions of the exposures needed for pregnant women to reach blood concentrations (Cmax or AUC) equivalent to those in pregnant rats exposed to the no observed adverse effect level (NOAEL) or LOAEL for developmental toxicity. The body of work on PBPK modeling of 2-methoxyethanol is exemplary of the power of these techniques for extrapolating across dose, developmental stage, route, and species.

Maternal metabolism of xenobiotics is an important and variable determinant of developmental toxicity. As for other health endpoints, the developing field of pharmacogenomics offers hope for increasing our ability to predict susceptible subpopulations based on empirical relationships between maternal genotype and fetal phenotype. These relationships will hopefully guide further work to elucidate mechanisms of toxicant-induced abnormal development.

RELATIONSHIPS BETWEEN MATERNAL AND DEVELOPMENTAL TOXICITY

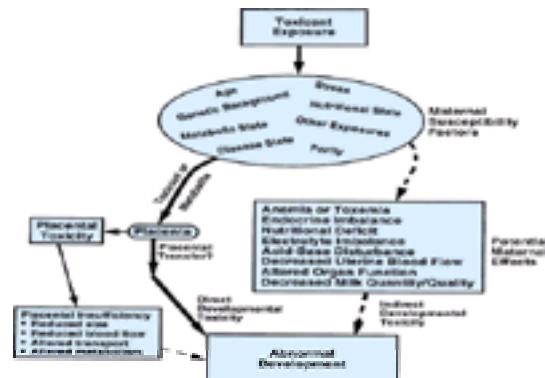
Although all developmental toxicity must ultimately result from an insult to the conceptus at the cellular level, the insult may occur through a direct effect on the embryo/fetus, indirectly through toxicity of the agent to the mother and/or the placenta, or a combination of direct and indirect effects. Maternal conditions capable of adversely affecting the developing organism include decreased uterine blood flow, maternal anemia, altered nutritional status, toxemia, altered organ function, autoimmune states, diabetes, electrolyte or acid-base disturbances, decreased milk quantity or quality, and abnormal behavior (Chernoff et al., 1989; Daston, 1994). Induction or exacerbation of such maternal conditions by toxic agents and the degree to which they manifest in abnormal development are dependent on maternal genetic background, age, parity, size, nutrition, disease, stress, and other health parameters and exposures (DeSesso, 1987; Chernoff, et al., 1989). These relationships are depicted in Fig. 10-7. In this section we will discuss maternal conditions known to adversely affect the conceptus, as well as examples of xenobiotics whose developmental toxicity results completely or in large part from maternal or placental toxicity.


Figure 10-7. Interrelationships between maternal susceptibility factors, metabolism, induction of maternal physiologic or functional alterations, placental transfer and toxicity, and developmental toxicity.

A developmental toxicant can cause abnormal development through any one or a combination of these pathways. Maternal susceptibility factors determine the predisposition of the mother to respond to a toxic insult, and the maternal effects listed can adversely affect the developing conceptus. Most chemicals traverse the placenta in some form, and the placenta can also be a target for toxicity. In most cases, developmental toxicity is probably mediated through a combination of these pathways.

The distinction between direct and indirect developmental toxicity is important for interpreting safety assessment tests in pregnant animals, as the highest dosage level in these experiments is chosen based on its ability to produce some maternal toxicity (e.g., decreased food or water intake, weight loss, clinical signs). However, maternal toxicity defined only by such manifestations gives little insight to the toxic actions of a xenobiotic. When developmental toxicity is observed only in the presence of maternal toxicity, the developmental effects may be indirect; however, understanding of the physiologic changes underlying the observed maternal toxicity and elucidation of the association with developmental effects is needed before one can begin to address the relevance of the observations to human safety assessment. Many known human developmental toxicants, including ethanol and cocaine, adversely affect the embryo/fetus predominately at maternally toxic levels, and part of their developmental toxicity may be ascribed to secondary effects of maternal physiological disturbances. For example, the nutritional status of alcoholics is generally inadequate, and effects on the conceptus may be exacerbated by effects of alcohol on placental transfer of nutrients. Effects of chronic alcohol abuse on maternal folate and zinc metabolism may be particularly important in the induction of fetal alcohol syndrome (Dreosti, 1994).

Maternal Factors Affecting Development

Genetics The genetic makeup of the pregnant female has been well documented as a determinant of developmental outcome in both humans and animals. The incidence of cleft lip and/or palate [CL(P)], which occurs more frequently in whites than in blacks, has been investigated in offspring of interracial couples in the United States (Khoury et al., 1983). Offspring of white mothers had a higher incidence of CL(P) than offspring of black mothers after correcting for paternal race, while offspring of white fathers did not have a higher incidence of CL(P) than offspring of black fathers after correcting for maternal race.

Among experimental animals, the "A" family of inbred mice has a high spontaneous occurrence of cleft lip and palate (Kalter, 1979). Two related mouse strains, A/J and CL/Fr, produce spontaneous CL(P) at 8 to 10 percent and 18 to 26 percent frequencies, respectively. The incidence of CL(P) in offspring depends on the genotype of the mother rather than that of the embryo (Juriloff and Fraser, 1980). The response to vitamin A of murine embryos heterozygous for the curly-tail mutation depends on the genotype of the mother (Seller et al., 1983). The teratogenicity of phenytoin has been compared in several inbred strains of mice. The susceptibility of offspring of crosses between susceptible A/J mice and resistant C57BL/6J mice was determined by the maternal, but not the embryonic genome (Hansen and Hodes, 1983). New genomic approaches have begun to identify genes associated with differential susceptibility of mouse strains to valproic acid (Finnell et al., 1997; Craig et al., 2000; Bennett et al., 2000; Faiella et al., 2000).

Disease Chronic hypertension is a risk factor for the development of preeclampsia, eclampsia, and toxemia of pregnancy, and hypertension is a leading cause of pregnancy-associated maternal deaths. Uncontrolled maternal diabetes mellitus is a significant cause of prenatal morbidity. Certain maternal infections can adversely effect the conceptus (e.g., rubella virus, discussed earlier), either through indirect disease-related maternal alterations or direct transplacental infection. Cytomegalovirus infection is associated with fetal death, microcephaly, mental retardation, blindness, and deafness (MacDonald and Tobin, 1978) and maternal infection with *Toxoplasma gondii* is known to induce hydrocephaly and chorioretinitis in infants (Alford et al., 1974).

One factor common to many disease states is hyperthermia. Hyperthermia is a potent experimental animal teratogen (Edwards, 1986), and there is a body of evidence associating maternal febrile illness during the first trimester of pregnancy with birth defects in humans, most notably malformations of the central nervous system (Warkany, 1986; Milunsky, et al., 1992).

Nutrition A wide spectrum of dietary insufficiencies ranging from protein-calorie malnutrition to deficiencies of vitamins, trace elements and/or enzyme cofactors is known to adversely affect pregnancy (Keen et al., 1993). Among the most significant findings related to human nutrition and pregnancy outcome in recent years are results of studies in which pregnant women at risk for having infants with neural tube defects (NTDs) were supplemented with folate (Wald, 1993). The largest and most convincing study is the Medical Research Council (MRC) Vitamin Study, in which supplementation with 4 mg of folic acid reduced NTD recurrence by over 70 percent (MRC, 1991; Bendich, 1993). Results of these studies have prompted the U.S. Centers for Disease Control and Prevention to recommend folate supplementation for women of childbearing age and folate supplementation of some foodstuffs.

Stress Diverse forms of maternal toxicity may have in common the induction of a physiologic stress response. Understanding potential effects of maternal stress on development may help interpret developmental toxicity observed in experimental animals at maternally toxic dosages. Various forms of physical stress have been applied to pregnant animals in attempts to isolate the developmental effects of stress. Subjecting pregnant rats or mice to noise stress throughout gestation can produce developmental toxicity (Kimmel et al., 1976; Nawrot et al., 1980, 1981). Restraint stress produces increased fetal death in rats (Euker and Riegle, 1973) and cleft palate (Barlow et al., 1975), fused and supernumerary ribs, and encephaloceles in mice (Beyer and Chernoff, 1986).

Objective data on effects of stress in humans are difficult to obtain. Nevertheless, studies investigating the relationship of maternal stress and pregnancy outcome have indicated a positive correlation between stress and adverse developmental effects, including low birth weight and congenital malformations (Stott, 1973; Gorsuch and Key, 1974).

Placental Toxicity The placenta is the interface between the mother and the conceptus, providing attachment, nutrition, gas exchange, and waste removal. The placenta also produces hormones critical to the maintenance of pregnancy, and it can metabolize and/or store xenobiotics. Placental toxicity may compromise these functions and produce or contribute to untoward effects on the conceptus. Slikker and Miller (1994) list 46 toxicants known to be toxic to the yolk sac or chorioallantoic placenta, including metals such as cadmium (Cd), arsenic or mercury, cigarette smoke, ethanol, cocaine, endotoxin and sodium salicylate (Daston, 1994; Slikker and Miller, 1994). Cd is among the best studied of these, and it appears that the developmental toxicity of Cd during mid- to late gestation involves both placental toxicity (necrosis, reduced blood flow) and inhibition of nutrient transport across the placenta. Maternal injection of Cd during late gestation results in fetal death in rats, despite little cadmium entering the fetus (Parizek, 1964; Levin and Miller, 1980). Fetal death occurs concomitant with reduced uteroplacental blood flow within 10 h (Levin and Miller, 1980). The authors' conclusion that fetal death was caused by placental toxicity was supported by experiments in which fetuses were directly injected with Cd. Despite fetal Cd burdens almost tenfold higher than those following maternal administration, only a slight increase in fetal death was observed.

Cd is a transition metal similar in its physicochemical properties to the essential metal zinc (Zn). Cadmium interferes with Zn transfer across the placenta (Ahokas et al., 1981; Sorell and Graziano, 1990), possibly via metallothionein (MT), a metal-binding protein induced in the placenta by Cd. Because of its high affinity for Zn, MT may sequester Zn in the placenta, impeding transfer to the conceptus (induction of maternal hepatic MT by Cd or other agents can also induce fetal Zn deficiency, as discussed below). Cadmium inhibits Zn uptake by human placental microvesicles (Page et al., 1992) suggesting that Cd may also compete directly with Zn for membrane transport. Cadmium may also competitively inhibit other Zn-dependent processes in the placenta. Coadministration of Zn ameliorates the developmental toxicity of administered Cd, further indicating that interference of Cd with Zn metabolism is a key to its developmental toxicity (Ferm and Carpenter, 1967, 1968;

Daston, 1982).

Maternal Toxicity A retrospective analysis of relationships between maternal toxicity and specific types of prenatal effects found species-specific associations between maternal toxicity and specific adverse developmental effects. Yet, among rat, rabbit, and hamster studies, 22 percent failed to show any developmental toxicity in the presence of significant maternal toxicity (Khera, 1984, 1985). The approach of tabulating literature data suffers from possible bias in the types of studies published (e.g., negative results may not be published), incomplete reporting of maternal and developmental effects, and lack of standard criteria for the evaluation of maternal and developmental toxicity. In a study designed to test the potential of maternal toxicity to affect development, Kavlock et al. (1985) acutely administered 10 structurally unrelated compounds to pregnant mice at maternotoxic dosages. Developmental effects were agent-specific, ranging from complete resorption to lack of effect. An exception was an increased incidence of supernumerary ribs (ribs on the first lumbar vertebra), which occurred with 7 of the 10 compounds. Chernoff et al. (1990) dosed pregnant rats for 10 days with a series of compounds chosen because they exhibited little or no developmental toxicity in previous studies. When these compounds were administered at high dosages producing maternal toxicity (weight loss or lethality), a variety of adverse developmental outcomes was noted, including increased intrauterine death (two compounds), decreased fetal weight (two compounds), supernumerary ribs (two compounds), and enlarged renal pelves (two compounds). In addition, two of the compounds produced no developmental toxicity despite substantial maternal toxicity. These diverse developmental responses led the authors to conclude that maternal toxicity defined by weight loss or mortality is not associated with any consistent syndrome of developmental effects in the rat.

There have been a number of studies directly relating specific forms of maternal toxicity to developmental toxicity, including those in which the test chemical causes maternal effects that exacerbate the agent's developmental toxicity, as well as instances in which developmental toxicity is thought to be the direct result of adverse maternal effects. However, clear delineation of the relative role(s) of indirect maternal and direct embryo/fetal toxicity is difficult.

Acetazolamide inhibits carbonic anhydrase and is teratogenic in mice (Hirsch and Scott, 1983). Although maternal weight loss is not correlated with malformation frequency, maternal hypercapnia potentiates the teratogenicity of acetazolamide. In C57Bl/6J mice, maternal hypercapnia alone results in right forelimb ectrodactyly, the characteristic malformation induced by acetazolamide. Correction of maternal acidosis failed to reduce developmental toxicity, suggesting that the primary teratogenic factor was elevated maternal plasma CO_2 tension (Weaver and Scott, 1984a,1984b).

Diflunisal, an analgesic and anti-inflammatory drug, causes axial skeletal defects in rabbits. Developmentally toxic dosages resulted in severe maternal anemia (hematocrit=20–24 percent vs. 37 percent in controls) and depletion of erythrocyte ATP levels (Clark et al., 1984). Teratogenicity, anemia, and ATP depletion were unique to the rabbit among the species studied. A single dose of diflunisal on day 5 of gestation produced a maternal anemia that lasted through day 15. Concentration of the drug in the embryo was less than 5 percent of the peak maternal blood level, and diflunisal was cleared from maternal blood before day 9, the critical day for induction of similar axial skeletal defects by hypoxia. Thus, the teratogenicity of diflunisal in the rabbit was probably due to hypoxia resulting from maternal anemia.

Phenytoin, an anticonvulsant, can affect maternal folate metabolism in experimental animals, and these alterations may play a role in the teratogenicity of this drug (Hansen and Billings, 1985). Further, maternal heart rates were monitored on gestation day 10 after administration to susceptible A/J mice and resistant C57Bl/6J mice (Watkinson and Millikovsky, 1983). Heart rates were depressed by phenytoin in a dose-related manner in the A/J mice but not in C57Bl/6J mice. A mechanism of teratogenesis was proposed relating depressed maternal heart rate and embryonic hypoxia. Supporting studies have demonstrated that hyperoxia reduces the teratogenicity of phenytoin in mice (Millicovsky and Johnston, 1981). Reduced uterine blood flow, has been proposed as a mechanism of teratogenicity caused by hydroxyurea, which produces elevated systolic blood pressure, altered heart rate, decreased cardiac output, severely decreased uterine blood flow, and increased vascular resistance in pregnant rabbits (Millicovsky et al., 1981). Embryos exhibited craniofacial and pericardial hemorrhages immediately after treatment (Millicovsky and DeSesso, 1980a), and identical embryopathies were achieved by clamping the uterine vessels of pregnant rabbits for 10 minutes (Millicovsky and DeSesso, 1980b).

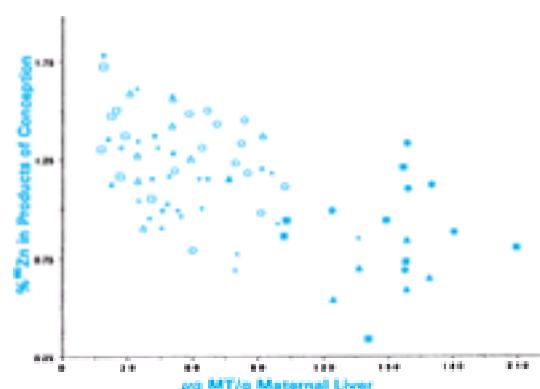
Metallothionein synthesis is inducible by a wide variety of chemical and physical agents including metals, alcohols, urethane, endotoxin, alkylating agents, hyper- or hypothermia, and ionizing radiation (Daston, 1994). MT synthesis is also induced by endogenous mediators such as glucocorticoids and certain of the cytokines (Klaassen and Lehman-McKeeman, 1989). A mechanism common to the developmental toxicity of these diverse agents may be Zn deficiency of the conceptus secondary to induction of maternal MT. Induction of MT synthesis can produce hepatic MT concentrations over an order of magnitude higher than normal, leading to substantial sequestration of circulating Zn in maternal liver, lowered plasma Zn concentrations, and reduced Zn availability to the conceptus. Embryofetal zinc deficiency secondary to maternal hepatic MT induction has been demonstrated for diverse chemicals including valproic acid (Keen et al., 1989), 6-mercaptopurine (Amemiya et al., 1986, 1989), urethane (Daston et al., 1991), ethanol, and a-hederin (Taubeneck et al., 1994). In a study combining data for many of these compounds, Taubeneck and coworkers (1994) found a strong positive relationship between maternal hepatic MT induction and maternal hepatic [65]Zn retention, and a negative relationship between maternal MT induction and [65]Zn distribution to the litter (Fig. 10-8).


Figure 10-8. Transfer of [65]Zn to the products of conception as a function of maternal hepatic metallothionein (MT) concentration.

Pregnant rats were dosed on gestation day 11 with: ● a-hederin; □ dimethylsulfoxide; □ ethanol;▲ urethane; +melphalan; ◆ acidified alcohol; or □ styrene, or were ○ food-deprived or △ food-restricted. □: Saline control. Eight hours after dosing, dams were orally gavaged with a diet slurry containing [65]Zn. The amount of [65]Zn transferred to the conceptuses was inversely correlated with the degree of treatment-related maternal hepatic MT induction. [Adapted from Taubeneck et al. (1994) with permission.]

DEVELOPMENTAL TOXICITY OF ENDOCRINE-DISRUPTING CHEMICALS

One of the most pressing environmental issues facing developmental and reproductive toxicology in recent years has been the growing concern that exposure to chemicals that can interact with the endocrine system may pose a serious health hazard (Toppari, et al., 1996; Kavlock et al 1996; National Research Council, 1999). An "endocrine disruptor" has been broadly defined as "an exogenous agent that interferes with the production, release, transport, metabolism, binding, action, or elimination of natural hormones responsible for the maintenance of homeostasis and the regulation of developmental processes" (Kavlock et al., 1996). Due to the critical role of hormones in directing differentiation in many tissues, the developing organism is particularly vulnerable to fluctuations in the timing or intensity of exposure to chemicals with hormonal (or antihormonal) activity. Chemicals from a wide variety of chemical classes (e.g., pesticides, herbicides, fungicides, plasticizers, surfactants, organometals, halogenated polyaromatic hydrocarbons, phytoestrogens) have been shown to induce developmental toxicity via at least four modes of action involving the endocrine system: (1) by serving as steroid receptors ligands; (2) by modifying steroid hormone metabolizing enzymes; (3) by perturbing hypothalamic-pituitary release of trophic hormones; and (4) by as yet uncharacterized proximate modes of action. Interactions with the functions of estrogens, androgens, and thyroid hormones have been the most studied.

Laboratory Animal Evidence

Chemicals with estrogenic activity are a well-described class of developmental toxicants based on standard criteria of causing specific malformations during critical developmental periods of relatively short duration (Schardein, 2000). Estrogens induce pleiotropic effects, acting on many types of cells with estrogen receptors, and

can display cell and organ-specific agonist and antagonist actions. The pattern of outcomes is generally similar across different estrogens, although not all possible outcomes have been described for each. Diethylstilbestrol (DES) provides one of the most well characterized examples of the effects of an estrogen on development. Manifestations of DES exposure include malformations and adverse functional alterations of the male and female reproductive tract and brain. In the CD-1 mouse, effective exposures are in the range of 0.01 to 100 µg/kg on GD 9-16 (Newbold, 1995). At the higher end of the exposure range (10 to 100 µg/kg), total sterility of female offspring is noted, due in part to structural abnormalities of the oviduct, uterus, cervix, and vagina and to depletion and abnormalities of ovarian follicles. In adulthood, male offspring show hypospadias, while females exhibit excessive vaginal keratinization and epidermoid tumors of the vagina. Vaginal adenocarcinoma is seen at dosages as low as 2.5 µg/kg. Benign uterine tumors (leiomyomas) are seen as low as 0.1 µg/kg. In male offspring, sterility is observed at high doses, the result of retained rete testes and Mullerian duct remnants, abnormal sperm morphology and motility, lesions in the reproductive tract (including cryptorchidism and rete testis adenocarcinoma), abnormal reproductive tract secretions, and inflammation (Newbold, 1995). Other estrogenic (or anti-estrogenic) developmental toxicants include estradiol (Biegel et al., 1998, Cook et al., 1998), ethynyl estradiol, antiestrogenic drugs such as tamoxifen and clomiphene citrate (Branham et al., 1988), and pesticides and industrial chemicals such as methoxychlor (Gray et al., 1989), *o,p*'-DDT (Heinrichs et al., 1971), kepone (Gellert, 1978; Guzelian, 1982), Zdioxins (Mably et al., 1992, Gray et al., 1997a, 1997b), bisphenol A (Nagel et al., 1997), and phytoestrogens such as genistein and coumestrol (Medlock et al., 1995). Female offspring are generally more sensitive than males and altered pubertal development, reduced fertility, and reproductive tract anomalies are common findings.

While most of the studies on estrogens have indicated traditional dose–response patterns of effect, with severity and incidence increasing with dose, vom Saal and coworkers (vom Saal et al., 1997; Nagel et al., 1997) have reported that unusual dose–response patterns may occur for endocrine effects on some endpoints. In their studies, a 50 percent elevation in fetal serum estradiol concentration resulting from implantation of estradiol–containing Silastic capsules on days 13 to 19 of gestation in mice caused a 30 percent increase in adult prostate weight, whereas higher maternal serum concentrations were associated with decreased adult prostate weight. A similar pattern was observed for DES given on days 11 to 17 of gestation, as increased adult prostate weights were seen between 0.02 and 20 ng/kg/day, whereas 200 ng/kg/day resulted in smaller prostates. Bisphenol A (2 or 20 µg/kg/day on gestation days 11 to 17) also increased adult prostate weight in these mice. These examples indicate an inverted U-shaped dose–response curve for this endpoint, and bring into question the design of hazard identification studies in the risk assessment of endocrine-mediated developmental responses. However, the issue is controversial, as other researchers using similar testing paradigms have not seen this pattern (e.g., Cagen et al., 1999).

Antiandrogens represent another major class of endocrine disrupting chemicals. Principal manifestations of developmental exposure to an antiandrogen are generally restricted to males, and include hypospadias, retained nipples, reduced testes and accessory sex gland weights, and decreased sperm production. Examples of chemicals known to affect development via an antiandrogenic mechanism include pharmaceuticals such as the androgen receptor antagonist flutamide (Imperato-McGinley et al., 1992) and the 5a-reductase inhibitor finasteride (Clark et al., 1990), and environmentally relevant compounds such as the fungicide vinclozolin (Gray et al., 1994) and the DDT metabolite *p,p*'-DDE (Kelce et al., 1995; You et al., 1998) which are both androgen receptor antagonists. Recently, a phthalate ester (dibutylphthalate) has been shown to induce an antiandrogen phenotype in developing rats, but the effect does not appear to be mediated by direct interaction with the androgen receptor (Mylchreest et al., 1998, 1999). Hypothyroidism causes growth retardation, cognitive deficits, delayed eye opening, hyperactivity, and auditory defects in rodents. The most commonly used chemical to induce these outcomes is propylthiouracil. Polychlorinated biphenyls (PCBs) may act at several sites to lower thyroid hormone levels during development, and cause body weight and auditory deficits (Goldey et al., 1995; Goldey and Crofton, 1998). PCBs also cause learning deficits and alter locomotor activity patterns in rodents (Eriksson et al., 1991; Schantz et al., 1995) and monkeys (Bowman, 1982; Schantz et al., 1991). Some effects, such as deficits in spatial learning ability, closely resemble those seen following neonatal hypothyroidism (Porterfield, 1994). Interestingly, hypothyroidism induced by neonatal treatment of rats with Arochlor 1254 also increases testis weight and sperm production by prolonging the period in which Sertoli cell proliferation is possible (Cooke, Zhao, and Hansen, 1996).

Human Evidence

Despite the biological plausibility of effects demonstrated in numerous laboratory studies, it is not clear whether human health is being adversely impacted from exposures to endocrine disruptors present in the environment. In part this is due to the extraordinary difficulty in demonstrating cause-and-effect relationships in epidemiologic studies where the signals may be weak, the effects evident only long after an exposure, and the endpoints sensitive to a number of other factors. Reports in humans which are or may be relevant to developmental toxicity from endocrine disruption are of two types: (1) Observations of adverse effects on reproductive system development and function following exposure to chemicals with known endocrine activities that are present in medicines, contaminated food, or the workplace. These have tended to involve relatively higher exposure to chemicals with known endocrine effects. (2) Epidemiologic evidence of increasing trends in reproductive and developmental adverse outcomes that have an endocrine basis. With the exception of the classic case of DES (Herbst and Bern, 1981), evidence is either lacking to support a definitive link to an exposure, or appears to be variable across study populations as to whether the responses are observed at all. For example, secular trends have been reported for cryptorchidism (Toppari et al., 1996); hypospadias (Toppari et al., 1996; Pauluzzi et al., 1997; Pauluzzi, 1999); semen quality (Carlsen et al., 1992; Skakkebaek and Keiding, 1994; Olsen et al., 1995; Swan et al., 1997; Auger et al., 1995; de Mouzon et al., 1996; Irvine et al., 1996; Vierula et al., 1996; Bujan et al., 1996; Fisch and Goluboff, 1996), and testicular cancer (Toppari et al., 1996), but due to the lack of exposure assessment, such studies provide limited evidence of a cause and effect relationship.

The most convincing evidence for effects of endocrine-disrupting chemicals in humans comes from reports of neurobehavioral changes and learning deficits in children exposed to PCBs in utero or lactationally, either through their mothers' consumption of PCB-contaminated fish (Jacobson et al., 1990; Jacobson and Jacobson, 1996) or through exposure to background levels of PCBs in the United States (Rogan and Gladen, 1991) or the Netherlands (Koopman-Esseboom et al., 1996). In addition, there have been two occurrences of high level exposure to contaminated rice oil (in Japan in 1968 and in Taiwan in 1979) in which alterations in development of ectodermal tissues and delays in neurological development were seen (Hsu et al., 1985; Yu et al., 1991; Guo et al., 1994; Schecter et al., 1994). In these cases, there was co-exposure to polychlorinated dibenzofurans as well as PCBs. The precise mode of action of the developmental neurotoxicity of PCBs is, however, not yet understood.

Impact on Screening and Testing Programs

The findings of altered reproductive development following early life stage exposures to endocrine disrupting chemicals helped prompt revision of traditional safety evaluation tests such as those recently issued by the EPA (US EPA, 1997). These now include assessments of female estrous cyclicity, sperm parameters (total number, percent progressively motile and sperm morphology in both the parental and F1 generations), the age at puberty in the F1s (vaginal opening in the female, preputial separation in the males); an expanded list of organs for either pathology, gravimetric analysis, and/or histopathology to identify and characterize effects at the target organ; as well as some triggered endpoints including ano-genital distance in the F2s and primordial follicular counts in the parental and F1 generations. For the new prenatal developmental toxicity test guidelines, one important modification aimed at improved detection of endocrine disruptors was the expansion of the period of dosing from the end of organogenesis (i.e., palatal closure) to the end of pregnancy in order to include the developmental period of urogenital differentiation.

Over the past several years, two environmental laws enacted by the U.S. Congress specifically require the testing of pesticides and other chemicals found in or on food or in drinking water sources be tested for their potential to cause "estrogenic or other endocrine effects in humans." The Food Quality Protection Act of 1996 (FQPA) and the Safe Drinking Water Act Amendments of 1996 (SDWA) require the EPA to, within 2 years of enactment, develop a screening program using appropriate, valid test systems to determine whether substances may have estrogenic or other endocrine effects in humans. The screening program must undergo a public comment period and peer review and be implemented within 3 years. The laws require that the manufacturers, registrants, or importers conduct the testing of the pesticides and other substances according to the program the EPA develops. An external advisory to EPA, the Endocrine Disruptor Screening and Testing Advisory Committee (EDSTAC), has recommended a battery of assays both for screening and testing potential EDCs that will be used to address the mandates of the FQPA and SDWA (US EPA, 1998). The assays are intended to detect potential interaction with both the sex steroids (estrogen and testosterone) and with thyroid hormone function, and include assessment of both potential human health effects and effects in wildlife. To help prioritize chemicals for screening and testing, the EDSTAC recommended a high through put screening (HTPS) cell-based, receptor-mediated gene transcription assay for chemicals that act either as agonists or antagonists for the estrogen, androgen, or thyroid receptor. It has been estimated that perhaps 15,000 chemicals would be evaluated in the HTPS. The EDSTAC recommendation for the "tier 1" screening (T1S) battery includes three in vitro assays and five in vivo assays. The in vitro assays in T1S include an estrogen receptor binding or transcriptional activation assay; an androgen receptor binding or transcriptional activation assay; and a steroidogenesis assay using minced testis. The five in vivo screens recommended include the rodent 3-day uterotrophic assay; a rodent 20-day pubertal female assay for effects on thyroid function; a male rodent 5-7 day Hershberger assay; a frog metamorphosis assay for thyroid effects; and a fish partial life cycle test. It is estimated that perhaps as many as 1500 chemicals would enter the T1S, and positive chemicals would move into a second level (T2T) where more defined toxicological responses would be characterized. Protocols for these assays are currently being developed, and they should be in use within the 5 year time frame set forth in the legislation.

MODERN SAFETY ASSESSMENT

Experience with chemicals that have the potential to induce developmental toxicity indicates that both laboratory animal testing and surveillance of the human

population (i.e., epidemiologic studies) are necessary to provide adequate public health protection. Laboratory animal investigations are guided both by regulatory requirements for drug or chemical marketing as well as by the basic desire to understand mechanisms of toxicity.

Regulatory Guidelines for in Vivo Testing

Prior to the thalidomide tragedy, safety evaluations for reproductive effects were limited in both the types of chemicals evaluated and the sophistication of the endpoints. Subsequently, the FDA issued more extensive testing protocols (termed Segments I, II, and III) for application to a broader range of agents (US FDA, 1966). These testing protocols, with minor variations, were adopted by a variety of regulatory agencies around the world and remained similar for nearly thirty years. Several factors including the historical experience of testing thousands of chemicals, increased knowledge of basic reproductive processes, the ever-increasing cost of testing, the acknowledged redundancy and overlap of required protocols, a growing divergence in study design requirements of various countries, and the expanding international presence of the pharmaceutical industry have succeeded in producing new and streamlined testing protocols that have been accepted internationally (US FDA, 1994). These guidelines, the result of the International Conference of Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH), specifically include considerable flexibility in implementation depending on the particular circumstances of the agent under evaluation. Rather than specify study and technical details, they rely on the investigator to meet the primary goal of detecting and bringing to light any indication of toxicity to reproduction. Palmer (1993) has provided an overview of issues relevant to implementing the ICH guideline. Key elements of the FDA Segment I, II and III studies, the ICH protocols, and the OECD equivalent of the FDA Segment II test are provided in Table 10-4. In each protocol, guidance is provided on species/strain selection, route of administration, number and spacing of dosage levels, exposure duration, experimental sample size, observational techniques, statistical analysis, and reporting requirements. Details are available in the original publications as well as in several reviews (e.g., Manson, 1994; Claudio et al., 1999). Variation of these protocols also exist that include extensions of exposure to early or later time points in development and extensions of observations to postnatal ages with more sophisticated endpoints. For example, the EPA has developed a Developmental Neurotoxicity Protocol for the rat that includes exposure from gestation day 6 though lactation day 10, and observation of postnatal growth, developmental landmarks of puberty (balanopreputial separation, vaginal opening), motor activity, auditory startle, learning and memory, and neuropathology at various ages through postnatal day 60 (US EPA, 1998).

Table 10-4 Summary of in Vivo Regulatory Protocol Guidelines for Evaluation of Developmental Toxicity

The general goal of these regulatory studies is to identify the NOAEL, which is the highest dosage level that does not produce a significant increase in adverse effects in the offspring. These NOAELs are then used in the risk assessment process (see below) to assess the likelihood of effects in humans given certain exposure conditions.

Multigeneration Tests

Information pertaining to developmental toxicity can also be obtained from studies in which animals are exposed to the test substance continuously over one or more generations. For additional information on this approach, see Chap. 20.

Children's Health and the Food Quality Protection Act

In 1993, the National Academy of Sciences published a report entitled "Pesticides in the Diets of Infants and Children," which brought to light the fact that infants and children differ both qualitatively and quantitatively from adults in their exposure to pesticide residues in food because of different dietary composition and intake patterns and different activities (NRC, 1993). This report, along with the report from the International Life Sciences Institute entitled "Similarities and Differences between Children and Adults" (Guzelian et al., 1992) provided background and impetus for passage of the Food Quality Protection Act (FQPA) of 1996. The FQPA incorporates an additional tenfold safety factor for children, cumulative effects of toxicants acting through a common mode of action, aggregate exposure (i.e., same toxicant from different sources), and endocrine disruption (see above). The inclusion (at the discretion of the EPA) of the tenfold factor for calculating allowable intakes for children affects most strongly the pesticide industry, whose products appear as residues in food. The application of this safety factor is controversial, in part because its opponents claim that developmental susceptibility is already considered in other tests, such as the Segment II test for prenatal toxicity, the two-generation test, and the developmental neurotoxicity test. On the other hand, proponents applaud the measure and point to the numerous factors that may increase the exposure of infants and children to environmental toxicants and their susceptibility to harm from these exposures. Children have different diets than adults and also have activity patterns that change their exposure profile compared to adults, such as crawling on the floor or ground, putting their hands and foreign objects in their mouths, and raising dust and dirt during play. Even the level of their activity (i.e., closer to the ground) can affect their exposure to some toxicants. In addition to exposure differences, children are growing and developing, which makes them more susceptible to some types of insults. Effects of early childhood exposure, including neurobehavioral effects and cancer, may not be apparent until later in life. Debate continues over the approach to be used in risk assessment in consideration of infants and children.

Alternative Testing Strategies

A variety of alternative test systems have been proposed to refine, reduce, or replace reliance on the standard regulatory mammalian tests for assessing prenatal toxicity (Table 10-5). These can be grouped into assays based on cell cultures, cultures of embryos in vitro (including submammalian species), and short term in vivo tests. Some effort has been made to qualitatively and quantitatively compile results across both the standard and the alternative tests (Faustman, 1988; Kavlock, et al., 1991). Daston (1996) has discussed the theoretical and empirical underpinnings supporting the use of a number of these systems. Yet, validation of these alternative tests continues to be a major and as yet unresolved issue (Neubert, 1989; Welsch, 1990). Much of the early validation work used a selection of chemicals proposed by Smith et al. (1983) which has been criticized as being biased toward direct acting cytotoxicants and for not factoring in potential confounding of fetal effects by maternal toxicity (Johnson, 1985; Brown 1987). Lacking an accepted standard, assessing the significance of the sensitivity and specificity of results from the tests has been problematic. While it was initially hoped that the alternative approaches would become generally applicable to all chemicals, and help prioritize full scale testing, this has not been accomplished. Indeed, given the complexity of embryogenesis and the multiple mechanisms and target site of potential teratogens, it was perhaps unrealistic to have expected a single test, or even a small battery, to accurately prescreen the activity of chemicals in general. To date, their primary success has come from evaluating the relative potency of series of congeners when the prototype chemical has demonstrated appropriate concordance with the in vivo result (Kavlock, 1993). Over the past several years, a validation study of three in vitro embryotoxicity assays, the rat embryo limb bud micromass assay, the mouse embryonic stem cell test, and the rat embryo culture test, has been carried out (Genschow et al., 2000). This study involves interlaboratory blind trials to validate these assays, and the approach involves the development of "prediction models" which mathematically combine assay endpoints to determine which combination and formulation are most predictive of mammalian in vivo results.

Table 10-5 Brief Survey of Alternative Test Methodologies for Developmental Toxicity

An exception to the poor acceptance of alternate tests for prescreening for developmental toxicity is the in vivo test developed by Chernoff and Kavlock (1982). In this test, pregnant females are exposed during the period of major organogenesis to a limited number of dosage levels near those inducing maternal toxicity, and offspring are evaluated over a brief neonatal period for external malformations, growth, and viability. It has proven reliable over a large number of chemical agents and classes (Hardin et al., 1987), and a regulatory testing guideline has been developed (US EPA, 1985).

Epidemiology

Reproductive epidemiology is the study of the possible statistical associations between specific exposures of the father or pregnant woman and her conceptus and the outcome of pregnancy. In rare situations, such as rubella, thalidomide, and isotretinoin, where a relatively high risk exists and the outcome is a rare event, formal studies may not be needed to identify causes of abnormal birth outcomes. The plausibility of linking a particular exposure with a series of case reports increases with the rarity of the defect, the rarity of the exposure in the population, a small source population, a short time span for study, and biological plausibility for the association (Khoury et al., 1991). In other situations, such as occurred with ethanol and valproic acid, associations are sought through either a case-control or a cohort approach. Both approaches require accurate ascertainment of abnormal outcomes and exposures, and a large enough effect and study population to detect an elevated risk. Therein lies one of the difficulties for epidemiologists studying abnormal reproductive outcomes. For example, it has been estimated that the monitoring of more than 1 million births would have been necessary to detect a statistically significant increase in the frequency of spina bifida following the introduction of valproic acid in the United States, where the frequency of exposure was less than 1 in 1000 pregnancies and the risk was only a doubling over the background incidence (Khoury et al., 1987). Another challenge to epidemiologists is the high percentage of human pregnancy wastage, perhaps as much as 31 percent in the peri-implantation period (Wilcox et al., 1988) and an additional 15 percent that are clinically recognized. Therefore, pregnancy failures related to a particular exposure may go undetected in the general population. Furthermore, with the availability of prenatal diagnostic procedures, additional pregnancies of malformed embryos (particularly neural tube defects) are electively aborted. Thus, the incidence of abnormal outcomes at birth may not reflect the true rate of abnormalities, and the term prevalence, rather than incidence, is preferred when the denominator is the number of live births rather than total pregnancies. Other issues particularly relevant to reproductive epidemiology include homogeneity, recording proficiency and confounding. Homogeneity refers to the fact that a particular outcome may be described differently by various recording units and that, even given a specific outcome, there can be multiple pathogenetic origins (e.g., cleft palate could arise by a variety of mechanisms). Recording difficulties relate to inconsistencies of definitions and nomenclature, and to difficulties in ascertaining or recalling outcomes as well as exposures. For example, birth weights are usually accurately determined and recalled, but spontaneous abortions and certain malformations may not be. Last, confounding by factors such as maternal age and parity, dietary factors, diseases and drug usage, and social characteristics must be accounted for in order to control for variables that affect both exposure and outcome (Khoury et al., 1992).

Epidemiologic studies of abnormal reproductive outcomes are usually undertaken with three objectives in mind: the first is scientific research into the causes of abnormal birth outcomes and usually involves analysis of case reports or clusters; a second aim is prevention and is targeted at broader surveillance of trends by birth defect registries around the world; and the last objective is informing the public and providing assurance. In this regard, it is informative to consider the review by Schardein (1993) of the method and year by which humans teratogens were detected. For 23 of 28 chemicals (including nine cancer therapeutics, androgenic hormones, antithyroid drugs, aminoglycoside antibiotics, coumarin anticoagulants, diethylstilbestrol, methylmercury, hydantoins, primidone, penicillamine, lithium, vitamin A, and retinoic acid), case reports presented the first evidence in humans. For two of these (diethylstilbestrol and lithium), the case reports were soon followed by registries that provided confirmation, while for two others (methyl mercury and hydantoins) follow-up epidemiology studies added support. For only four chemicals, alcohol, PCBs, carbamazepine, and cocaine, did an analytical epidemiological study provide the first human evidence. Evidence for one chemical, valproic acid, was first obtained by analysis of a birth defect registry. For the 28 chemicals in that review, human evidence of developmental toxicity preceded published animal evidence in eleven instances. Cohort studies, with their prospective exposure assessment and ability to monitor both adverse and beneficial outcomes, may be the most methodologically robust approach to identifying human developmental toxicants. The lack of cohort studies demonstrating risk for pregnancy may be in part due to the difficulty in making such associations, but may also reflect the fact that use in pregnancy is not associated with increased risk for the majority of drugs (Irl and Hasford, 2000).

As the human genome project comes to completion, we will have found most of the 100,000 or so human genes (Collins, 1998), and tests for over 700 genes are already available (Pagon, 1998). With ongoing genetic research, information on differential genetic susceptibility to birth defects will be accruing (Khoury, 2000). This new knowledge promises to elucidate links between genetics and disease susceptibility at a pace not possible previously. Understanding the genetic basis of susceptibility to environmentally induced birth defects will not only allow more inclusive risk assessments but should also lead to a better understanding of the mechanisms of action of developmental toxicants.

Concordance of Data

There have been several extensive reviews of the similarity of responses of laboratory animals and humans for developmental toxicants. In general, these studies support the assumption that results from laboratory tests are predictive of potential human effects. Concordance is strongest when there are positive data from more than one test species, although even in this case the results are not applicable to extrapolating specific types of effects across species. The predictiveness of animal data for presumed negative human developmental toxicants is less than that for positive agents, a finding probably related to the problems associated with ascertaining a negative response in humans as well as issues of inappropriate design or interpretation of animal studies. In a quantitative sense, the few comparisons that have been made suggest that humans tend to be more sensitive to developmental toxicants than is the most sensitive test species. While concordance among species for agents reported as positive is high, often special steps must be taken retrospectively to produce an animal model that reflects the nature of outcome in humans (e.g., valproic acid (Ehlers et al., 1992)).

Frankos (1985) reviewed data for 38 compounds having demonstrated or suspect activity in humans; all except tobramycin, which caused otologic defects, were positive in at least one and 76 percent were positive in more than one test species. Predictiveness was highest in the mouse (85 percent) and rat (80 percent), with lower rates for rabbits (60 percent) and hamsters (40 percent). Frankos identified 165 chemicals with no evidence of human effects; only 29 percent were negative in all species tested while 51 percent were negative in more than one species. Schardein and Keller (1989) examined concordance by species and developmental manifestation for 51 potential human developmental toxicants that had adequate animal data (three human developmental toxicants did not). Thalidomide received the widest testing, with data from 19 species; 53 percent had data from 3 species, while 18 percent had data from four or five species. Across all chemicals, the most common findings in humans, rabbits, and monkeys were spontaneous abortion and fetal/neonatal death followed by malformations and then growth retardation. In the rat, prenatal death, growth retardation, and then malformations was the typical pattern. The concordance of results is presented in Table 10-6. All species showed at least one positive response for 64 percent of the human developmental toxicants and, with only a single exception, all of the potential human developmental toxicants showed a positive response in at least one species. Overall, the match to the human, regardless of the nature of the developmental response, was rat, 98 percent; mouse, 91 percent; hamster, 85 percent; monkey, 82 percent; and rabbit, 77 percent. Jelovsek et al. (1989) reviewed the predictiveness of animal data for 84 negative human developmental toxicants, 33 with unknown activity, 26 considered suspicious and 32 considered positive. Variables considered included the response of each species, the number of positive and negative species, percent positive and negative species, and mutagenicity and carcinogenicity. The compounds were correctly classified 63–91 percent of the time based on animal data, depending upon how the suspect and unknown human toxicants were considered. The various models had a sensitivity of 62–75 percent, a positive predictive value of 75–100 percent, and a negative predictive value of 64 to 91 percent.

Table 10-6 Predictiveness of Animal Data for 51 Potential Human Developmental Toxicants

In addition to qualitative comparisons among species, several attempts at quantitative comparisons of potencies have been developed, although these have been based upon administered dosage and have not attempted to factor in pharmacokinetic differences. Schardein and Keller (1989) estimated the human and animal "threshold" dosages for 21 chemicals. In only two cases, aminopterin and carbon disulfide, were developmental effects seen at lower dosages in animal studies than were believed to cause effects in humans. For the other chemicals, ratios of the "threshold" dosages in the most sensitive animals to those in humans ranged from 1.2 to 200. Newman et al. (1993) looked at the data for four well-characterized human developmental toxicants: valproic acid, isotretinoin, thalidomide, and methotrexate. The monkey was the most sensitive test species for the first three chemicals, while the rabbit was the most sensitive to methotrexate. Base upon the NOAEL of the most sensitive test species, human embryos were 0.9 to approximately 10 times more sensitive.

Elements of Risk Assessment

The extrapolation of animal test data for developmental toxicity follows two basic directions, one for drugs where exposure is voluntary and usually to high dosages, the other for environmental agents where exposure is generally involuntary and to low levels. For drugs, a use-in-pregnancy rating is utilized (US FDA, 1979). In this system the letters A, B, C, D, and X are used to classify the evidence that a chemical poses a risk to the human conceptus. For example, drugs are placed in category A if adequate, well-controlled studies in pregnant humans have failed to demonstrate a risk, and in category X (contraindicated for pregnancy) if studies in animals or humans, or investigational or postmarketing reports have shown fetal risk which clearly outweighs any possible benefit to the patient. The default category is C (risks cannot be rule out), assigned when there is a lack of human studies and animal studies are either lacking or are positive for fetal risk, but the benefits may justify the potential risk. Categories B and D represent areas of relatively lesser, or greater concern for risk, respectively. Manson (1993) reviewed the 1992 Physicians' Desk Reference and found 7 percent of the 1033 drugs belonged to category X, 66 percent to category C, and only 0.7 percent to category A. The FDA categorization procedure has been criticized (Teratology Society, 1994) as being too reliant on risk/benefit comparisons, especially given that the magnitude of risk is often unknown, or the benefits are not an issue (e.g., after the drug in question has been taken during early pregnancy and the question is then directed to the management of the exposed pregnancy). The FDA system has also been criticized for demanding an unrealistically high quality of data for assignment to category A (negative controlled studies in pregnant women) and overuse of category C, interpreted as "risks cannot be ruled out" (Sannerstedt et al., 1996). This is an important issue, because presently the perception of teratogenic risk is strong among both patients and prescribers even for safe drugs (Pole et al., 2000).

For environmental agents, the purpose of the risk assessment process for noncancer endpoints such as developmental toxicity is generally to define the dose, route, timing, and duration of exposure which induces effects at the lowest level in the most relevant laboratory animal model (US EPA, 1991). The exposure associated with this "critical effect" is then subjected to a variety of safety or uncertainty factors in order to derive an exposure level for humans that is presumed to be relatively safe (see Chap. 4, "Risk Assessment"). The principal uncertainty factors include one for interspecies extrapolation and one for variability in the human population. The default value for each of these factors is 10. In the absence of firm evidence upon which to base decisions on whether or not to extrapolate animal test data, certain default assumptions are generally made. They include (1) an agent that produces an adverse developmental effect in experimental animals will potentially pose a hazard to humans following sufficient exposure during development; (2) all four manifestations of developmental toxicity (death, structural abnormalities, growth alterations, and functional deficits) are of concern; (3) the specific types of developmental effects seen in animal studies are not necessarily the same as those that may be produced in humans; (4) the most appropriate species is used to estimate human risk when data are available (in the absence of such data, the most sensitive species is appropriate); and (5) in general, a threshold is assumed for the dose–response curve for agents that produce developmental toxicity.

One of the more troubling and subjective aspects of risk assessment for developmental toxicants is distinguishing between adverse effects (defined as an unwanted effect determined to be detrimental to health) and lesser effects, which while different than those observed in control groups, are not considered significant to human health. Considerations relevant to this issue can be categorized into two areas: (1) the observance of the finding and related events in the same or associated experiments; and (2) the understanding of the biology of the effect. The interpretation of reduced fetal growth in developmental toxicity studies illustrates most of the issues. While we have accepted definitions of low birth weight in humans and understand how intrauterine growth retardation translates to an elevated risk of infant mortality and mental retardation, we do not have similar knowledge for fetal weight in rodents, and we seldom even know if reduced fetal weight recorded in prenatal toxicity studies persists beyond birth. Further complicating matters, recent epidemiological evidence suggests that birth weight in humans is a predictor of adult-onset diseases including hypertension, cardiovascular disease, and diabetes (Rich-Edwards, et al., 1999; Osmond and Barker, 2000). Exposure to famine prenatally is also predictive of obesity at 50 years of age in women (Ravelli et al., 1999) and obstructive airway disease in adulthood (Lopuhaa et al., 2000). Animal models of the long-term latent effects of prenatal conditions and toxic exposures have not been developed.

New Approaches

The Benchmark-Dose Approach The use of safety or uncertainty factors applied to an experimentally derived NOAEL to arrive at a presumed safe level of human exposure is predicated on the risk assessment assumption that a threshold for developmental toxicity exists (see "Principles of Developmental Toxicology," above). A threshold should not be confused with the NOAEL, as the NOAEL is dependent entirely on the power of the study and, as will be seen later, is associated with risks perhaps on the order of 5 percent over the control incidence in typical studies. Also, the value obtained by the application of uncertainty factors to the NOAEL should not be confused with a threshold, as this exposure is only assumed to be without appreciable added risk.

The use of the NOAEL in the risk assessment process has been criticized for several reasons. For example, since it is dependent on statistical power to detect pair-wise differences between a treated and a control group, the use of larger sample sizes and more dose groups (which might better characterize the dose–response relationship) can only yield lower NOAELs, and thus better experimental designs are actually penalized by this approach. In addition, the NOAEL is limited to an experimental dose level, and an experiment might need to be repeated to develop a NOAEL for risk assessment. A final point relates to the fact that, given varying experimental designs and variability of control values, NOAELs actually represent different levels of risk across studies.

Crump (1984) proposed using a mathematical model to estimate the lower confidence bounds on a predetermined level of risk [the "benchmark dose" (BMD)]) as a means of avoiding many of the disadvantages of the NOAEL. The application of this approach to a large compilation of Segment II type data sets (Faustman et al., 1994; Allen, et al., 1994a,1994b; Kavlock, 1995) demonstrated that a variety of mathematical models, including those that incorporate developmental-specific features such as litter size and intra-litter correlations, can be readily applied to standard test results. On average, benchmark doses based on a 5 percent added risk of effect calculated on quantal endpoints (e.g., whether an implant was affected or not) were approximately equivalent to traditionally determined NOAELs. When the litter was used as the unit of response (did it contain at least one affected implant?), benchmarks calculated for a 10 percent added risk were most similar to the correspondingly determined NOAEL. Discrepancies between the benchmark dose and the NOAEL were most pronounced when one or more of the following conditions were present: a shallow dose–response, small sample sizes, wide spacing of experimental dosage levels, or more than the typical number of dose levels. These features tend to make determination of the NOAEL more problematic (usually higher) and the confidence limits around the maximum likelihood estimate broader (resulting in lower BMDs).

Biologically Based Dose–Response Modeling The introduction of statistical dose–response models for noncancer endpoints is the first step in developing quantitative, mechanistic models that will help reduce the major uncertainties of high-to-low dose and species-to-species extrapolation of experimental data. These biologically based dose–response models integrate pharmacokinetic information on target tissue dosimetry with molecular/biochemical responses, cellular/tissue responses, and developmental toxicity (O'Flaherty, 1997; Lau and Setzer, 2000). Gaylor and Razzaghi (1992) proposed a model which related induction of cleft palate to fetal growth inhibition, and Gaylor and Chen (1993) proposed a model relating fetal weight and the probability of fetal abnormality. Shuey et al. (1994) presented a

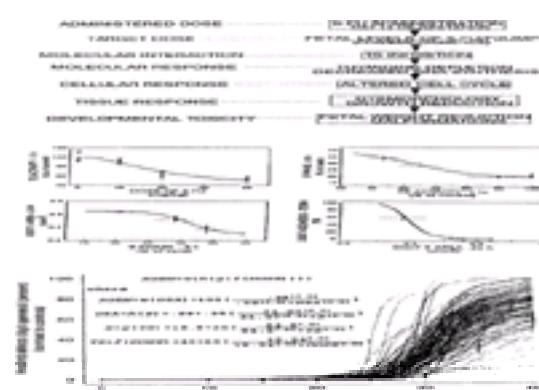
model using the cancer chemotherapeutic 5-fluorouracil (Fig. 10-9). They postulated that the developmental toxicity observed in the term fetus was due to an active metabolite (FdUMP) inhibiting the enzyme thymidylate synthetase, with subsequent depletion of thymidine, decreased DNA synthetic rates, reduced cell proliferation, and, ultimately, reduce tissue growth and differentiation. Each step in the process was determined experimentally and the relationships were described by Hill equations. The individual equations were then linked in an integrated model to describe the entire relationship between administered dose and the incidence of hind limb defects. While this is still an empirically based model, the process clearly demonstrated the utility of the approach in understanding the relative importance of various pathways of abnormal development in the ultimate manifestation and in providing a basis for models which could incorporate species-specific response parameters. Leroux and coworkers (1996) took a more theoretical approach, using a cell kinetic model in which a progenitor cell would either divide, differentiate, or die, each event proceeding at a certain rate. These authors constructed a stochastic model based on the premise that a malformation occurs when the number of differentiated cells is less than a critical number for a given stage of development. Ultimately, BBDR models will need to be generalizable across dose, route of exposure, species, and perhaps even chemicals of similar mechanistic classes.


Figure 10-9. Biologically based dose response modeling of the developmental toxicity of 5-fluorouracil (5-FU) following maternal administration on gestation day 14.

Top: Proposed model for the developmental toxicity of 5-FU based on thymidylate synthetase (TS) inhibition, decreased DNA synthesis, cell cycle alterations, and growth deficits and hind-limb dysmorphogenesis. Shaded events were measured experimentally.

Middle: Relationships between successive endpoints are shown in these four panels (hind-limb bud TS activity versus 5-FU dose, S-phase accumulation versus TS activity, limb digit 5 area at 24 h postdose versus proportion of cells in S phase, and digit agenesis at term versus limb digit 5 area at 24 h). Data were fitted with Hill equations.

Bottom: Model for induction of hind-limb defects induced by 5-FU, generated by integration of the individual Hill equations describing the relationships between successive model endpoints as presented in the middle panels. These individual equations are listed here, and the curves were generated by Monte Carlo simulation to estimate variability around the predicted relationship. The simulation results indicate that variability in the intermediate endpoints can account for differences between the predicted and actual dose response. AGEN: digit agenesis at term; D5A: digit 5 area; S: percent of cells in S phase. [Adapted from Shuey et al. (1994), with permission.]

PATHWAYS TO THE FUTURE

Since the last edition of this text, The National Research Council has assembled a committee to assess the state of the science in the area of mechanisms of normal and abnormal development and to explore opportunities to bring new knowledge and approaches to bear on developmental toxicology and risk assessment. In 2000, the committee released its report, "Scientific Frontiers in Developmental Toxicology and Risk Assessment" (NRC, 2000). The report presents a number of exciting findings and ideas, and should serve as a framework to help advance the field of developmental toxicology in the next decade.

The NRC committee reports that major discoveries have been made about mechanisms of normal development, that these mechanisms are conserved in diverse animals, many of which have been used extensively in developmental biology and genetics, including the fruit fly, roundworm, zebrafish, frog, chick and mouse. Seventeen conserved intercellular signaling pathways are described which are used repeatedly at different times and locations during development of these and other animal species, as well as in humans (Table 10-7). The conserved nature of these key pathways provides a strong scientific rationale for using these animal models to advantage for developmental toxicology. Not only are these organisms advantageous for developmental toxicity studies due to their well-known genetics and embryology and their rapid generation time, but they are also amenable to genetic manipulation to enhance the sensitivity of specific developmental pathways or to incorporate human genes, such as those of drug metabolizing enzymes, to answer questions of interspecies extrapolation.

Table 10-7 The 17 Intercellular Signaling Pathways Used in Development by Most Metazoans

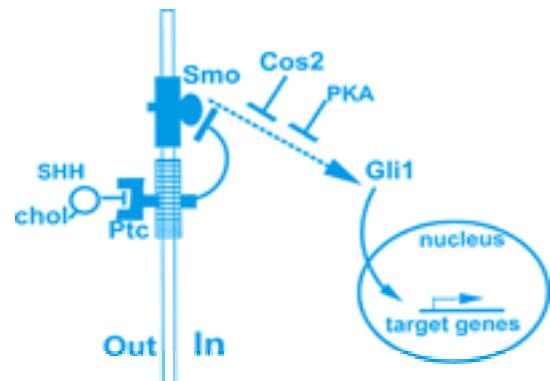
The Hedgehog signaling pathway serves as an example of the exciting linkages being made between embryology, genetics, and toxicology. This pathway, first discovered in *Drosophila,* is also present in vertebrates and is important in the development of a number of organs including the central nervous system, the limbs and the face. Ligands for the hedgehog family receptors require proteolytic cleavage and addition of cholesterol for activation, and this pathway is exemplified by the Sonic Hedgehog (SHH) pathway in Fig. 10-10. The receptor for the SHH ligand, called *patched (ptc),* is associated with and normally represses function of the membrane protein *smoothened (smo).* Binding of SHH to *ptc* derepresses function of *smo,* leading to activation of specific transcription factors and transcription of target genes. Mutations of the SHH gene lead to holoprosencephaly (a malformation involving the forebrain and associated structures) in mice and humans. Toxicologically, cyclopamine and jervine, plant alkaloids that bind to *ptc,* can induce holoprosencephaly in animals. Further, covalent binding of cholesterol is required for SHH activity, and cholesterol synthesis inhibitors have also been shown to cause holoprosencephaly. Understanding of the biochemistry and function of this signaling pathway in normal development elucidates the mechanisms of toxicity leading to holoprosencephaly. Conversely, use of such specific toxicants as pharmacological probes allows confirmation of the role of this pathway in brain development.


Figure 10-10. Diagram showing the transduction of the Sonic Hedgehog (SHH) signal through the patched (ptc) and smoothened (smo) receptor complex.

The SHH protein requires proteolytic cleavage and covalent binding to cholesterol (chol) prior to binding to ptc. Binding to ptc derepresses smo, which activates a signal cascade of transcription factor (gli) activation and target-gene transcription.

Other avenues of increased understanding and progress enumerated in the NRC report include increased understanding of human genetic polymorphisms and their contribution to susceptibility to birth defects, use of sensitized animal models for high to low dose extrapolation, use of stress/checkpoint pathways as indicators of developmental toxicity, implementation of bioinformatic systems to improve data archival and retrieval, and increased multidisciplinary education and research on the causes of birth defects. Hopefully, there will be much to report on the progress of these efforts by the next addition of this text.

CHAPTER 11

TOXIC RESPONSES OF THE BLOOD

John C. Bloom and John T. Brandt

BLOOD AS A TARGET ORGAN

Hematotoxicology is the study of adverse effects of drugs, nontherapeutic chemicals and other agents in our environment on blood and blood-forming tissues (Bloom, 1997). This subspecialty draws on the discipline of hematology and the principles of toxicology. Scientific understanding of the former began with the contributions of Leeuwenhoek and others in the seventeenth century, with the microscopic examination of blood (Wintrobe, 1985). Hematology was later recognized as an applied laboratory science but limited to quatitation of formed elements of the blood and the study of their morphology, along with that of bone marrow, spleen, and lymphoid tissues. It is now a diverse medical specialty, which—perhaps more than any other discipline—has made tremendous contributions to molecular medicine (Kaushansky, 2000).

The vital functions that blood cells perform, together with the susceptibility of this highly proliferative tissue to intoxication, makes the hematopoietic system unique as a target organ. Accordingly, it ranks with liver and kidney as one of the most important considerations in the risk assessment of individual patient populations exposed to potential toxicants in the environment, workplace, and medicine cabinet.

The delivery of oxygen to tissues throughout the body, maintaining vascular integrity and providing the many affector and effector immune functions necessary for host defense, requires a prodigious proliferative and regenerative capacity. The various blood cells (erythrocytes, granulocytes, and platelets) are each produced at a rate of approximately 1 to 3 million per second in a healthy adult and up to several times that rate in conditions where demand for these cells is high, as in hemolytic anemia or suppurative inflammation (Testa and Molineux, 1993). As with intestinal mucosa and gonads, this characteristic makes hematopoietic tissue a particularly sensitive target for cytoreductive or antimitotic agents, such as those used to treat cancer, infection, and immune-mediated disorders. This tissue is also susceptible to secondary effects of toxic agents that affect the supply of nutrients, such as iron; the clearance of toxins and metabolites, such as urea; or the production of vital growth factors, such as erythropoietin.

The consequences of direct or indirect damage to blood cells and their precursors are predictable and potentially life-threatening. They include hypoxia, hemorrhage, and infection. These effects may be subclinical and slowly progressive or acute and fulminant, with dramatic clinical presentations. Hematotoxicity is usually assessed in the context of risk versus benefit. It may be used to define dosage in treatment modalities in which these effects are limiting, such as those employing certain anticancer, antiviral, and antithrombotic agents.

Hematotoxicity is generally regarded as unacceptable, however, in treatments for less serious illnesses, such as mild hypertension or arthritis or following exposure to contaminated foods or environmental contaminants. Risk-versus-benefit decisions involving hematotoxicity may be controversial, especially when the incidence of these effects is very low. Whether the effect is linked to the pharmacologic action of the agent, as with cytoreductive or thrombolytic agents, or unrelated to its intended action, the right balance between risk and benefit is not always clear.

Hematotoxicity may be regarded as *primary,* where one or more blood components are directly affected, or *secondary,* where the toxic effect is a consequence of other tissue injury or systemic disturbances. Primary toxicity is regarded as among the more common serious effects of xenobiotics, particularly drugs (Magee and Beeley, 1991). Secondary toxicity is exceedingly common, due to the propensity of blood cells to reflect a wide range of local and systemic effects of toxicants on other tissues. These secondary effects on hematopoietic tissue are often more reactive or compensatory than toxic and provide the toxicologist with an important and accessible tool for monitoring and characterizing toxic responses.

HEMATOPOIESIS
