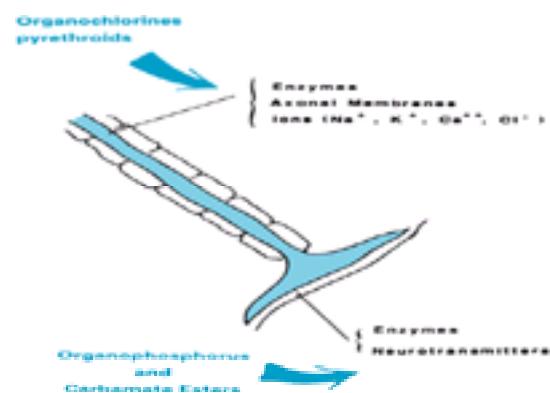
All of the chemical insecticides in use today are neurotoxicants and act by poisoning the nervous systems of the target organisms. The central nervous system (CNS) of insects is highly developed and not unlike that of the mammal (O'Brien, 1960). While the peripheral nervous system (PNS) of insects is not as complex as that of mammals, there are striking similarities (O'Brien, 1960). The development of insecticides has been based on specific structure-activity relationships requiring the manipulation of a basic chemical structure to obtain an optimal shape and configuration for specificity toward a unique biochemical or physiologic feature of the nervous system. Given the fact that insecticides are not selective and affect nontarget species as readily as target organisms, it is not surprising that a chemical that acts on the insect's nervous system will elicit similar effects in higher forms of life. The target sites and/or mechanism(s) of action may be similar in all species; only the dosage (level of exposure and duration) will dictate the intensity of biological effects. It is sufficient at this stage to indicate the potential sites of action of the insecticide classes (Fig. 22-5) and their interference with the membrane transport of sodium, potassium, calcium, or chloride ions; inhibition of selective enzymatic activities; or contribution to the release and/or the persistence of chemical transmitters at nerve endings.


Figure 22-5. Potential sites of action of classes of insecticides on the axon and terminal portions of the nerve.

Organochlorine Compounds

No longer considered an important class of insecticides in North America and Europe, the organochlorine insecticides see continued use in developing, tropical countries because they are effective, inexpensive, essential chemicals in agriculture, forestry, structural protection, and public health. The risk-benefit ratio is highly weighted in favor of their continued use for the control of insects causing devastation to crops and human health. For example, technical-grade hexachlorocyclohexane (HCH), banned in Canada, the United States, China, the Soviet Union, and Australia in 1971, 1976, 1983, 1990 and 1994, respectively, still sees extensive use in a number of African nations, Brazil, India, and others (Li, 1999). While banned in the early 1970s, DDT was still being manufactured in the United States and exported at the rate of 1 ton per day in 1994 (Smith, 1995). Global transport of such chemicals from equatorial regions to Arctic and Antarctic regions, with contamination of wildlife food sources, suggests that these agents are still toxicologically important. Currently, major concerns are centered on the indigenous people living in Arctic regions, where the sources of dietary protein (fish, seals, walruses, whales, etc.) have proven to be major depositories of organochlorine insecticides and other chlorinated hydrocarbons (PCBs, PBBs, PCDDs, PSDFs) (Berti et al., 1998; Chan, 1998).

The properties (low volatility, chemical stability, lipid solubility, slow rate of biotransformation and degradation) that made these chemicals such effective insecticides also brought about their demise because of their persistence in the environment, bioconcentration and biomagnification in food chains, and the acquisition of biologically active body burdens at higher trophic levels (Carson, 1962). Definitive studies in wild, domestic, and laboratory species demonstrated potent enzyme-inducing and/or estrogenic properties, with interference indirectly or directly with fertility and reproduction (Stickel, 1968; McFarland and Lacy, 1969; Peakall, 1970; Longcore et al., 1971; McBlain et al., 1977; Crum et al., 1993).

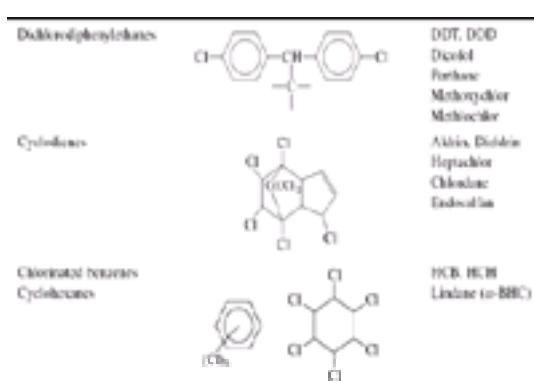
The organochlorine (chlorinated hydrocarbon) insecticides are a diverse group of agents belonging to three distinct chemical classes including the dichlorodiphenylethane-, chlorinated cyclo- diene- and chlorinated benzene- and cyclohexane-related structures (Table 22-5). The historical development of these chemicals from the mid-1940s and their impact on agriculture and human health can be found in O'Brien (1967), Metcalf (1973), and Brooks (1974).


Table 22-5 Structural Classification of Organochlorine Insecticides

Signs and Symptoms of Poisoning Given the diversity of chemical structures, it is not surprising that the signs and symptoms of toxicity and the mechanisms of action are somewhat different (Table 22-6).

Table 22-6 Signs and Symptoms of Acute and Chronic Toxicity Following Exposure to Organochlorine Insecticides

Exposure of humans and animals to high oral doses of DDT results in paresthesia of the tongue, lips, and face; apprehension; hypersusceptibilty to external (light, touch, sound) stimuli; irritability, dizziness, and vertigo; tremor and tonic and clonic convulsions. Motor unrest and fine tremors associated with voluntary movements progress to coarse tremors without interruption in moderate to severe poisonings. Symptoms generally appear several hours (6 to 24 h) after exposure to large doses. Little toxicity is seen following the dermal exposure to DDT, presumably because the agent is poorly absorbed through the skin, a physiologic phenomenon that has contributed to the fairly good safety record of DDT despite careless handling by applicators and formulators (Hayes, 1971). It has been estimated that a dose of 10 mg/kg will cause signs of poisoning in humans. Chronic exposure to moderate concentrations of DDT causes somewhat milder signs to toxicity, as listed in Table 22-6.

Although the functional injury of DDT poisoning can be associated with effects on the CNS in humans, few pathologic changes can be demonstrated in CNS tissue in animals. However, following exposure to moderate or high nonfatal doses or subsequent to subacute or chronic feeding, major pathologic changes are observed in the liver and reproductive organs. Morphologic changes in mammalian liver include hypertrophy of hepatocytes and subcellular organelles such as mitochondria, proliferation of smooth endoplasmic reticulum and the formation of inclusion bodies, centrolobular necrosis following exposure to high concentrations, and an increase in the incidence of hepatic tumors (Hayes, 1959; Hansell and Ecobichon, 1974; IARC, 1974). However, there has yet to be conclusive epidemiologic evidence linking DDT to carcinogenicity in humans (Hayes, 1982; Baris et al., 1998; Takayama et al., 1999). When technical-grade DDT (20 percent *o,p*-DDT plus 80 percent *p,p*-DDT) was administered to male cockerels or rats, reduced testicular size was observed and, in female rats, the estrogenic effects of the *o,p'*-isomer were observed in the edematous, blood-engorged uteri (Hayes, 1959; Ecobichon and MacKenzie, 1974). The *o,p'*-isomer has been shown to compete with estradiol for binding the estrogen receptors in rat uterine cytosol (Kupfer and Bulger, 1976). The DDT analog methoxychlor [1,1,1-trichloro-2,2-bis(4-methoxyphenyl) ethane] is estrogenic in the mouse; problems in initiating and/or maintaining a pregnancy are seen, due possibly to alterations in preimplantation embryonic development and estrogenic effects on the oviduct and uterus (Hall et al., 1997; Swartz and Eroschenko, 1998).

Dicofol (*p-p'*-dichlorodiphenyl-2,2,2-trichloroethanol)—an analog of DDT still registered as an agricultural miticide for cotton, beans, citrus, and grapes—has been associated with acute toxicity (nausea, dizziness, double vision, ataxia, confusion, disorientation) in a 12-year-old male whose clothing because saturated in an accident (Lessenger and Riley, 1991). These acute effects progressed to chronic signs (headaches, blurred vision, horizontal nystagmus, numbness/tingling in the legs with shooting pains, clumsiness, memory loss and decreasing academic performance, impulsive behavior, restlessness and fatigue), which persisted in some fashion for up to 4 months. Continuing emotional and academic difficulties, impairment of certain cognitive skills, poor self-esteem and depression, all of which were subtle cognitive and psychological changes, persisted for over 18 months. Dicofol is known to be contaminated by a small percentage of *p-p'*-DDT, showing estrogenicity in birds (Peakall, 1970).

Unlike the situation with DDT, in which there have been few recorded fatalities following poisoning, there have been a number of fatalities following poisoning by the cyclodiene- and hexachlorocyclohexane-type insecticides. The chlorinated cyclodiene insecticides are among the most toxic and environmentally persistent pesticides known (Hayes, 1982). One recent study of two patients, one with a history of chronic exposure to aldrin and the other with a chronic exposure to lindane/heptachlor, reported death within 2 years of developing clinical and electromyographic signs and symptoms of chronic motor disease with aggravation of dysphagia and weight loss resulting in the mobilization of adipose tissue and stored insecticide to enhance the neuronal toxicity (Fonseca et al., 1993). Even at low doses, these chemicals tend to induce convulsions before less serious signs of illness occur. Although the sequence of signs generally follows the appearance of headaches, nausea, vertigo, and mild clonic jerking, motor hyperexcitability, and hyperreflexia, some patients have convulsions without warning symptoms (Hayes, 1982). An important difference between DDT and the chlorinated cyclodienes is that the latter are efficiently absorbed through the skin and therefore pose an appreciable hazard to occupationally exposed individuals. Chronic exposure to low or moderate concentrations of these agents elicits a spectrum of signs and symptoms, involving both sensory and motor components of the CNS (Table 22-6). In addition to the recognized neurotoxicity, aldrin and dieldrin interfere with reproduction, with increased pup losses (vitality, viability) being reported in studies in rats and dogs (Kitselman, 1953; Treon and Cleveland 1955). Treatment with dieldrin during pregnancy caused a reduction in fertility and increased pup mortality (Treon and Cleveland, 1955). The treatment of pregnant mice with dieldrin resulted in teratologic effects (delayed ossification, increases in supernumerary ribs) (Chernoff et al., 1975).

Exposure to lindane (the g-isomer of hexachlorocyclohexane, HCH) produces signs of poisoning that resemble those caused by DDT (e.g., tremors, ataxia, convulsions, stimulated respiration, and prostration). In severe cases of acute poisoning, violent tonic and clinic convulsions occur and degenerative changes in the liver and renal tubules have been noted. Technical-grade HCH used in insecticidal preparations contains a mixture of isomers: the g- and a-isomer are convulsant poisons; the b- and d-isomers are CNS depressants. The mechanisms of action remain unknown. Lifetime feeding studies in mice have revealed that technical-grade HCH and some of the isomers caused an increase in hepatocellular tumors (IARC, 1974). Only the g-isomer (lindane) sees any medicinal use today, as a component of a pediculicide shampoo for head lice. One undocumented case of lindane toxicity, known to the author, resulted in mild tremors in a child on whose head the shampoo was used vigorously and repeatedly for more than a week. The symptoms disappeared rapidly when the treatment was terminated.

Industrial carelessness during the manufacture of an organochlorine compound chlordecone (Kepone) brought this agent and mirex, the closely related insecticide, to the attention of toxicologists in 1975, when 76 of 148 workers in a factory in Hopewell, Virginia, developed a severe neurologic syndrome (Cannon et al., 1978; Taylor et al., 1978; Guzelian, 1982). This condition, known as the "Kepone shakes," was characterized by tremors, altered gait, behavioral changes, ocular flutter (opsoclonus), arthralgia, headache, chest pains, weight loss, hepatomegaly, splenomegaly, and impotence, the onset of symptoms generally occurring with a latency of approximately 30 days from the initiation of exposure and persisting for many months after the termination of exposure (Joy, 1994a). Laboratory tests showed a reduced sperm count and reduced sperm motility. Routine neurologic studies showed nothing untoward, but microscopic examination of biopsies of the sural nerve

revealed relative decreases in the populations of small myelinated and unmyelinated axons. With electron microscopy, a number of abnormalities were visible; the significant findings included damage to Schwann cells (membranous inclusions, cytoplasmic folds), prominent endoneural collagen pockets, vacuolization of unmyelinated fibers, focal degeneration of axons with condensations of neurofilaments and neurotubules, focal interlamellar splitting of myelin sheaths, and the formation of myelin bodies and a complex infolding of inner mesaxonal membranes into axoplasm (Martinez et al., 1977). The involvement of unmyelinated fibers and small myelinated fibers may partially explain the clinical picture. It has been suggested that chlordecone may interfere with metabolic processes in Schwann cells. However, it should be noted that all of these degenerative changes are nonspecific in nature and are commonly seen in other toxic polyneuropathies. Many of the toxic manifestations of chlordecone poisoning in these workers have been confirmed in animal studies, the major target organs being the CNS, liver, adrenals, and testes, as summarized by Joy (1994a). As with other organochlorine insecticides, chlordecone is an excellent inducer of hepatic microsomal monooxygenase enzymes and, in rats and mice, has been associated with the formation of hepatomas and malignant tumors in organs other than the liver, female animals being more susceptible than male (Guzelian, 1982). In many ways, mirex behaves like chlordecone, and there is evidence for the oxidative biotransformation of mirex to chlordecone in vivo. Mirex causes hepatomegaly and a dose-dependent increase in neoplastic nodules and hepatocellular carcinomas, particularly in male animals (Innes et al., 1969; Waters et al., 1977).

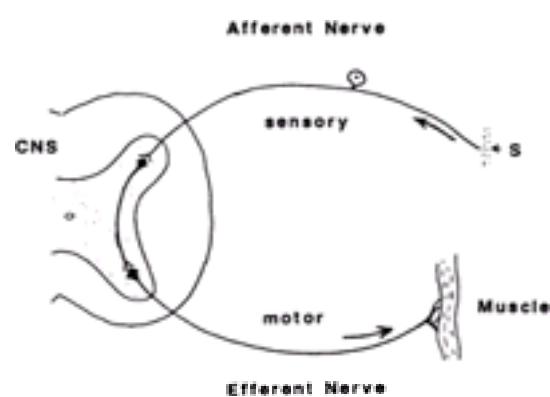
Site and Mechanism of Toxic Actions Essential to the action of organochlorine insecticides is an intact reflex are consisting of afferent (sensory) peripheral neurons impinging on interneurons in the spinal cord, with accompanying ramifications and interconnections up and down the CNS and interactions with efferent motor neurons, as shown schematically in Fig. 22-6. In terms of the mechanism of action of the DDT-type insecticides, the most striking observation in a poisoned insect or mammal is the display of periodic sequences of persistent tremoring and/or convulsive seizures suggestive of repetitive discharges in neurons. These characteristic episodes of hyperactivity interspersed with normal function were recognized as early as 1946. The second most striking observation is that these repetitive tremors, seizures, and electrical activity can be initiated by tactile and auditory stimuli, suggesting that the sensory nervous system appears to be much more responsive to stimuli. An examination of the sequence of electrical events in normal and DDT-poisoned nerves reveals that, in the latter, a characteristic prolongation of the falling phase of the action potential (the negative afterpotential) occurs (Fig. 22-7). The nerve membrane remains in a partially depolarized state and is extremely sensitive to complete depolarization again by very small stimuli (Joy, 1994a). Thus, following exposure to DDT, the repetitive stimulation of the peripheral sensory nerves by touch or sound is magnified in the CNS, causing generalized tremoring throughout the body.


Figure 22-6. A simple, intact reflex arc involving a peripheral, afferent (sensory) neuron, interneurons, and a peripheral, efferent (motor) neuron that innervates a muscle.
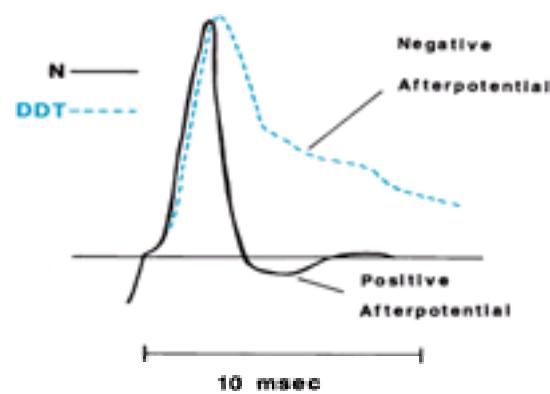

Figure 22-7. A schematic diagram of an oscilloscope recording of the depolarization and repolarization of a normal neuron (————) and one from a DDT-treated (---)animal, showing the prolonged, negative afterpotential (AP).

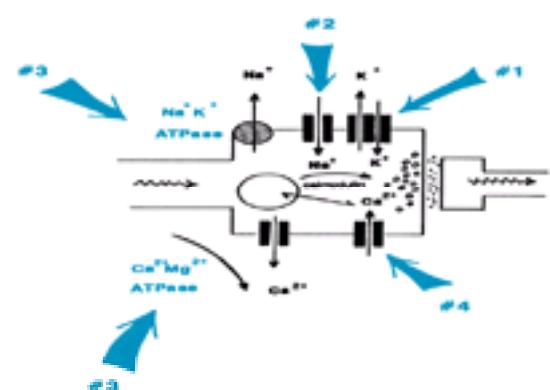
How does DDT elicit this effect? There are at least four mechanisms, possibly all functioning simultaneously (Matsumura, 1985), as seen in Fig. 22-8. At the level of the neuronal membrane, DDT affects the permeability to potassium ions, reducing potassium transport across the membrane. DDT alters the porous channels through which sodium ions pass. These channels activate (open) normally, but, once open, are inactivated (closed) slowly, thereby interfering with the active transport of sodium out of the nerve axon during repolarization. DDT inhibits neuronal adenosine triphosphatase (ATPase), particularly the Na$^+$,K$^+$-ATPase and Ca^{2+}-ATPase, which play vital roles in neuronal repolarization. DDT also inhibits the ability of calmodulin, a calcium mediator in nerves, to transport calcium ions essential for the intraneuronal release of neurotransmitters. All of these inhibited functions reduce the rate at which depolarization occurs and increase the sensitivity of the neurons to small stimuli that would not elicit a response in a fully depolarized neuron.


Figure 22-8. Proposed sites of action of DDT on (1) reducing potassium transport through pores, (2) inactivating sodium channel closure, (3) inhibiting sodium-potassium and calcium-magnesium ATPases, and (4) calmodulin-calcium binding with the release of neurotransmitter.

The chlorinated cyclodiene-, benzene-, and cyclohexane-type insecticides are different from DDT in many respects, both in the appearance of the intoxicated individual and possibly also in the mechanism(s), which appear to be localized more in the CNS than in the sensory division of the PNS (Table 22-6). The overall appearance of the intoxicated individual is one of CNS stimulation. As shown in Fig. 22-9, the cyclodiene compounds antagonize the action of the neurotransmitter gamma-aminobutyric acid (GABA) acting at the GABA$_A$ receptors in rat dorsal root ganglia and effectively blocking the GABA-induced uptake of chloride ions by desensitizing the current in the receptor-channel complex (Nagata and Narahashi, 1994). A more recent paper explains the fact that dieldrin has a dual effect on the GABA$_A$ receptor-channel: an initial enhancement of the GABA-induced chloride ion current (with an EC$_{50}$ of 754 nM) followed by a suppression (Narahashi et al.,

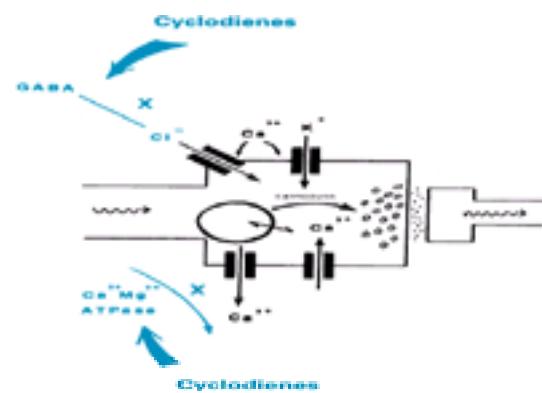
1995). Two types of chloride currents exist, one having a high sensitivity to dieldrin (IC_{50}=5 nM) and the other having a lower sensitivity to dieldrin (IC_{50}=92 nM). The dieldrin-suppressive action is responsible for the hyperactivity observed in poisoned animals. The nature of the GABA$_A$ receptor-channel is still being explored. The cyclodienes are also potent inhibitors of Na^+,K^+-ATPase and, more importantly, of the enzyme Ca^{2+}, Mg^{2+}-ATPase essential for the transport (uptake and release) of calcium across membranes (Matsumura, 1985; Wafford et al., 1989). Evidence suggests that gamma-hexachlorocyclohexane (g-HCH, lindane) neurotoxicity is primarily related to the blockade of chloride ion flux through the inotropic GABA$_A$ receptors, resulting in depolarization and hyperexcitation of post-synaptic membranes (Matsumura and Tanaka, 1984). There is also evidence that g-HCH can alter calcium homeostasis, elevating free calcium ion levels intracellularly with the release of neurotransmitters (Joy, 1994a). The inhibition of Ca^{2+}, Mg^{2+}-ATPase, located in the terminal ends of neurons in synaptic membranes, results in an accumulation of intracellular free calcium ions with the promotion of calcium-induced release of neurotransmitters from storage vesicles and the subsequent depolarization of adjacent neurons and the propagation of stimuli throughout the CNS.


Figure 22-9. Proposed sites of action of cyclodiene-type organochlorine insecticides on chloride ion transport through inhibition of the GABA $_A$ receptor channel as well as inhibition of calcium-magnesium ATPase.

Biotransformation, Distribution, and Storage The phenomenon of bioconcentration and biomagnification of the organochlorine insecticides in food chains has been mentioned. Once acquired, biotransformation/degradation proceeds at an exceptionally slow pace, in part due to the complex aromatic ring structures and the number of the chlorine substituents, the latter being exceedingly difficult to remove by the enzymatic processes available in tissues. The biotransformation of the various organochlorines has been extensively studied—for example, DDT (Ecobichon and Saschenbrecker, 1968), aldrin and heptachlor conversion to dieldrin and heptachlor epoxide, respectively (Keane and Zavon, 1969; Matthews and Matsumura, 1969); chlordane (Menzie, 1969); hexachlorocyclohexane (Egan et al., 1965; O'Brien, 1967; Abbott et al., 1969); and toxaphene (Saleh et al., 1977; Turner et al., 1977). With the exception of aldrin, chlordane, and heptachlor, most biotransformation reactions reduce the neurotoxicant activities but marginally affect the weak estrogenicity of the agents.

Slow biotransformation, in addition to the highly lipophilic nature of the organochlorine compounds, guarantees that these agents will be sequestered in body tissue having a high lipid content, where some biological action may result. In the case of adipose tissue, the agents will remain stored and undisturbed, only small amounts equilibrating with the blood and being degraded and/or excreted (Dale and Quinby, 1963; Davies et al., 1972). The depuration of these chemicals from systems occurs slowly, in a matter of a few weeks for chlordane, and months to years for aldrin/dieldrin, DDT, and others (Laben et al., 1965; Ecobichon and Saschenbrecker, 1969; Craan and Haines, 1998; Delorme et al., 1999).

It is not surprising that humans acquired body burdens of these chemicals during the 1950s and 1960s, when they were used on almost all food crops. Depending on the region of the world, the intensity of use, the extent of occupational and accidental exposure, and dietary habits, the bioconcentration/bioaccumulation of DDT in human adipose tissue resulted in levels on the order of 5 ppm DDT and approximately 15 ppm of total DDT-derived material (Quinby et al., 1965; Fiserova-Bergerova et al., 1967; Abbott et al., 1968; Morgan and Roan, 1970). The levels of other organochlorine insecticides sequestered in body fat were never as high as those of DDT. With declining use and the eventual ban of this class on insecticides from the North American market, body burdens of these insecticides declined slowly. By the late 1960s, adipose levels of 2 ppm DDT(0 ppm of total DDT-derived material) were detectable. Whereas the daily intake of DDT in the United States was approximately 0.2 mg/day in 1958, this had decreased to about 0.04 mg/day by 1970 (Hayes, 1971). Today, only trace levels of DDT, less than 2.0 ppm of total DDT-derived material, are detectable in human adipose tissue (Mes et al., 1982; Redetzke and Applegate, 1993; Stevens et al., 1993).

Treatment of Poisoning The life-threatening situation in organochlorine insecticide poisoning is associated with tremors, motor seizures, and interference with respiratory function (hypoxemia and resulting acidosis) arising from repetitve stimulation of the CNS. In addition to general decontamination and supportive treatment, diazepam (0.3 mg/kg IV; maximum dose of 10 mg) or phenobarbital (15 mg/kg IV; maximum dose of 1.0 g) may be administered by slow injection to control the convulsions. It may be necessary to repeat the treatment.

Anticholinesterase Agents

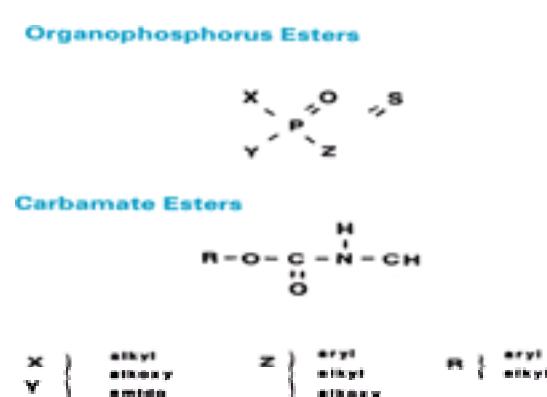
The agents comprising this type of insecticide have a common mechanism of action but arise from two distinctly different chemical classes, the esters of phosphoric or phosphorothioic acid and those of carbamic acid (Fig. 22-10). The anticholinesterase insecticides are represented by a vast array of structures that have demonstrated the ultimate in structure-activity relationships in attempts to produce potent and selective insect toxicity while minimizing the toxicity toward nontarget species. Today, there are some 200 different organophosphorus ester insecticides and approximately 25 carbamic acid ester insecticides in the marketplace, formulated into literally thousands of products. For detailed discussions on the nomenclature, chemistry, and development of these insecticides, the reader is referred to the books of O'Brien (1960), Heath (1961), Melnikov (1971), Fest and Schmidt (1973), Eto (1974), Kuhr and Dorough (1976), Ecobichon and Joy (1994), and Matsumura (1985) and a review by Holmstedt (1959).


Figure 22-10. The basic backbone structures of the two types of anticholinesterase-class insecticides, the organophosphorus and carbamate esters.

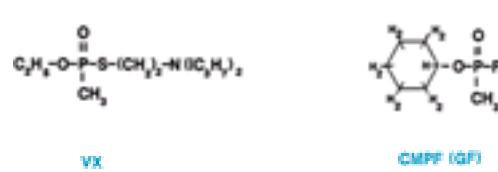
The organophosphorus ester insecticides were first synthesized in 1937 by a group of German chemists led by Gerhard Schrader at Farbenfabriken Bayer AG (Schrader and Kukenthal, 1937). Many of their trial compounds proved to be exceedingly toxic and unfortunately, under the management of the Nazis in World War II, some were developed as potential chemical warfare agents. It is unwise to dismiss the chemical warfare nerve gases completely as the weapons of a past, more barbaric era, because it is known that at least one country has stocks of a number of these agents (Fig. 22-11) (Clement, 1994; Gee, 1992). The physicochemical and toxicologic properties of these agents have been reviewed (Sidell, 1992; Somani et al., 1992). Sarin (C-isopropyl methylphosphonofluoridate) was used in Iraq against Kurdish villages in northern Iraq in 1988 and residues of isopropyl methylphosphonic acid were found in soil samples along with minute traces of sarin (Webb, 1993). These potent agents should not be ignored, since they are relatively easy to manufacture in small amounts and have been the toxicants of choice of terrorists in at least two documented attacks in Japan, in Matsumoto on June 27, 1994 (Morita et al., 1995), and in the Tokyo subway on March 20, 1995 (Masuda et al., 1995;

Nazaki and Aikowa, 1995; Nazaki et al., 1995; Suzuki et al., 1995). The acute and chronic toxicologic effects of these incidents are discussed below.


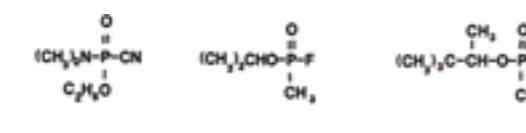


Figure 22-11. Structures of the organophosphorus ester chemical warfare nerve gases, the forerunners of the organophosphorus ester insecticides.

Although it is true that all of the organoposphorus esters were derived from "nerve gases" (chemicals such as soman, sarin, and tabun), a fact that the media continually emphasizes, the insecticides used today are at least four generations of development away from those highly toxic chemicals. The first organophosphorus ester insecticide to be used commercially was tetraethylpyrophosphate (TEPP); although effective, it was extremely, toxic to all forms of life and chemical stability was a major problem in that TEPP hydrolyzed readily in the presenced of moisture. Further development was directed toward the synthesis of more stable chemicals having moderate environmental persistence, giving rise to parathion (*O,O*-diethyl-*O*-nitrophenyl phosphorothioate, E-605) in 1944 and the oxygen analog paraoxon (*O,O*-diethyl-*O*-p-nitrophenyl phosphate) at a later date. Although these two chemicals had the properties desired in an insecticide (low volatility, chemical stability in sunlight and in the presence of water, environmental persistence for efficacy), they both exhibited a marked mammalian toxicy and were unselective with respect to target and nontarget species. The replacement of DDT with parathion in the 1950s resulted in a series of fatal poisonings and bizarre accidents arising from the fact that workers did not appreciate that this agent was far different from the relatively innocuous organochlorine insecticides with which they were familiar (Ecobichon, 1994a). The number of severe poisonings attributed to parathion provided the stimulus for a search for analogs more selective in their toxicity to target species and less toxic to nontarget organisms, including wildlife, domestic stock, and humans.

The first pesticidal carbamic acid esters were synthesized in the 1930s and were marketed as fungicides. Since these aliphatic esters possessed poor insecticidal activity, interest lay dormant until the mid-1950s, when renewed interest in insecticides having anticholinesterase activity but reduced mammalian toxicity led to the synthesis of several potent aryl esters of methylcarbamic acid. The insecticidal carbamates were synthesized on purely chemical grounds as analogs of the drug physostigmine, a toxic anticholinesterase alkaloid extracted from the seeds of the plant *Physostigma venenosum,* the Calabar bean.

Signs and Symptoms of Poisoning Although their structures are diverse in nature, the mechanism by which the organophosphorus and carbamate ester insecticides elicit their toxicity is identical and is associated with the inhibition of the nervous tissue acetylcholinesterase (AChE), the enzyme responsible the the destruction and termination of the biological activity of the neurotransmitter acetylcholine (ACh). With the accumulation of free, unbound ACh at the nerve endings of all cholinergic nerves, there is continual stimulation of electrical activity. The signs of toxicity include those resulting from stimulation of the muscarinic receptors of the parasympathetic autonomic nervous system (increased secretions, bronchoconstriction, miosis, gastrointestinal cramps, diarrhea, urination, bradycardia); those resulting from the parasympathetic divisions of the autonomic nervous system as well as the junctions between nerves and muscles (causing tachycardia, hypertension, muscle fasciculation, tremors, muscle weakness, and/or flaccid paralysis); and those resulting from effects on the CNS (restlessness, emotional liability, ataxia, lethargy, mental confusion, loss of memory, generalized weakness, convulsion, cyanosis, coma) (Table 22-7).

Table 22-7 Signs and Symptoms of Anticholinesterase Insecticide Poisoning

The classic picture of anticholinesterase insecticide intoxication, first described by DuBois (DuBois, 1948; DuBois et al., 1949), has become more complicated in recent years by the recognition of additional and persistent signs of neurotoxicity not previously associated with these chemicals. First, and frequently associated with exposure to high concentrations of the insecticides (resulting from suicide attempts or drenching with dilute or concentrated chemicals), are effects that may persist for several months following exposure and may involve neurobehavioral, cognitive, and neuromuscular functions (Marrs, 1993; Ecobichon, 1994a; Jamal, 1997; Ecobichon, 1998b). One author describes this as a chronic organophosphate-induced neuropsychiatric disorder (COPIND) (Jamal, 1997). The first evidence of this type of syndrome, delayed psychopathologic-neurologic lesions, was reported by Spiegelberg (1963), who had been studying workers involved in the production and handling of the highly toxic nerve gases in Germany during World War II. The characteristic symptomatology subdivided these patients into two distinct groups. The first and largest group was characterized by persistently lowered vitality and ambition; defective autonomic regulation leading to cephalalgia and gastrointestinal and cardiovascular symptoms; premature decline in potency and libido; intolerance to alcohol, nicotine, and various medicines; and an impression of premature aging. The second group, in addition to the above symptoms, showed one or more of the following: depressive or subdepressive disorders of vital function; cerebral vegetative (syncopal) attacks; slight or moderate amnestic or demential effects; and slight organoneurologic defects. These symptoms developed and persisted for some 5 to 10 years following exposure to these most toxic organophosphorus esters during the war years. The controversial paper of Gershon and Shaw (1961), a study of 16 cases of pesticide applicators exposed primarily to organophosphorus ester insecticides for 10 to 15 years, reported a wide range of persistent signs of toxicity, including tinnitus, nystagmus, pyrexia, ataxia, tremor, paresthesia, polyneuritits, paralysis, speech difficulty (slurring), loss of memory, insomnia, somnambulism, excessive dreaming, drowsiness, lassitude, generalized weakness, emotional liability, mental confusion, difficulty in concentration, restlessness, anxiety, depression, dissociation, and schizophrenic reactions. Although the results of other studies have been equivocal in their support of such an array of long-term signs and symptoms, there is a persistent recurrence of the symptomatology in a number of anecdotal and documented reports (Ecobichon, 1994a; Marrs, 1993; Jamal, 1997). The literature on potential, suspected, and established sequelae of organophosphorus ester insecticide intoxications does not confirm the frequently seen statement that clinical recovery from nonfatal poisoning is always complete in a few days. Continuous and close observation of acutely intoxicated patients for some weeks following their recovery from the initial toxicity and treatment thereof would be necessary to identify the subtle changes indicated above. The emergency service physician rarely sees the patient following stabilization and initial "recovery." Definitive examples in which such observation has been possible are few, but one such fortuitous case illustrates what can be achieved if there is close follow-up (Ecobichon et al., 1977).

While most clinical manifestations of acute poisoning are resolved within days to weeks, some symptoms, particularly those of a neuropsychological nature, appear to persist for months or longer. Complete reviews of this aspect have been published recently (Ecobichon, 1994a; Jamal, 1997). A 4-month surveillance of 19 acutely poisoned farm workers revealed many subjective signs and symptoms (blurred vision, muscle weakness, nausea, headaches, night sweats) to persist through the study period, accompanied by a slow recovery of plasma and erythrocytic cholinesterases (Whorton and Obrinsky, 1983). Rosenstock and coworkers (1991) described the neuropsychological testing of 36 poisoned Nicaraguan agricultural workers some 2 years postexposure, reporting that the poisoned group did much worse than controls on all subtests, with significantly worse performance on five of six subtests in the World Health Organization (WHO) neuropsychological test battery and on three of six additional tests that assessed verbal and visual attention, visual memory, visuomotor speed, sequencing and problem solving, motor

steadiness, and dexterity (Ecobichon, 1998b). More recent examples of acute intoxications—e.g. "dippers' flu" from repeated exposure to organophosphorus esters (diazinon, propetamphos, chlorfenvinphos) used in sheep dip—have revealed persistent adverse neurophysiological and psychological/behavioral effects that can be evaluated by suitable test batteries (Cook, 1992; Murray et al., 1992; Sims, 1992; Stephens et al., 1995; Beach et al., 1996; Stephens et al., 1996). As has been seen with signs and symptoms in acute intoxications, those afflicted did not show adverse responses to all test battery parameters; only some responses were significantly different from normal-range values. However, such poisoning incidents have progressed from an anecdotal stage to a testable basis, with refined test parameters revealing subtle but distinct changes in memory, academic and motor skills, abstraction, and flexibility in thinking (Ecobichon, 1998b).

A second distinct manifestation of exposure to organophosphorus ester insecticides has been described by clinicians in Sri Lanka involved in the treatment of suicide attempts (Senanayake and Karalliedde, 1987). This paralytic condition, called the *intermediate syndrome,* consisted of a sequence of neurologic signs that appeared some 24 to 96 h after the acute cholinergic crisis but before the expected onset of delayed neuropathy, the major effect being muscle weakness, primarily affecting muscles innervated by the cranial nerves (neck flexors, muscles of respiration) as well as those of the limbs. Cranial nerve palsies were common. There was a distinct risk of death during this time interval because of respiratory depression and distress that required urgent ventilatory support and was not responsive to atropine or oximes. The chemicals involved in these distinctive intoxications included fenthion, dimethoate, monocrotophos, and methamidophos. There were no obvious clinical differences during the acute intoxication phase in those patients who developed the intermediate syndrome and others who did not, and all patients were treated in the same manner.

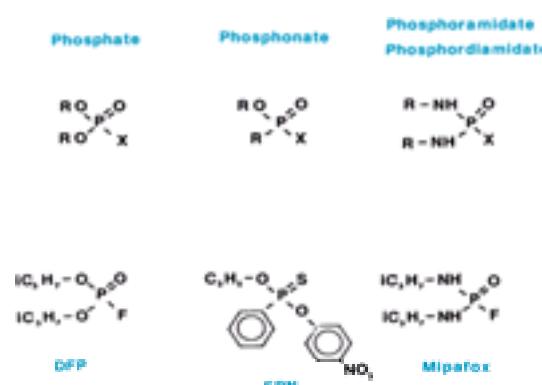
A third syndrome, that of organophosphate-induced delayed neurotoxicity (OPIDN), is caused by some phosphate, phosphonate, and phosphoramidate esters, very few of which have ever been used as insecticides (Fig. 22-12). Historically, this syndrome has been known for almost 100 years and has been associated with the chemical tri-*o*-tolyl phosphate (TOTP) (Ecobichon, 1994a). The first major epidemic of OPIDN occurred during the prohibition years in the United States, resulting from the consumption of a particular brand of alcoholic extract of Jamaican ginger contaminated or adulterated with mixed tolyl phosphate esters. The syndrome, affecting some 20,000 individuals to varying degrees, was known as *ginger jake paralysis* or *jake leg* and was studied in detail by Maurice Smith of the U.S. Public Health Service. He not only confirmed that the condition could be reproduced in animals (e.g., rabbits, dogs, monkeys, calves) but also demonstrated that only one of the three isomers found in commercial tri-tolyl phosphate, the ortho-isomer, was responsible for the toxicity (Smith and Lillie, 1931). The initial flaccidity, characterized by muscle weakness in the arms and legs—giving rise to a clumsy shuffling gait—was replaced by spasticity, hypertonicity, hyperreflexia, clonus, and abnormal reflexes, indicative of damage to the pyramidal tracts and a permanent upper motor neuron syndrome (Ecobichon, 1994a). In many patients, recovery was limited to the arms and hands and damage to the lower extremities (foot drop, spasticity, and hyperactive reflexes) was permanent, suggesting damage to the spinal cord (Moregan and Penovich 1978), Recent studies have demonstrated that other commercial triarylphosphates (flame retardants in lubricants and plastics) did not elicit significant OPIDN-type neurotoxicity at the maximum dose of 2000 mg/kg (Weiner and Jortner, 1999). An OPIDN-type neuropathy occurred with an experimental organophosphorus ester insecticide, mipafox, following an accident in a manufacturing pilot plant. Details of the effects on two of the workers were described by Bidstrup and coworkers (1953) and Ecobichon (1994a). The poisoning of water buffalo in the early 1970s in Egypt by a phosphonate insecticide, leptophos, revealed a neurologic syndrome similar to that observed following exposure to TOTP (Abou-Donia, 1981). There was also evidence of leptophos-induced neuropathies among workers in a manufacturing plant in the United States, but the controversial observations were obscured by concomitant exposure of the workers to *n*-hexane, another neurotoxic chemical (Xintaris et al., 1978).


Figure 22-12. *The basic structures and nomenclature of organophosphorus esters, with examples, capable of causing organophosphate-induced delayed neurotoxicity (OPIDN).*

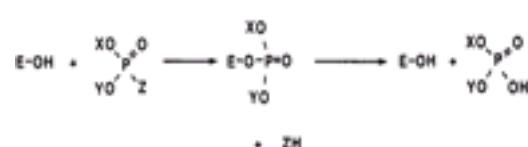
A number of organophosphorus insecticides—including omethoate, trichloronate, trichlorfon, parathion, methamidophos, fenthion, and chlorpyrifos—have been implicated in causing OPIDN in humans (Abou-Donia and Lapadula, 1990). However, it should be emphasized that these incidents all involved accidental or suicidal exposure to excessively high levels. Concern that many of the over 200 organophosphorus ester insecticides in use might cause this unique neuropathy has resulted in an intensive study of the syndrome, the identification of the most susceptible species (the hen and the cat), the development of standard protocols to test all insecticides, and at least a partial elucidation of the mechanisms by which agents elicit this condition. Histologic examination of the nervous systems of hens treated with a suitable agent [e.g., TOTP, *O,O*-diisopropyl phosphorofluoridate (DFP), mipafox, leptophos] has revealed a wallerian "dying-back" degeneration of large-diameter axons and their myelin sheaths in distal parts of the peripheral nerves and of long spinal cord tracts—the rostral ends of ascending tracts and the distal ends of descending tracts (Cavanagh, 1954; Sprague and Bickford, 1981). At autopsy, examination of an unfortunate victim who died 15 months after the sarin attack in the Tokyo subway revealed moderate-to-severe fiber loss in the sural and sciatic nerves with little effect in the CNS, results consistent with the dying-back degeneration of the PNS described above (Himuro et al., 1998). Surviving victims also showed a higher frequency of sister chromatid exchanges (SCEs) in peripheral blood lymphocytes (Li et al., 1998). Biochemical studies have demonstrated that the above-mentioned agents inhibit a neuronal, nonspecific carboxylesterase, neuropathic target esterase (NTE), which appears to have some, as yet unknown, role in lipid metabolism in neurons (Johnson, 1982). If acute exposure to an appropriate organophosphorus ester results in >70 percent inhibition of NTE, the characteristic OPIDN usually follows, with ataxia being observed some 7 to 14 days following treatment and progression to moderate to severe muscular weakness and paralysis with concomitant changes in neuronal morphology (Johnson, 1982; Slott and Ecobichon, 1984). It is the considered opinion of many investigators that many of the commonly used phosphate and phosphorothioate ester insecticides might be capable of causing this syndrome if only sufficient concentrations of the agents could be attained in vivo. However, taking paraoxon as an example of such a phosphate ester, the animal(s) would either die as a consequence of other acute toxic effects or would rapidly detoxify the agent, thereby preventing the acquisition of sufficient paraoxon to inhibit NTE. There also appear to be subtle structure-activity relationships between organophosphorus esters and the active site on the NTE protein, because many phosphate esters are not good inhibitors of NTE (Ohkawa et al., 1980; Abou-Donia, 1981). Conversely, while the nerve gases cause a marked inhibition of NTE, the exposed animals do not develop OPIDN, suggesting that NTE inhibition may not be obligatory (Johnson et al., 1985, Lotti, 1992; Marrs, 1993; Jamal, 1997). It should be emphasized that although NTE inhibition remains a useful function for monitoring the potential of organophosphorus esters to induce OPIDN, the role of this enzyme in the initiation of the syndrome remains unknown and histopathologic evidence is a requirement of the U.S. EPA protocol. However, a recently reported poisoning by methamidophos proved that lymphocyte NTE inhibition was predictive of the subsequent OPIDN, the level of activity increasing from 3.1 to 13.3 nmol/min/mg protein between day 3 after poisoning and day 52 (McConnell et al., 1999). Interestingly, serum autoantibodies (IgM, IgG) to glial fibrillary acidic protein (GFAP), myelin basic protein (MBP), and cytoskeletal elements increased immediately after poisoning in this case and persisted to day 52, suggesting that these parameters might be useful markers. Two noninsecticidal organophosphorus esters, the tri- *S*-alkyl defoliant *S,S,S*-tributyl phosphorotrithioite (Merphos) and its oxidation product, *S,S,S*-tributyl phosphorotrithioate (DEF), have been implicated in producing OPIDN in at least one agricultural worker and cause a characteristic delayed neurotoxicity in hens (Abou-Donia and Lapadula, 1990).

The signs and symptoms of acute intoxication by carbamate insecticides are similar to those described for organophosphorus compounds, differing only in the duration and intensity of the toxicity. The most apparent reasons are that (1) carbamate insecticides are reversible inhibitors of nervous tissue AChE, unlike most of the organophosphorus esters (see below, "Mechanism of Toxic Action") and (2) they are rapidly biotransformed in vivo. Despite the extensive toxicologic short-term toxicity following acute administration, carbamate insecticide toxicity has been reported in humans and fatalities have occurred (Ecobichon, 1994b; Hayes, 1982, Feldman, 1999). Invariably, these serious poisonings have involved carbaryl and have occurred as a consequence of accidental or purposeful (suicidal) exposure to high concentrations (Hayes, 1982; Cranmer, 1986). Information on the incidences of human intoxication by carbaryl can be found in the Carbaryl Decision Document (EPA, 1980). For the period 1966–1980, a total of 195 human intoxication cases were reported (3 fatalities, 16 hos-pitalizations, and 176 cases receiving medical attention). A single oral dose of 250 mg of carbaryl (2.8 mg/kg body weight) is sufficient to elicit moderately severe poisoning in an adult man (Cranmer, 1986). Moderate but transient toxicity has also been observed following exposure to a few of the more potent carbamate ester insecticides methomyl (Lannate) and propoxur (Baygon) (Fandekar et al., 1968, 1971; Liddle et al., 1979). More recently the illegal use of aldicarb (Temik), a very acutely toxic carbamate ester, on watermelons in California and on English cucumbers in British Columbia, Canada, resulted in moderate to severe toxicity in consumers of these products, with signs and symptoms

including nausea, vomiting, gastrointestinal cramps, and diarrhea (Goldman et al., 1990a,b).


While there is little evidence of prolonged neurotoxicity after exposure to carbamate ester insecticides, this statement should be made cautiously because the signal danger appears to involve acute single exposures to massive doses or at least repeated exposures to large doses. Examining a number of carbamate (aldicarb, methomyl) intoxications in children and adults, Lifshitz et al. (1997) discovered that the predominant symptoms in adults were miosis and muscle fasciculations, while the children were more likely to reveal CNS effects (stupor and/or coma) in addition to diarrhea and hypotension. The authors suggested that the blood-brain barrier was more permeable in the children.

Bizarre anecdotal cases exist that are contrary to everything that we know about carbamates. One case, that of a farmer who hand-sprayed a vegetable garden with a water-wettable formulation of carbaryl, drenching himself in the process, developed a chronic polyneuropathy, persistent photophobia and paresthesia, recent memory loss, muscular weakness, fatigue, and lassitude (Ecobichon, 1994b). The case study presented by Branch and Jacqz (1986) developed into a persistent, stocking-and-glove peripheral neuropathy accompanied by mental confusion and weakness in major skeletal muscle groups, with fasciculations and cerebral atrophy. Grendon et al. (1994) presented long-term observations of a group of men who had been exposed acutely to aldicarb, several experiencing symptoms 3 years after the initial severe intoxication. Feldman (1999) conducted extensive neurologic and psychological investigations on three individuals exposed accidentally to aerially applied carbaryl some three to five years before. Their persisting subjective symptoms were confirmed by peripheral nerve conduction studies, electromyography, and neuropsychological assessment, both peripheral and central impairment being documented.

There is evidence in animal studies, albeit at near toxic doses, of a wallerian-type degeneration of spinal cord tracts in rabbits and hens following treatment with sodium diethyldithiocarbamate (Edingon and Howell, 1969). Carbaryl, when fed to hogs (150 mg/kg per day for 72 or 83 days), caused a rear leg paralysis, minimal at rest but, when the animals were forced to move, resulting in marked incoordination, ataxia, tremors, clonic muscle contractions, and prostration, with histologic evidence of lesions in the CNS and in skeletal muscle (Smalley et al., 1969). Carbamate ester insecticides do no inhibit NTE or elicit OPIDN-type neurotoxicity. Behavioral changes have been noted in a number of animal studies following the subchronic or chronic administration of different carbamate insecticides (Santalucito and Morrison, 1971; Desi et al., 1974).

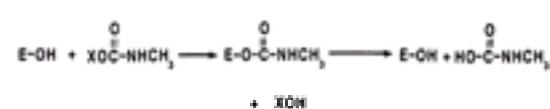
Mechanism of Toxic Action Although the anticholinesterase-type insecticides have a common mode of action, there are significant difference between organophosphorus and carbamate esters. The reaction between and organophosphorus ester and the active site in the AChE protein (a serine hydroxyl group) results in the formation of a transient intermediate complex that partially hydrolyzes with the loss of the "Z" substituent group, leaving a stable, phosphorylated, and largely unreactive inhibited enzyme that, under normal circumstances, can be reactivated only at a very slow rate (Fig. 22-13). With many organophosphorus ester insecticides, an irreversibly inhibited enzyme is formed, and the signs and symptoms of intoxication are prolonged and persistent, requiring vigorous medical intervention including the reactivation of the enzyme with specific chemical antidotes (see " Treatment of Poisoning," below, this section). Without intervention, the toxicity will persist until sufficient quantities of "new" AChE are synthesized in 20 to 30 days to destroy efficiently the excess neurotransmitter. The nature of the substituent groups at "X," "Y," and "Z" plays an important role in the specificity for the enzyme, the tenacity of binding to the active site, and the rate at which the phosphorylated enzyme dissociates to produce free enzyme. More recently introduced organophosphorus esters (acephate, temephos, dichlorvos, trichlorfon) are less tenacious inhibitors of nervous tissue AChE, the phosphorylated enzyme being more readily and spontaneously dissociated.


Figure 22-13. The interaction between an organophosphorus or carbamate ester with the serine hydroxyl groups in the active site of the enzyme acetylcholinesterase (E-OH). The intermediate, unstable complexes formed before the release of the "leaving" groups (ZH and XOH) are not shown. The dephosphorylation or decarbamoylation of the inhibited enzyme is the rate-limiting step to forming free enzymes.

In contrast, carbamic acid esters, which attach to the reactive site of the AChE, undergo hydrolysis in two stages: the first stage is the removal of the "X" substituent (an aryl or alkyl group) with the formation of a carbamylated enzyme; the second stage is the decarbamylation of the inhibited enzyme with the generation of free, active enzyme (Fig. 22-13). Carbamic acid esters are nothing more than poor substrates for the cholinesterase-type enzymes.

When the concept of the interaction between organophosphorus and carbamic esters with AChE is presented in another manner (Table 22-8), one can see that the only distinctive difference between the two anticholinesterase-type insecticides lies in the rate at which the dephosphorylation or decarbamylation takes place. The rate is exceedingly slow for organophosphorus esters, so much so that the enzyme is frequently considered to be irreversibly inhibited. The rate of decarbamylation is sufficiently rapid that these esters are often considered to be reversible inhibitors with low turnover rates. The characteristics of the various rate constants for the natural substrate (ACh), organophosphorus, and carbamylation esters are shown in Table 22-8. It is important to appreciate that the rate at which step 3 proceeds is thousands of times slower with carbamate esters than with ACh, whereas with organophosphorus esters it is several orders of manitude slower (Ecobichon, 1979). This subject has been extensively reviewed by Aldridge and Reiner (1972). A number of organophosphorus (phosphate, phosphonate, and phosphoramidate) esters (Fig. 22-12)—the chemical warfare agents sarin, soman, and tabun, and a few other compounds such as DFP, mipafox, and leptophos—have the ability to bind tenaciously to the active site of AChE and NTE to produce an irreversibly inhibited enzyme by a mechanism known as *aging*. The aging process is dependent on the size and configuration of the alkyl (R) substituent, with the potency of the ester increasing in the order of diethyl, dipropyl, and dibutyl for such analogs as DFP and mipafox (Aldridge and Johnson, 1971). The aging process is generally accepted as being caused by the dealkylation of the intermediate dialkylphosphorylated enzymes by one of two possible mechanisms (Fig. 22-14). The first involves the hydrolysis of a P–O bond following a nucleophile (base) attack on the phosphorus atom. The second mechanism involves the hydrolysis of an O–C bond by an acid catalysis, resulting in the formation of a carbonium ion as the leaving group (O'Brien, 1960; Eto, 1974; Johnson, 1982). The aging process is believed to fix an extra charge to the protein, causing some perturbation to the active site and thereby preventing dephosphorylation. While the exact nature of this reaction has not been demonstrated for AChE and NTE, evidence from experiments with saligenin cyclic phosphorus esters (derivatives of TOTP) and a-chymotrypsin points to the possibility of two stabilized forms of "aged" enzyme (Toia and Casida, 1979). Both of the reactions utilize the imidazole group of a neighboring histidine. In one reaction, the hydroxylated substituent is released and the phosphorylated enzyme is stabilized by a hydrogen on the imidazole group. In the other reaction, the leaving substituent becomes attached to the imidazole, yielding a N–C-hydroxylated derivative of the phospyhorylated enzyme. Johnson (1982) proposed that, in the case of NTE, if one or two of the P–R bonds were P–O–C (as in phosphates and phosphonates), aging would occur rapidly, whereas if the P–R bonds were P–C (as in phosphinates), aging would not be possible.

ESTERS	IE + AE ⇌ EIAE → EI + IX → EI + AOH COMPLEX FORMATION $(k_{+1} = L_{+1}L_{+1})$	ACYLATION (k_2)	DEACYLATION (k_3)
Substrates	Small	Extremely fast	Extremely fast
Organophosphorus esters	Small	Moderately fast	Slow or extremely slow
Carbamate esters	Small	Slow	Slow

Table 22-8 Kinectics of Ester Hydrolysis

Figure 22-14. A schematic diagram illustrating two mechanisms by which the "aging" of organophosphorus ester–inhibited acetyl-cholinesterase may occur. See text for details.

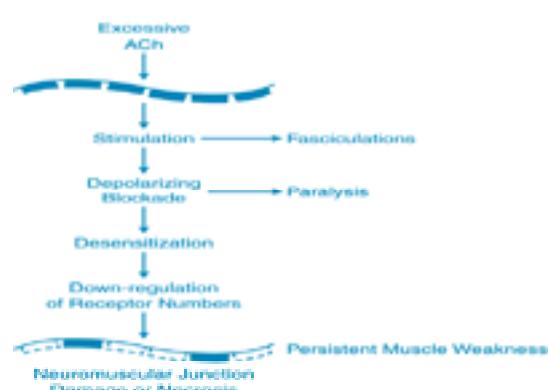
A number of acute, high-level exposures and intoxications by organophosphorus and carbamate esters have resulted in persistent CNS effects as well as debilitating muscle weakness, particularly in the legs, that cannot be explained on the basis of nervous tissue AChE inhibition alone. One hypothesis has been put forward that the excessive amount of undestroyed acetylcholine (ACh) may be involved by an action at nicotinic (nAChR) and muscarinic (mAChR) acetylcholine receptors (Ecobichon, 1994a). As shown in Fig. 22-15, the ACh accumulating at nAChR would elicit stimulation of the neuromuscular junctions, causing fasciculations (repetitive stimulation) followed by a depolarizing blockade if the ACh levels remained elevated, leading subsequently to a desensitization process with a more or less permanent reduction in nAChR numbers and causing the persistent muscle weakness observed through a lack of response to stimuli. Support for this hypothesis has been seen in studies revealing chronic abnormal electromyographic (EMG) activity in human intoxications by anticholinesterase insecticides, the details of which can be found in Ecobichon (1994a) and Feldman (1999). An alternative theory bears examination.


Figure 22-15. A schematic diagram illustrating the impact of excessive concentrations of acetylcholine (ACh) on muscarinic and nicotinic acetylcholine receptors in order to explain neuromuscular weakness and damage.

In an acute tabun study in rats, necrotic diaphragmatic muscle was observed, the effect being prevented by sectioning the phrenic nerve to a portion of the diaphragm (Ariens et al., 1969). Similar diaphragmatic damage has been observed in human poisonings (DeRueck and Willens, 1975; Wecker et al., 1986). Early work by Dettbarn and colleagues demonstrated that close intramuscular injections of parathion or paraoxon resulted in a skeletal myopathy accompanied by necrosis of the nerve terminal membrane and of the underlying muscle (summarized in Ecobichon, 1994a). There is evidence that organophosphate-induced AChE inhibition causes muscle hyperactivity as an initial step that triggers free radical–induced lipid peroxidation before muscle injury (Yang and Dettbarn, 1996; Yang et al., 1996). More recent studies, conducted at the level of brain mAChR and nAChR, have demonstrated that organophosphorus esters (soman, VX, DFP, parathion, paraoxon, chlorpyrifos) bind to both receptor types, particularly if the circulatory concentrations are in the micromolar range as would be encountered in poisoning cases, resulting in desensitization (Bakry et al., 1988; Eldefrawi et al., 1988; Huff et al., 1994; Katz et al., 1997). There is also evidence of differential down-regulation of nAChR subtypes through reduction of messenger RNA expression in rat brain following repeated injections of parathion (Jett et al., 1993, 1994; Ward and Mundy, 1996). Adult mice, exposed to DFP on postnatal day 3 or 10, showed decreases in brain nAChR density as well as significant alterations in spontaneous motor behavior (Ahlbom et al., 1995).

Can the carbamate esters induce muscle damage and receptor alterations through mechanisms involving ACh, direct binding to receptors, or through receptor expression? The repeated injection of such reversible anticholinesterase carbamates as physostigmine or neostigmine has produced myopathies qualitatively similar to those produced by paraoxon, possibly supporting the ACh-related theory (Wecker et al., 1978). Skeletal muscle lesions (myodegeneration, vacuolization) were observed in swine fed carbaryl over a period of 80+ days (Smalley et al., 1969). The peripheral neuropathy of a carbaryl-exposed elderly male has been described (Branch and Jacqz, 1986). Some interesting experiments could be performed with some of the more potent carbamate insecticides.

Biotransformation, Distribution, and Storage Both the organophosphorus and carbamate ester insecticides undergo extensive biotransformation in all forms of life. Both the route(s) and the rate(s) of metabolism are highly species-specific and dependent on the substituent chemical groups attached to the basic "backbone" structure of these esters (Fig. 22-10). Tissue enzymes of both phase I (oxidative, reductive, hydrolytic) and phase II (transfer or conjugative reactions with glutathione, glucuronic acid, glycine, and so forth) types are founds in a widespread pattern in plant, invertebrate, and vertebrate species and, indeed, are responsible for some aspects of the species sensitivity and/or both natural and acquired restance to many of these insecticides. The phase I detoxification processes usually form reactive metabolites, whereas phase II processes conjugate the polar phase I metabolites with some natural body substituent to form a product with enhanced water solubility and excretability. The biotransformation of anticholinesterase-type insecticides has been extensively reviewed in the literature and the reader is referred to such sources as O'Brien (1967), Menzie (1969), Eto (1974), Kulkarni and Hodgson (1984), and Matsumura (1985) for details on the various mechanisms involved.

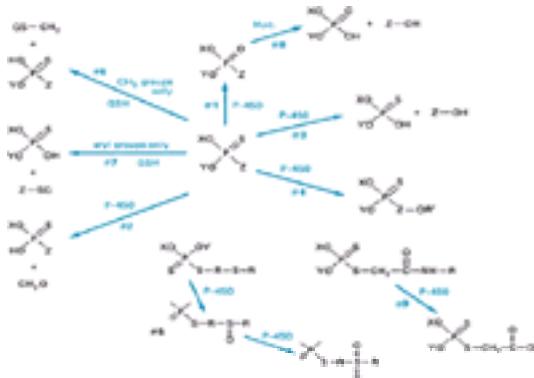
Organophosphorus esters undergo simultaneous oxidative biotransformation at a number of points in the molecule (Fig. 22-16), the enzymes utilizing the ubiquitous cytochrome P450 isoenzyme system. One reaction, that of oxidative desulfuration of phosphorothioate (parathion, methyl parathion, fenitrothion, etc.) and phosphorodithioate (azinophos methyl, malathion, etc.) esters, results in a significant increase in the toxicity of the biotransformation products, oxygen analogs (mechanism 1). This reaction is a major obligatory pathway in ester detoxification in mammals equipped with tissue aryl and aliphatic hydrolases (mechanism 8), whereas insects are deficient in these enzymes, making them more susceptible. Dealkylation with the formation of an aldehyde occurs readily (mechanism 2), but this pathway does not function efficiently when the alkyl group becomes longer. Dearylation occurs with the formation of a phenol and either a dialkylphosphoric or dialkylphosphorothioic acid (mechanism 3). The cytochrome system can also catalyze (1) aromatic ring hydroxylation (mechanism 4); (2) thioether oxidation (mechanism 5); (3) deamination; (4) alkyl and N-hydroxylation; (5) N-oxide formation; and (6) N-dealkylation. A number of transferases use glutathione (gamma-glutamyl-L-cysteinyl glycine, GSH) as a cofactor and acceptor for O-alkyl (methyl) and O-aryl groups (mechanisms 6 and 7) to yield monodesmethyl products plus S-methylglutathione or aryl-glutathione derivatives plus the respective phosphoric or phosphorothioic acids.


Figure 22-16. A schematic diagram depicting the various phase I and II biotransformation pathways of an organophosphorus ester and the nature of the products formed as a consequence of oxidative, hydrolytic, GSH-mediated transfer and conjugation of intermediates in mammals. See text for details.

Hydrolysis of phosphoric and phosphorothioic acid ester occurs via a number of different tissue hydrolases (nonspecific carboxylesterases, arylesterases, phosphorylphosphatases, phosphotriesteraes, carboxyamidases) scattered ubiquitously throughout the plant and animal kingdoms, with activity being highly dependent on the nature of the substituents (Ecobichon, 1979). Slight structural modifications to substituents on the insecticide molecule can dramatically alter the specificity of these enzymes toward an agent and affect species selectivity. The arylesterases [aromatic or A-esterases (ArE), EC 3.1.1.2] preferentially hydrolyze aryl (phenol, naphtol, indole) esters of short-chain aliphatic or phosphorus acids, particulary if there is a double bond present in the alcohol moiety in position a with respect to the ester bond (mechanism 8). Carboxylesterases [carboxylic acid ester hydrolases (CE), EC 3.1.1.] are capable of hydrolyzing a variety of aliphatic and aryl esters of short-chain fatty acids. The most important example of this reaction involving organophosphorus ester insecticides is with malathion [*O,O*-dimethyl-*S*-(1,2-dicarbethoxyethyl) phosphorodithioate], in which one of the two available ethylated carboxylic ester groups is hydrolyzed to yield malathion (or malaoxon) a-monoacids that are biologically inactive (Dauterman and Main, 1966). This CE-catalyzed reaction is an important feature of resistance to this insecticide in insects and to tolerance in mammals. Potentiation of anticholinergic effects can be produced by the combined administration of certain pairs of organophosphate ester insecticides, such as EPN (*O*-ethyl-*O-p*-nitrophenylbenzenethiophosphonate) and malathion (Frawley et al., 1957). The mechanism for this effect involves the inhibition of carboxyesterases by EPN (Murphy, 1969, 1972, 1980). Carboxyamidases (acylamide amdiohydrolase, EC 3.5.1.4), found extensively in plant, insect, and vertebrate tissues, are of limited current interest in the degradation of insecticides; dimethoate (*O,O*-dimethyl-*S*-(*N*-methylcarbamoylmethyl) phosphorodithioate] is the only organophosphorus ester insecticide shown to be hydrolyzed by mammalian tissue amidases (mechanism 9). Phosphorylphosphatases and phosphotriesterases have limited involvement in the biotransformation of organophosphorus ester insecticides but play a role in the detoxification of some of the chemical warfare agents.

Phase II conjugative reactions are of limited use in the biotransformation of organophosphorus ester insecticides, and they are usually relegated to the task of glucuronidating or sulfating the aromatic phenols, cresols, and other substances hydrolyzed from the ester (Yang, 1976). However, one must be wary of these enzyme systems because metabolism studies of chlorfenvinphos (2-chloro-1-(29,49-dichlorophenyl)vinyl diethylphosphate) revealed the presence of glucuronide and glycine conjugates of several products, whereas studies with trichlorfon (*O,O*-dimethyl-1-hydroxy-2,2,2-trichloroethyl phosphonate) revealed direct glucuronidation of the insecticide without prior biotransformation (Hutson et al., 1967; Bull, 1972).

Carbamate ester insecticides can undergo simultaneous attack at several points in the molecule, depending on the nature of the substituents attached to the basic structure. In addition to the hydrolysis of the carbamate ester group by tissue CE and the release of a substituted phenol, carbon dioxide, and methylamine (Fig. 22-10), (mechanism 1), several oxidative and reductive reactions involving cytochrome P450–related monooxygenases can proceed, the ultimate products being considerably more polar than the parent insecticide. The extent of hydrolysis of carbamate ester insecticides varies greatly between species, ranging from 30 to 95 percent hydrolysis. The type of oxidative reactions observed with carbamate esters can be simplified into two main groups: (1) direct ring hydroxylation (mechanism 2) and (2) oxidation of appropriate side chains as is shown for this "mythical" methylcarbamate, resulting in the hydroxylation of *N*-methyl groups or methyl groups to form hydroxymethyl groups (mechanism 3), *N*-demethylation of secondary and tertiary amines (mechanism 4), *O*-dealkylation of alkoxy side chains (mechanism 5), thioether oxidation (mechanism 6), and so forth. Phase II conjugative reactions can occur at any free reactive grouping with glucuronide and sulfate derivatives (mechanism 7), and GSH conjugates (mercapturates) may be formed (mechanism 8). For a comprehensive exposition of the various mechanisms involved, the reader is referred to those reviews mentioned above, this section, as well as to pertinent articles by Ryan (1971), Fukuto (1972), and Kuhr and Dorough (1976).

Treatment of Poisoning Despite the qualitative and quantitative differences between organophosphorus and carbamate insecticide intoxications, all cases of anticholinesterase poisoning should be treated as serious medical emergencies and the patient should be hospitalized as quickly as possible. The status of the patient should be monitored by repeated analysis of the plasma (serum) cholinesterase and the erythrocyte AChE; the inhibition of the activities of these two enzymes is a good indicator of the severity of organophosphorus ester poisoning, because only the erythrocytic AChE is inhibited by carbamate esters (except at excessively high levels of exposure). As a consequence of the extensive involvement of the entire nervous system, the life-threatening signs (respiratory depression, bronchospasm, bronchial secretions, pulmonary edema, muscular weakness) resulting in hypoxemia will require immediate artificial respiration and suctioning via an endotracheal tube to maintain a patent airway. Arterial blood gases and cardiac function should be monitored.

The regimen for the treatment of organophosphorus ester insecticide intoxication, based on the analysis of serum pseudocholinesterase, is described in Table 22-9 (Namba et al., 1971; Ecobichon et al., 1977; Marrs, 1993). Atropine is used to counteract the initial muscarinic effects of the accumulating neurotransmitter. However, atropine is a highly toxic antidote and great care must be taken. Frequent small doses of atropine (subcutaneously or intravenously) are indicated for mild signs and symptoms following a brief, intense exposure. Large cumulative doses of atropine, up to 50 mg daily, may be essential to control severe muscarinic symptoms. The status of the patient must be monitored continuously by examining for the disappearance of secretions (dry mouth and nose) and sweating, facial flushing, and mydriasis (dilatation of pupils). Supplementary treatment to offset moderate to severe nicotinic and CNS signs and symptoms usually takes the form of one of the specific antidotal chemicals, the oximes (pralidoxime chloride or 2-PAM, pralidoxime methanesulfonate or P2S), administered intravenously to reactivate the inhibited nervous tissue AChE. The use of oximes may not be necessary for cases of mild intoxication and should be reserved for moderate to severe poisonings. Treatment by slow intravenous infusion of doses of 1.0 g should be initiated as soon as possible, because the longer the interval between exposure and treatment, the less effective the oxime will be. In many poisonings, a single treatment with pralidoxime will be sufficient to elicit a reversal of the signs and symptoms and to reduce the amount of atropine needed. In severe poisoning cases, a prodigious amount of pralidoxime may be needed. If absorption, distribution, and/or metabolism of the organophosphorus ester is delayed in the body, pralidoxime may be administered repeatedly over several days after the initial treatment. Care should be taken with repeated dosing because pralidoxime effectively binds calcium ions and causes muscle spasms not unlike those elicited by the organophosphorus esters. Severe muscle cramping, particularly in the extremities, may be alleviated by oral or intravenous calcium solutions (Ecobichon et al., 1977).

Table 22-9 Classification and Treatment of Organophosphorus Insecticide Poisoning Based on Plasma Pseudocholinesterase Activity Measurement

The therapeutic action of the oxime compounds resides in their capacity to reactivate AChE without contributing markedly toxic actions of their own. Those organophosphorus esters that possess good "leaving groups" (i.e., the "X" moiety) phosphorylate the nervous tissue AChE by a mechanism similar to that of

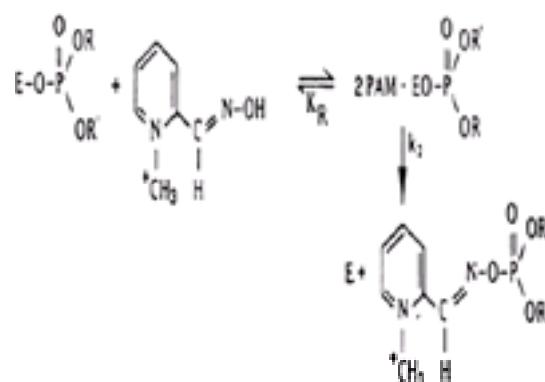
acetylation by the substrate ACh. These esters are frequently called *irreversible inhibitors* because the hydrolysis of the phosphorylated enzyme by water is exceedingly slow (Table 22-8). However, various nucleophilic agents containing a substituted ammonium group will dephosphorylate the phosphorylated enzyme at a much more rapid rate than water. The basic requirements for a reactivating molecule consist of a rigid structure containing a quaternary ammonium group and an acidic nucleophile, which would be complementary with the phosphorylated enzyme, in such a way that the nucleophilic oxygen would be positioned close to the electrophilic phosphorus atom. These structure-activity requirements led to the development of the pralidoxime compounds, with the *syn*-isomer of 2-PAM (2-formyl-*N*-methylpyridinium chloride oxime) being particularly active (Childs et al., 1955; Askew, 1956; Kewitz and Wilson, 1956; Namba and Hiraki, 1958). The reaction of 2-PAM with the phosphorylated enzyme proceeds as shown in Fig. 22-17.


Figure 22-17. The pralidoxime-catalyzed reactivation of an organo-phosphate-inhibited molecule of acetylcholinesterase, showing the release of active enzyme and the formation of an oxime-phosphate complex.

The reactivation is an equilibrium reaction, the oxime reacting either with the phosphorylated enzyme or with free, unbound organophosphorus ester, and the product is a phosphorylated oxime which in itself can be a potent cholinesterase inhibitor if it is stable in an aqueous medium (Schoene, 1972). In general, the phosphorylated oxime degrades quickly in water.

A practical limitation on the usefulness of oxime reactivators lies in the inability of these agents to reactivate "aged" AChE, that enzyme in which the phosphorylated enzyme has been further dealkylated and the phosphoryl group becomes tightly bound to the reactive site (see Fig. 22-14). Success with the pyridinium analogs led to an intensive search for more effective oximes and the discovery of the bispyridinium compounds toxogonin or obidoxime [bis(4-formyl- *N*-methylpyridinium oxime) ether dichloride], TMB-4 [*N,N*-trimethylene bis(pyridine-4-aldoxime) bromide], and, more recently, the H-series compounds. However, these agents are not without toxicity and only pralidoxime and toxogonin have seen extensive antidotal use (Engelhard and Erdmann, 1964; Steinberg et al., 1977).

With the apparent availability of organophosphorus nerve gases and their known ability to form rapidly aging complexes with AChE, the relative ineffectiveness of atropine and pralidoxime in such poisonings must be taken into account when the treatment of individuals exposed to these agents is confronted (Koplovitz et al., 1992; Webb, 1993; Clement, 1994). Toxogonin (obidoxime chloride) appears to be effective in tabun poisoning while, of the H-series of bis-pyridinium monooximes, HI-6 appears to be efficacious in soman and cyclohexylmethyl phosphorofluoridate (CMPF, or CF) poisonings. However, despite striking therapeutic effects, the issue is clouded by the fact that little reactivation of erythrocytic or brain AChE occurs (Kusic et al., 1991; Shih, 1993).

The clinical treatment of carbamate toxicity is similar to that for organophosphorus ester insecticide intoxication with the exception that the use of oximes is contraindicated. Early reports, in which pralidoxime or toxogonin was used in treating carbaryl intoxications, revealed that the oxime enhanced the carbaryl-induced toxicity (Sterri et al., 1979; Ecobichon and Joy, 1994). However, the oximes appear to offer some antidotal properties in patients exposed to aliphatic oxime carbamates (aldicarb, methomyl) (Feldman, 1999).

Diazepam (10 mg SC or IV) may be included in the treatment regimen of all but the mildest cases of organophosphorus and/or carbamate intoxications. In addition to relieving any mental anxiety associated with the exposure, diazepam counteracts some aspects of the CNS and neuromuscular signs that are not affected by atropine. Doses of 10 mg (SC or IV) are appropriate and may be repeated. Other centrally acting drugs that may depress respiration are not recommended in the absence of artificial respiration.

It is important to appreciate that vigorous treatment of anticholinesterase-type insecticide intoxications does not offer protection against the possibility of delayed-onset neurotoxicity or the persistent sensory, cognitive, and motor defects discussed earlier. These deficits, albeit reversible over a long time interval, appear consistently in intoxications and are caused by mechanisms as yet unknown. Certain evidence points to severe damage to the neuromuscular junctions in skeletal muscle, resulting in a persistent peripheral muscular weakness (Wecker et al., 1978).

Pyrethroid Esters

A major class of insecticides comprises the synthetic pyrethroids, a group of chemicals that entered the marketplace in 1980 but, by 1982, accounted for more than 30 percent of worldwide insecticide usage (Anon., 1977; Vijverberg and van den Bercken, 1982). However, these synthetics arise from a much older class of botanical insecticides, pyrethrum, a mixture of six insecticidal esters (pyrethrins, cinerins, and jasmolins) extracted from dried pyrethrum or chrysanthemum flowers (*Chrysanthemum cinerariaefolium, Chrysanthemum coccineum*) (Hartley and West, 1969). Although it is believed that the natural pyrethroids were discovered by the Chinese in the first century A.D., the first written accounts of these agents are found in the seventeenth-century literature and commercial preparations made their appearance in the mid-1800s (Neumann and Peter, 1987). Japanese woodblock prints from the early 1800s exist in which one can see smoldering insecticide coils of pressed pyrethrum powder not unlike those manufactured and used today.

In 1965, the world output of pyrethrum was approximately 20,000 tons, with Kenya alone producing some 10,000 tons (Cremlyn, 1978). The ever-increasing demand for this product has far exceeded the limited world production, leading chemists to focus attention on the synthesis of new analogs, hopefully with better stability in light and air, better persistence, more selectivity in target species, and low mammalian toxicity. In addition to extensive agricultural use, the synthetic pyrethroids are components of household sprays, flea preparations for pets, plant sprays for home and greenhouse use, and other applications. For an in-depth discussion of the development of the pyrethroid ester insecticides, their chemistry, and their biological activity, the reader is referred to Elliott (1976), Cremlyn (1978), Casida et al. (1983), Leahey (1985), Matsumura (1985), Narahashi (1985), Narahashi et al. (1985), and Joy (1994b).

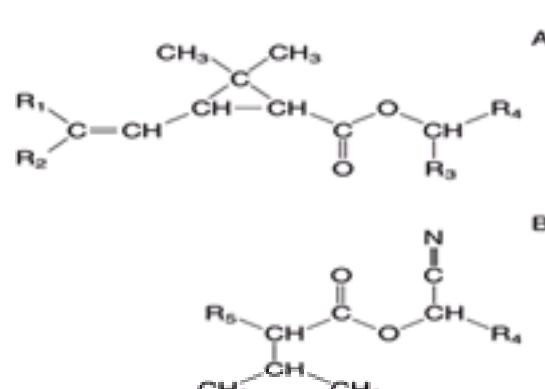
Natural pyrethrum consists of a mixture of six esters derived from two acids (chrysanthemic, pyrethric) and three alcohols (pyrethrolol, cinerolol, jasmolol), producing an effective contact and stomach poison mixture having both knockdown and lethality. When the complex structure was identified, the synthetic esters were marketed (Fig. 22-18). Distinctive molecular structures convey selectivity toward certain insect species and in some cases to toxicity in mammals. Several of the pyrethroid esters exist in isomeric forms around the cyclopropane nucleus, resulting in distinctly different toxicities and potencies (Casida et al., 1983).


Figure 22-18. The basic structures of the synthetic pyrethroid ester insecticides showing (A) the intact cyclopropane ring in type I esters, with R$_1$ and R$_2$ (methyl, bromine, chlorine, etc.), R$_3$ (hydrogens or cyano) and R$_4$ (3-phenoxybenzoate, other) substituents; and (B) the "open" structure of type II esters with R$_4$ (3-phenoxybenzoate, other) and R$_5$ (substituted phenyl substituents).

Signs and Symptoms of Poisoning Based on the symptoms produced in animals receiving acute toxic doses, the pyrethroids fall into two distinct classes of chemicals (Table 22-10). The type I poisoning syndrome or *T syndrome* is produced by esters lacking the a-cyano substituent and is characterized by restlessness, incoordination, prostration, and paralysis in the cockroach, as compared with the rat, which exhibits such signs as sparring and aggressive behavior, enhanced startle response, whole-body tremor, and prostration. The type II syndrome, also known as the *CS syndrome,* is produced by those esters containing the a-cyano substituent and elicits intense hyperactivity, incoordination, and convulsions in cockroaches, in contrast to rats, which display burrowing behavior, coarse tremors, clonic seizures, sinuous writhing (choreo-athetosis), and profuse salivation without lacrimation; hence the term *CS* (choreoathetosis/salivation) *syndrome*. A few of these agents, fenpropanthrin, for example, cause a mixture of type I and II effects, depending on the species (rat or mouse) treated and possibly on the route of administration (Verschoyle and Aldridge, 1980; Gammon et al., 1981; Lawrence and Casida, 1982). The bulk of evidence points to the fact that the type II syndrome involves primarily an action in the mammalian CNS, whereas with the type I syndrome, peripheral nerves are also involved. This hypothesis was based initially on the observed symptomatology, but more recent evidence has revealed a correlation between the severity of type II responses and brain concentrations of deltamethrin in mice, regardless of the route of administration (Barnes and Verschoyle, 1974; Ruzo et al., 1979). Agents eliciting the type II syndrome have greater potency when injected intracerebrally, relative to intraperitoneal injection, than those causing type I syndrome effects (Lawrence and Casida, 1982). There is no indication of a fundamental difference between the mode of action of pyrethroids on neurons of target and nontarget species, and the neurotoxicologic responses depend on a combination of physicochemical properties of the particular pyrethroid ester, the dose applied, the time interval after treatment, and the physiologic properties of the particular model used (Leaks et al., 1985).

SYNDROME	COCKROACH	RAT	CHEMICALS
Type I ("T" syndrome)	Restlessness Incoordination Prostration Paralysis	Hyperactivation Sparring Aggressiveness Enhanced startle response Whole-body tremor Prostration	Allethrin Cismethrin Phenothrin Pyrethrin I Resmethrin Tetramethrin
Type II ("CS" syndrome)	Hyperactivity Incoordination Convulsions	Burrowing Dermal tingling Clonic seizures Writhing Profuse salivation	Acrinathrin Cycloprothrin Cyfluthrin Cyhalothrin Cyphenothrin Cypermethrin Deltamethrin Esfenvalerate Fenvalerate Flucythrinate Fluvalinate

Table 22-10 Classification of Pyrethroid Ester Insecticides on the Basis of Chemical Structure and Observed Biological Activity

Although these insecticides cannot be considered to be highly toxic to mammals, their use indoors in enclosed and poorly ventilated spaces has resulted in some interesting signs and symptoms of toxicity to humans. Exposure to the natural pyrethrum mixture is known to cause contact dermatitis; descriptions of the effects range from localized erythema to a severe vesicular eruption (McCord et al., 1921). The allergenic nature of this natural product is not surprising, with asthma-like attacks and anaphylactic reactions and peripheral vascular collapse among the responses observed. Human toxicity associated with the natural pyrethrins stems from their allergenic properties rather than from direct neurotoxicity. There has been little evidence of the allergic-type reactions in humans exposed to synthetic pyrethroid esters.

One notable form of toxicity associated with synthetic pyrethroids has been a cutaneous paresthesia observed in workers spraying esters containing an a-cyano substituent (deltamethrin, cypermethrin, fenvalerate). The paresthesia developed several hours following exposure and was described as a stinging or burning sensation on the skin which, in some cases, progressed to a tingling and numbness, the effects lasting some 12 to 24 h (LeQuesne et al., 1980; Tucker and Flannigan, 1983; Zhang et al., 1991).

Reports have appeared in the literature from the People's Republic of China, where synthetic pyrethroids have been used on a large scale on cotton crops since 1982 (Stuart-Harte, 1988; He et al., 1988, 1989). Associated with the sloppy handling of deltamethrin and fenvalerate, both of which are type II compounds, some 573 cases of acute poisoning have occurred with some 229 cases of occupational exposure. Some 45 cases of intoxication involved cypermethrin. Occupational exposure resulted in some dizziness plus a burning, itching, or tingling sensation of the exposed skin, which was exacerbated by sweating and washing with warm water. The signs and symptoms disappeared by 24 h after exposure. Spilling these agents on the head, face, and eyes resulted in pain, lacrimation, photophobia, congestion, and edema of the conjunctiva and eyelids. Ingestion of pyrethroid esters caused epigastric pain, nausea and vomiting, headache, dizziness, anorexia, fatigue, tightness in the chest, blurred vision, paresthesia, palpitations, coarse muscular fasciculations in the large muscles of the extremities, and disturbances of consciousness. In severe poisonings, convulsive attacks persisting from 30 to 120 s were accompanied by flexion of the upper limbs and extension of the lower limbs, with opisthotonos and loss of consciousness. The frequency of these seizures was on the order of 10 to 30 times a day in the first week after exposure, gradually decreasing in incidence, with recovery within 2 to 3 weeks (He et al., 1989). The signs and symptoms of acute intoxication appear to be reversible and no chronic toxicity has been reported to date.

Site and Mechanism of Toxicity Several mechanisms of action of pyrethroid esters exist in the sensory, motor, and central nervous systems of insects and vertebrates, many of these actions being studied in vitro using cockroach, crayfish, and squid giant axon preparations or various cultured cell systems (Narahashi, 1971, 1976, 1985; Casida et al., 1983; Forshaw et al., 1993; Narahashi, 1998; Ray, 2000).

Both type I and type II esters modify the gating kinetics of sodium channels involved in the inward flow of sodium ions, producing the action potential in cells that are normally closed at the resting potential (Marban et al., 1998). The pyrethroids affect both the activation (opening) and inactivation (closing) of the channel, resulting in a hyperexcitable state as a consequence of a prolonged negative afterpotential that is raised to the threshold membrane potential and producing abnormal repetitive discharges (Ginsburg and Narahashi, 1993; Narahashi et al., 1998). The observed differences between type I and type II esters lie in the fact that the former hold sodium channels open for a relatively short time period (milliseconds), whereas type II esters keep the channel open for a prolonged time period (up to seconds) (Joy, 1994b). Although the repetitive discharges could occur in any region of the nervous system, those at presynaptic nerve terminals would have the most dramatic effect on synaptic transmission (i.e., on the CNS and peripheral sensory and motor ganglia), giving rise to the signs documented in Table 22-10. The depolarizing action would have a dramatic effect on the sensory nervous system because such neurons tend to discharge when depolarized even slightly, resulting in an increased number of discharges and accounting for the tingling and/or burning sensation felt on the skin and observed in particular with type II esters (van den Bercken and Vijverberg, 1983). The biological actions of different pyrethroid esters at sodium channels is highly variable in that (1) *cis* and *trans* stereospecificity exists, the *cis* isomers being as much as 10-fold more toxic than *trans* isomers (Soderlund, 1985); (2) an additional chiral center is produced if a cyano-substituent is added to the alcohol (Fig. 22-18), giving rise to eight possible isomers; (3) the binding of *cis* and *trans* isomers differs, being competitive at one site and noncompetitive at another (Narahashi, 1986); (4) tetrodotoxin-resistant sodium channels are 10-fold more sensitive to pyrethroids than are tetrodotoxin-sensitive channels (Ginsburg and Narahashi, 1993; Song and Narahashi, 1996); (5) affinity to sodium channels is dependent on the variable a-subunit composition of the 10 or more different channels identified to date (Marban et al., 1998); (6) insect sodium channels are 100-fold more sensitive than mammalian channels, thereby in part explaining species susceptibility (Warmke et al., 1997); (7) low temperature (25°C) exerts a greater inhibitory effect of pyrethroid esters (on sodium channels) than a higher (37°C) temperature due to increased current flow at low temperature (Narahashi et al., 1998). According to Narahashi et al. (1998), the most important factor that causes differential toxicity is the sodium channel of the nervous system.

Other sites of action have been noted for pyrethroid esters, as shown in Fig. 22-19. Calcium channels have been proposed targets, particularly in insects at levels of 10^{-7} M (Duce et al., 1999). Mammalian calcium channels appear to be less sensitive, with effects being seen only with type I esters. However, many of these experiments were conducted on cultured neuroblastoma cells, sinoatrial node cells, and so on, with results difficult to reconcile with neuronal actions. Several agents

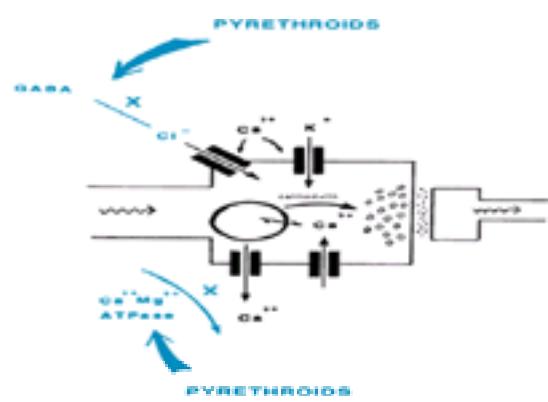
(permethrin, cypermethrin, deltamethrin) inhibit Ca^{2+}, Mg^{2+}-ATPase, the effect of which would result in increased intracellular calcium levels accompanied by increased neurotransmitter release and postsynaptic depolarization (Clark and Matsumura, 1982).


Figure 22-19. Other proposed cellular mechanisms by which pyrethroid esters interfere with neuronal function.

Type II esters at relatively high concentrations act on the GABA-gated chloride channels in mammalian brain, this action perhaps being related to the seizures seen with type II ester intoxication (Abalis et al., 1986; Bloomquist et al., 1986). However, other studies have shown pyrethroids to have no GABA-antagonistic activity (Joy and Albertson, 1991; Ray, 2000).

Voltage-sensitive calcium-independent chloride channels in nervous tissue control cell excitability and exist in functionally different kinds, those sensitive to pyrethroid esters belonging to the maxi -chloride channel type (Franciolini and Petris, 1990; Forshaw and Ray, 1993). The pyrethroid-induced decrease in chloride ion current would result in cell excitability, synergizing with the pyrethroid effect on sodium channels. Only type II esters affect maxi-chloride channels and may be responsible for the generation of salivation and myotonia along with those effects elicited on sodium channels (Joy, 1994; Ray et al., 1997; Ray, 2000).

Biotransformation, Distribution, and Storage Evidence to date suggests that pyrethroid esters elicit little chronic toxicity in either in animals or humans. Chronic animal feeding studies yield high "no effect" levels, suggesting that there is little storage or accumulation of a body burden of these agents and, perhaps, an efficient detoxification of the chemicals.

Two ester linkages exist in pyrethroid esters, a terminal methyl ester (pyrethrin II) and one more centrally located ester adjacent to the cyclopropane moiety (allethrin, tetramethrin, phenothrin, deltamethrin) and/or the a-cyano substituent (deltamethrin, cypermethrin, fenvalerate, cyphenothrin). Pyrethroid esters are susceptible to degradation by hydrolytic enzymes, possibly by nonspecific carboxylesterases found associated with the microsomal fraction of tissue homogenates in various species (Ecobichon, 1979; Casida et al., 1983). Hydrolysis of the methoxycarbonyl group in pyrethrin II by an esterase in rat liver has been reported, but the major site of hydrolytic activity would appear to be at the central ester linkage (Elliott et al., 1972; Shono et al., 1979; Glickman and Casida, 1982). The importance of ester hydrolysis as a route of detoxification is verified by the fact that many organophosphorus esters that are capable of inhibiting tissue esterases potentiate pyrethroid ester toxicity in a variety of species (Casida et al., 1983). Species susceptibility to pyrethroid ester toxicity would appear to be highly dependent on the nature of the tissue esterase, the level of activity detected, the substrate specificity, and rate of hydrolysis encountered in target and nontarget species. The microsomal monooxygenase system found in the tissues of almost all species is extensively involved in the detoxification of every pyrethroid ester in mammals and of some of these agents in insect and fish species. Much of the research in this field has been summarized by Shono et al. (1979), Kulkami and Hodgson (1984), and Casida et al., (1983). The importance of the oxidative mechanisms in detoxification is demonstrated by the inclusion of the synergist piperonyl butoxide, a classic monooxygenase inhibitor, in preparations toxic to houseflies and other insects, in order to enhance the potency of pyrethroid esters in the 10- to 300-fold range (Casida et al., 1983; Matsumura, 1985).

Treatment of Poisoning Limited experience with pyrethroid intoxications has restricted the development of acceptable protocols for treatment. Removal from exposure and lavage with vegetable and/or vitamin E cream will alleviate dermal paresthesia, presumably by binding the lipophilic pyrethroids (Flannigan et al., 1985). Most other therapies have been symptom-related topical steroids for contact dermatitis, antihistaminics, decongestants, and steroid nasal spray for rhinitis and inhaled steroids for asthma (O'Malley, 1997). Systemic poisoning is more difficult to treat, symptomatic and supportive measures being appropriate (He et al., 1989). Experimental therapies in animals have included local anesthetics, phenytoin, phenobarbitone, valproate, diazepam, mephenesin, and urethane, all at exceptionally high doses with interfering side effects (Ray, 2000). Only the chloride channel agonists ivermectin and pentobarbitone appeared to be of any benefit, particularly in type II ester intoxications (Forshaw, 2000).

Avermectins

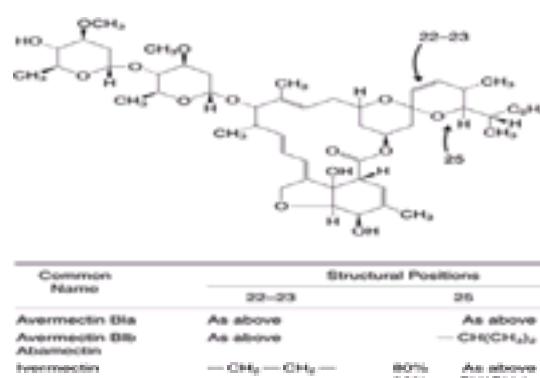
The avermectins were discovered in 1975, isolated from a culture of the actinomycete *Streptomyces avermitilis* in a soil sample made available to Merck and Co. by the Kitisato Institute in Japan (Campbell et al., 1983; Campbell, 1989; Fisher and Mrozik, 1992). Avermectins are derived from 16-member macrocyclic lactones, three of which—avermectin B1a, the homolog B1b (abamectin), and the semisynthetic ivermectin—have come into wide use in veterinary medicine as potent insecticidal, acaricidal, and anthelmintic agents (Fisher and Mrozik, 1992) (Fig. 22-20). Ivermectin is used for a wide range of ecto- and endoparasites of domestic and wild animals. Potent anthelmintic activity against most gastrointestinal and systemic nematodes has been identified at exceptionally low (0.001 to 0.05 mg/kg body weight) dose levels, but this efficacy does not extend to tapeworms or flukes (Campbell et al., 1983). Administered topically or subcutaneously (systemically), ivermectin controls grubs, lice, mites, certain ticks, and biting flies on cattle, horses, sheep, swine, and dogs (except the collie breed, which appears to be uniquely susceptible) (Fisher and Mrozik, 1992). Ivermectin treatment does not result in the rapid death of biting insects but appears to disrupt engorgement, molting, and reproduction (Campbell et al., 1983). A mixture of avermectins B1a and B1b is also used currently as a foliar spray on crops against various mites, Colorado potato beetle, tomato hornworm, Mexican bean beetle, pea aphid, cabbage looper, corn earworm, and southern army worm (Fisher and Mrozik, 1992). Emamectin (MK-244), a derivative of avermectin B1, is more effective against Lepidoptera larvae.


Figure 22-20. A structural representation of the macrocyclic lactone avermectin (B1a), abamectin (B1b), and the semisynthetic insecticide ivermectin showing the structural differences at positions 22 to 23 and 25 of the ring.

The discovery that ivermectin was efficacious against the skin-dwelling microfilaria of *Onchocerca* species in cattle and horses suggested that it might be of use in treating onchocerciasis (river blindness) in humans, a debilitating disease caused by the organism *Onchocerca volvulus* (Taylor and Green, 1989). It has become the drug of choice in treating lightly infected individuals, markedly reducing the number of microfilaria in the skin though without effect on the adult worms (Aziz et al., 1982; Taylor and Greene, 1989). It is a safe, long-acting microfilaricide, an applied single dose (150 ug/kg body weight) killing the immature microfilaria and keeping

the numbers of reappearing microfilaria well below pretreatment levels for up to 1 year (Fisher and Mrozik, 1992). Ivermectin treatment can significantly reduce the incidence of onchocerciasis by limiting the source of infection.

While the avermectins are highly lipid soluble, dermal absorption is less than 1.0 percent of the applied dose (Fisher and Mrozik, 1992). Minimal oxidative biotransformation occurs, 2,4-hydroxymethyl ivermectin and 3'- O-desmethyl ivermectin being formed. Regardless of the route of administration, urinary excretion accounts for only 0.5 to 2.0 percent of the dose, the remainder being excreted slowly in the feces (Campbell et al., 1983). While the liver and adipose tissue took up the agent(s), very little residue was found in muscle, kidney or brain. In the case of the brain, presumably the agent could not penetrate the blood-brain barrier. In 28 days, almost complete elimination of ivermectin occurred from the tissues of treated cattle with the exception of the liver and body fat (Fisher and Mrozik, 1992).

Toxicologically, ivermectin is acutely toxic to rodents and other species, the oral and intraperitoneal LD $_{50}$ values being of the order of 25 to 80 mg/kg body weight (Fisher and Mrozik, 1992). Dermal toxicity is low, the LD_{50} for rats and rabbits being >660 and 406 mg/kg body weight, respectively. In subchronic studies, no treatment-related effects were observed in rats, dogs, and monkeys at the usual therapeutic dosage range (0.1 to 1.2 mg/kg body weight per day). Ivermectin showed no positive genotoxic effects in microbial assays, in a forward mutation assay (mouse lymphoma), or in an unscheduled DNA synthesis assay. In developmental/reproductive studies, offspring abnormalities were observed only at maternotoxic doses in mice, rats, and rabbits. Oncogenic effects were not found in studies with abamectin.

Mechanism of Action Early studies, with a variety of invertebrate species and model systems, resulted in a number of possible mechanisms of action on neuronal transmission, chloride channels, and GABA-like effects, summarized in Fisher and Mrozik (1992). However, care must be taken in interpreting such results, since interneuronal and neuromuscular junctions are known to differ considerably between species (Gerschenfeld, 1973). The low water solubility and extensive (nonspecific) binding of avermectins preclude accurate estimations of target-site concentrations, overestimating the actual target-site concentrations (Fisher and Mrozik, 1992). More recent binding affinity studies in rat brain and in insect and nematode nerve tissue preparations have revealed that, in invertebrates, biological activity occurred at nanomolar and picomolar concentrations (Schaeffer et al., 1989; Fisher and Mrozik, 1992). Higher concentrations appear to cause secondary events and/or artifacts. While there may be different species-specific avermectin "receptors," this insecticide class has a high binding affinity to chloride-channel proteins, opening the channels, reducing membrane resistance, and increasing conductance inward. Such binding sites appear to be distinct from those of other effector molecules and involve GABA-insensitive chloride channels (Arena et al., 1991; Payne and Soderlund, 1991). Explaining the selective specificity of avermectins (wide range of nematodes, arthropods, insects but not tapeworms, flukes, and adult filaria) must await the molecular study of the receptor proteins in these species. In mammals, in the nematode *Caenorhabditis elegans,* and the housefly, avermectins interact with the GABA-receptor complex, as has been shown by avermectin-induced changes in GABA receptor – directed ligands (Deng and Casida, 1992; Arena et al., 1995; Lankas et al., 1997).

Newer Chemical Insecticides

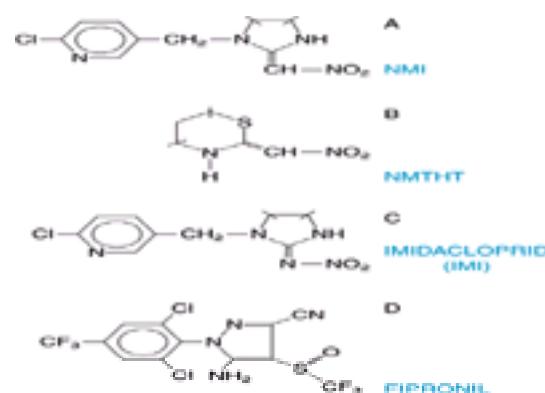
With the development of insect resistance to various classes of chemical insecticides, new approaches to insect control are needed. Utilizing a better understanding of insect neurobiology, some new and highly specific agents have been developed, capitalizing on the recognition that various receptors in insect nervous systems are significantly different from those in mammals. Shown in Fig. 22-21 are the structures of three types of new agents entering or available in the marketplace: (1) the nitromethylene heterocycles, developed from the cyclodienes and cyclohexanes; (2) the nitroimino derivatives (chloronicotinyl or neonicotinoids), similar to nicotine; and (3) the phenylpyrazoles. These chemicals are effective at low application rates (8 to 10 g/ha), are not environmentally persistent, and show negligible toxicity toward vertebrates. They possess unique and selective mechanisms of action and perhaps point the way to future insecticide development. To date, there have been no reports of toxicity in humans.


Figure 22-21. Representative structures of the nitromethylene, chlor-onicotinyl, and phenylpyrazole insecticides.

Nitromethylenes A search for new classes of insecticides led to a study of various aromatic heterocycles containing a nitromethylene substituent, only those containing a pyridine system being insecticidal (Fig. 22-21*A* and Fig. 22-21*B*) (Soloway et al., 1979). The nitromethylene heterocycle (NMH) insecticides are fast-acting neurotoxicants, effective by both contact or oral ingestion; they are relatively safe to vertebrates and degrade rapidly in the environment (Schroeder and Flattum, 1984).

Using the cockroach ventral nerve cord (the sixth abdominal ganglion nerve) preparation, various NMHs at micromolar concentrations produced a biphasic effect characterized by an initial increase in the frequency of spontaneous discharges followed by a blockade of nerve impulse conduction (Schroeder and Flattum, 1984). Elegant, classic neuropharmacologic experiments conducted by these authors demonstrated that the NMHs acted as neurotransmitter mimics and had both excitatory depressant effects, eventually blocking postsynaptic nicotinic receptors (nAChR). More recent experiments with 2(nitromethylene)tetrahydro-1,3-thiazine (NMTHT) (Fig. 22-21*B*) confirmed the biphasic action at nAChRs in several insect species and suggested that a binding site resided on the a-subunits of insect nAChRs (Leech et al., 1991).

Chloronicotinyl An outgrowth of studies of the nitromethylene-type insecticides was the discovery of the nitroimino heterocycles best known by the compound imidacloprid (Fig. 22-21 *C*), developed in Japan in the mid-1980s. This agent combines high potency to insects with exceptionally low mammalian toxicity and a favorable persistence (Liu et al., 1993; Bayer Corp., 1994). The potency of imidacloprid and several analogs can be correlated with the binding affinity to house fly head membranes and mouse brain membranes, these agents having a low affinity to the latter (Liu et al., 1993, 1995; Chao and Casida, 1997). Extensive studies have demonstrated that imidacloprid binds specifically to nAChRs in various insects' nervous systems (Liu and Casida, 1993; Nishimura et al., 1994; Liu et al., 1995). Imidacloprid acts as a partial agonist at the nAChR channel, generating subconductance-state currents (Nagata et al., 1997). Characterization of cloned nAChRs from insects (*Myzus persicae,* peach aphid) revealed that imidacloprid affinity was influenced strongly by the a-subunit content of the receptor (Huang et al., 1999). Investigations of a nAChR structure and function will prove to be a boon to further insecticide development.

Phenylpyrazoles The phenylpyrazole derivatives show extensive biological activity, including insecticidal, herbicidal, and miticidal properties. The compound fipronil (Fig. 22-21*D*) is insecticidal and has been shown to be highly effective against a broad range of insect pests at low-level foliar or soil application. It was first studied by Rhone-Poulenc Agro in 1987 and is now available commercially (Gant et al., 1998). It is considered to be a second generation removed from the earlier organochlorine insecticides (lindane, a-endosulfan) acting at the GABA receptor to block the chloride channel (Damgaard et al., 1999).

Fipronil has a unique mode of action in that it blocks the passage of chloride ions through the GABA-regulated chloride channel, disrupting CNS activity, since GABA is an inhibitory neurotransmitter. Fipronil is a noncompetitive inhibitor of GABA-induced effects, the effects in neurons being an increase in rapid bursts of electrical activity (Gant et al., 1998). Fipronil, a sulfoxide, is biotransformed to the corresponding sulfone in biological systems, the latter compound still being a potent insecticide. This conversion can be blocked by piperonyl butoxide, the cytochrome-P450 inhibitor. There is also a photoproduct, desulfinyl fipronil. Fipronyl and the sulfone selctively bind with high affinity to insect GABA receptors and with much lower affinity to vertebrate brain receptors (Cole et al., 1993; Hainzl et al., 1998). Comparing fipronil and its derivatives to earlier chloride-channel blockers, the IC $_{50}$ vertebrate/IC$_{50}$ insect ratios are 158 for fipronil, 140 for lindane, 31 for the desulfinyl product, 19 for fipronil sulfone, and 4 for a-endosulfan (Hainzl et al., 1998). The selectivity ratios relative to human GABA receptor are 135 for fipronil, 17 for the sulfone, and 16 for the desulfinyl photoproduct (Hainzl et al., 1998).

All of the above receptor-specific insecticides have provided new ligand probes for neurotransmitter receptors as well as a new approach to insecticide development. The only worrisome concern is that, with increasing use and reliance on such agents, target insects may develop resistance to these new compounds through mechanisms similar to those seen for other neurotransmitters. In the meantime, the high insect selectivity, low mammalian toxicity, and low rates of application may provide a breathing space in the ongoing search for efficacious, nontoxic chemical insecticides.

BOTANICAL INSECTICIDES

Naturally occurring agents of plant origin have been used to control insect pests. These chemicals ranged from highly toxic agents (to both target and nontarget species), such as nicotine, to relatively innocuous substances, such as derris root. Interestingly, despite the overwhelming number of synthetic insecticide formulations on the market, the two above-mentioned agents can still be purchased and are still considered effective insecticides.

Nicotine

Nicotine, first used as an insecticide in 1763, has been used as a contact insecticide, stomach poison, and fumigant in the form of nicotine alkaloid, the sulfate salt, or in the form of other derivatives. Commercially, nicotine is extracted from the leaves of *Nicotiana tabacum* and *Nicotiana rustica* by alkali treatment and steam distillation or by extraction with benzene, trichloroethylene, or diethyl ether. Nicotine makes up some 97 percent of the alkaloid content of commercial tobacco. It is marketed under the trade name of Black Leaf 40, an aqueous solution of the sulfate salt of nicotine, containing 40 percent nicotine.

Nicotine is extremely toxic, the acute oral LD_{50} in rats being on the order of 50 to 60 mg/kg. It is readily absorbed through the skin, and any contact with nicotine solutions should be washed off immediately. Anecdotal accounts of experiences by people who sprayed this chemical as an agricultural insecticide make an interesting collection of stories, all pointing to the fact that nicotine mimics the action of acetylcholine at all ganglionic synapses and at neuromuscular junctions, causing muscular fasciculations, convulsions, and death from paralysis of the respiratory muscles via blockade of the neuromuscular junctions (see Table 22-7). It functions as an insecticide in much the same manner, causing a blockade of synapses associated with motor nerves in insects.

Rotenoids

Six rotenoid esters occur naturally and are isolated from the plant *Derris eliptica* found in Southeast Asia or from the plant *Lonchocarpus utilis* or *Lonchocarpus urucu,* native to South America. Rotenone, one of the alkaloids, is the most potent and can be purified by solvent extraction and recrystallization. It can be used either as a contact or a stomach poison. However, it is unstable in light and heat and almost all toxicity can be lost after 2 to 3 days during the summer. Rotenone is very toxic to fish, and one of its main uses by native people over the centuries was to paralyze fish for capture and consumption. The mammalian toxicity varies greatly with the species exposed, the method of administration, and the type of formulation. Crystalline rotenone has an acute oral LD_{50} of 60, 132, and 3000 mg/kg for guinea pigs, rats, and rabbits, respectively (Matsumura, 1985). Because the toxicity of derris powders exceeds that of the equivalent content of rotenone, it is obvious that the other esters in crude preparations have significant biological activity. Acute poisoning in animals is characterized by an initial respiratory stimulation followed by respiratory depression, ataxia, convulsions, and death by respiratory arrest (Shimkin and Anderson, 1936). The anesthetic-like action on nerves appears to be related to the ability of rotenone to block electron transport in mitochondria by inhibiting oxidation linked to $NADH_2$, this resulting in nerve conduction blockade (O'Brien, 1967; Corbett, 1974). Although toxicity in laboratory and domestic animals has been reported with acute LD_{50} values of 10 to 30 mg/kg, human intoxications are rare. The estimated fatal oral dose for a 70-kg man is of the order of 10 to 100 g. Rotenone has been used topically for treatment of head lice, scabies, and other ectoparasites, but the dust is highly irritating to the eyes (potentially causing conjunctivitis), the skin (causing contact dermatitis), and the upper respiratory tract (causing rhinitis) and throat (linked with pharyngitis).

HERBICIDES

A herbicide, in the broadest definition, is any compound that is capable of either killing or severely injuring plants; it may be used for the elimination of plant growth or the killing off of plant parts (Jager, 1983). Many of the early chemicals—such as sulfuric acid, sodium chlorate, arsenic trioxide, sodium arsenite, petroleum oils, iron and copper sulfate, or sodium borate—were frequently hard to handle and/or were very toxic, relatively nonspecific, or phytotoxic to the crop as well as the unwanted plant life if not applied at exactly the proper time. In the late 1930s, many studies were initiated to find agents that would selectively destroy certain plant species. Many of these early chemicals were more effective but still possessed considerable mammalian toxicity. However, a few compounds served as prototype chemicals for further development. Summaries of the early days of herbicide development are presented by Cremlyn (l978), McEwen and Stephenson (1979), Kirby (1980), and Jager (1983).

In the past two decades, the herbicides have represented the most rapidly growing section of the agrochemical pesticide business due in part to (1) movement into monocultural practices, where the risk of weed infestation has increased because fallowing and crop rotation, which would change weed species, are no longer in vogue; and (2) mechanization of agricultural practices (planting, tending, harvesting) because of increased labor costs. The annual rate of growth of herbicide production on a worldwide basis between 1980 and 1985 was 1.9 percent per year, more than double the rate of growth for insecticides during the same period (Marquis, 1986). The result has been a plethora of chemically diverse structures rivaling the innovative chemistry of the insecticides, the aim being to protect desirable crops and obtain high yields by selectively eliminating unwanted plant species, thereby reducing the competition for nutrients.

Herbicides may be classified by chemical structure, although this is not very enlightening because of overlapping biological effects for a variety of chemical structures. The second method of classification pertains to how and when the agents are applied. *Preplanting* herbicides are applied to the soil before a crop is seeded. *Preemergent* herbicides are applied to the soil before the usual time of appearance of the unwanted vegetation. *Postemergent* herbicides are applied to the soil or foliage after the germination of the crop and/or weeds. Plant biochemists classify herbicides according to their mechanism of toxicity in plants; their action is referred to as *selective* (toxic to some species), *contact* (act when impinging on the plant foliage), or *translocated* (being absorbed via the soil or through the foliage into the plant xylem and phloem).

In this chapter, herbicides are classified by their ability to interfere with specific biochemical processes essential for normal growth and development—interactions that result in severe injury to the plant and its eventual death. In Table 22-11, the various mechanisms by which herbicides exert their biological effects are shown, along with the generic and chemical names of the classes of herbicides and some examples of each class. The claim has been made that, because the modes of action involve biochemical phytoprocesses having no counterparts in mammalian systems, no risk of mammalian toxicity is associated with these chemicals. With the exception of a few chemicals, the herbicides have demonstrated low toxicity in mammals.

Table 22-11 Mechanisms of Action of Herbicides

However, the current controversy around these chemicals centers on demonstrated or suspected mutagenicity, teratogenicity, and/or carcinogenicity associated either with the agent(s) or with contaminants and by-products of manufacture found in trace amounts in technical-grade material. The presence of some of these

contaminants has been largely ignored without any recognition that the toxicities associated with them are different from those observed with the herbicidal chemical and frequently occur at far lower dosages.

In terms of general toxicity, because the major route of exposure to herbicides is dermal and these agents tend to be strong acids, amines, esters, and phenols, they are dermal irritants, causing skin rashes and contact dermatitis even when exposure involves diluted formulations. There appear to be subpopulations of individuals who are hypersensitive to dermal contact with solutions or aerosolized mists of certain types of herbicides, and moderate to severe urticaria has been observed to persist for 5 to 10 days following exposure. Certain individuals, particularly those prone to allergic reactions, may experience severe contact dermatitis, asthma-like attacks, and even anaphylactic reactions following dermal or inhalation contact with formulated herbicides. Whether these effects are chemical-specific for the herbicide or for emulsifiers, cosolvents, and so-called inerts found in formulations has not been established. One such example is discussed below. Although skin patch testing of herbicidal chemicals has usually proven to be negative, it is possible that patients' responses may be associated with a generalized, nonspecific irritant effect of the formulation. Many of these dermal and pulmonary reactions respond satisfactorily to treatment with antihistaminic agents.

In contrast, there are other herbicides that can elicit a range of acute and chronic effects following exposure, and it is on these chemicals that attention is focused here.

Chlorophenoxy Compounds

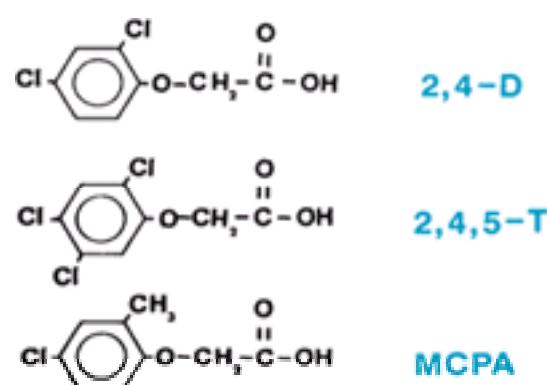
During World War II, considerable effort was directed toward the development of effective, broad-spectrum herbicides in both the United States and the United Kingdom with a view to both increasing food production and finding potential chemical warfare agents (Kirby, 1980). The chlorophenoxy compounds (Fig. 22-22)—including the acids, salts, amines, and esters—were the first commercially available products evolving from this research in 1946. This class of herbicides has seen continuous, extensive, and uninterrupted use since 1947 in agriculture for broad-leafed weeds and in the control of woody plants along roadside, railway, and utilities' rights of way and in reforestation programs. In plants, these chemicals mimic the action of auxins, hormones chemically related to indoleacetic acid, that stimulate growth. No hormonal activity is observed in mammals and other species, and beyond target organ toxicity that can be associated with the pharmacokinetics, biotransformation, and/or elimination of these chemicals, their mechanisms of toxic action are poorly understood. The chlorophenoxy herbicides are no longer the agents of choice because of concerns over the formation of chlorinated dibenzofurans and dibenzodioxins, particularly 2,3,7,8-tetrachlorodibenzo- p-dioxin (TCDD), as a consequence of poorly monitored manufacturing practices or improper product storage in steel drums sitting beside runways under the tropical sun. However, since they are still used in developing nations around the world, their toxicology cannot be ignored.


Figure 22-22. The molecular structure of the three most common chlorophenoxyacetic acid herbicides: 2,4-dichlorophenoxyacetic acid (2,4-D), 2,4,5-trichlorophenoxyacetic acid (2,4,5-T), and 4-chloro- o-toloxyacetic acid (MCPA). Ester and amine salt derivatives are also marketed.

A tremendous volume of mammalian toxicity data has been collected over the past 42 years from both animal studies and incidents of human exposure (Hayes, 1982; Stevens and Sumner, 1991). It is of interest to note that, in a recent toxicologic reevaluation of 2,4-D for the purposes of providing the U.S. EPA with a new toxicity database for the chemical, an industry task force discovered nothing of toxicologic significance that was not already known about the chemical, with one exception (Mullison, 1986). The exceptional finding was the appearance of astrocytomas in the brains of male Fischer 344 strain rats exposed to the highest (45 mg/kg per day) dosage. A subsequent review of the findings suggested that this tumor incidence was not treatment-related (Koestner, 1986; Solleveld et al., 1984). The acute toxicity elicited by chlorophenoxy herbicides has been described by Hayes (1982). The oral LD$_{50}$ values ranged from 300 to >1000 mg/kg in different animal species, and only the dog appeared to be particularly sensitive, possibly on the basis that it has considerable difficulty in the renal elimination of such organic acids (Gehring et al., 1976).

Accidental and/or occupational intoxications have been reviewed (Hayes, 1982; Stevens and Sumner, 1991; Ecobichon, 1996). An industrial accident in 1949 in a 2,4,5-T manufacturing plant in Nitro, West Virginia, presented the first large occupational exposure, with acute symptoms of exposure to the reaction products, including skin, eye, and respiratory tract irritation; headache; dizziness; nausea; acneiform eruptions; severe muscle pain in the thorax, shoulders and extremities; fatigue; nervousness; irritability; dyspnea; complaints of decreased libido; and intolerance to cold (Ashe and Suskind, 1953). In an epidemiologic study of these same workers conducted in 1984, clinical evidence of chloracne persisted in some 55.7 percent of those exposed (113 out of 204), and an association was found between the persistence of chloracne and the presence and severity of actinic elastosis of the skin (Suskind and Hertzberg, 1984). There was no evidence of increased risk of cardiovascular, hepatic, or renal disease or of central or peripheral nervous tissue damage. One study documented neurotoxicity, decreased peripheral conduction velocities being observed in workers employed in the manufacture of 2,4-D and 2,4,5-T (Singer et al., 1982). Earlier literature reported significant peripheral neuropathies in three sprayers using 2,4-D ester, signs and symptoms progressing from muscle pain and paresthesias to severe paralysis, all of which was supported by electromyographic analysis (Goldstein et al., 1959). Chloracne, or "weed bumps," has been the most persistent effect observed in almost all incidents of chlorophenoxy herbicide exposure, although this is not a specific effect, being caused by a number of halogenated aromatic compounds including polyhalogenated biphenyls, dibenzo-p-dioxins, dibenzofurans, and naphthalenes (Schultz, 1968; Poland et al., 1971).

A wide range of human lethal dosages of 2,4-D has been reported, the average being in excess of 300 mg/kg, although it may be as low as 80 mg/kg. The oral dose required to elicit symptoms is of the order of 50 to 60 mg/kg. Since these chemicals are irritants, oral ingestion has caused focal submucosal hemorrhage, moderate congestion, and edema as well as necrosis of the intestinal tract, fatty infiltration and necrosis of the liver, degeneration of the convoluted tubules of the kidney, and pneumonitis and inflammation in the terminal bronchioles (Hayes, 1982).

In hindsight, many of the above-mentioned signs and symptoms might be attributed to contaminants found in chlorophenoxy herbicides from early production times, principally from a mixture of polychlorinated dibenzo- p-dioxins, the main one being TCDD, found in samples of 2,4,5-T at levels of 30 to 50 ug/g (Hay, 1982; Gough, 1986). The teratogenicity (cleft palate, renal anomalies) produced by commercial, TCDD-contaminated (30 ug/g) 2,4,5-T was not reproduced when highly purified 2,4,5-T was used (Courtney et al., 1970; Courtney and Moore, 1971). Recent in vitro and in vivo genotoxicity studies of 2,4-D have proven negative (Charles et al., 1999a, b; Gollapudi et al., 1999). Recent accidental/occupational exposures to chlorophenoxy herbicides have not resulted in peripheral neuropathies, a fact confirmed in animal studies using purified 2,4-D dimethylamine salt (Mattsson et al., 1986). While the carcinogenicity of purified 2,4-D and 2,4,5-T has not been established in rodent studies, that of TCDD has (Van Miller et al., 1977; Kociba et al., 1978). The toxicology of the polychlorinated dioxins and furans is discussed in other chapters.

Public concerns about the chlorophenoxy herbicides have focused on birth defects, cancers, and the spurious illnesses reported among military personnel exposed to the defoliant Agent Orange (a 50:50 mixture of the n-butyl esters of 2,4-D and 2,4,5-T) sprayed extensively during the Vietnam conflict and found to be contaminated with TCDD to a maximum of 47 ug/g (Hay, 1982; Greenwald et al., 1984; Gough, 1986; CDC, 1988; Stellman et al., 1988; Tamburro, 1992). While exposure to this persistent contaminant can be verified by blood analysis of veterans, the multifaceted nature of the adverse effects has precluded a definitive association (Ketchum et al., 1999). Epidemiologic studies of cancer in farmers and others occupationally exposed to chlorophenoxy herbicides for long periods of time have suggested an association with soft tissue sarcomas, non-Hodgkin's lymphoma (NHL), and Hodgkin's lymphoma (HL) without any definitive conclusions (Hardell and Sandstrom, 1979; Ott et al., 1980; Eriksson et al., 1981; Hardell et al., 1981; Cantor, 1982; Theiss et al., 1982; Lynge, 1985; Schumacher, 1985; Hoar et al., 1986; Pearce et al., 1986; Bond et al., 1988; Bond and Rossbacher, 1993). A study of wheat farmers in western Canada, where 2,4-D has been used almost exclusively from 1947, showed an overall lower mortality and cancer rate than expected (Wigle et al., 1990). A review of published studies presented evidence of an association between occupational exposure to chlorophenoxy herbicides and an increased risk of NHL (Morrison et al., 1992). The study of an international database set up by

IARC/NIEHS revealed no clearly detectable excess for NHL and HL but a sixfold excess of soft tissue sarcomas in the cohort and a ninefold excess among sprayers (Saracci et al., 1991). An increase in prostate cancer mortality among Canadian farmers has been reported (Morrison et al., 1993). Other studies of databases have suggested that the carcinogenic impact of chlorophenoxy compounds was negligible (Munro et al., 1992; Bond and Rossbacher, 1993). Lacking the ideal "definitive, clean" study, this controversy will continue in the literature. In the meantime, the chlorophenoxy herbicides have been phased out of use in developed nations, being replaced by other agents. However, the concerns persist, particularly in developing countries where use continues and in Vietnam, where exposure was so heavy.

Animals will tolerate repeated oral exposure to doses of chlorophenoxy herbicides marginally below the single, toxic oral dose without showing significant signs of toxicity, an observation suggesting that there is little cumulative effect on target organs. At dosages causing toxicity, few specific signs other than muscular and neuromuscular involvement were observed in animals, although tenseness, stiffness in extremities, muscular weakness, ataxia, and paralysis have been reported. Hepatic and renal injury in addition to irritation of the gastrointestinal mucosa have been observed in acute lethality studies in animals.

Bipyridyl Derivatives

One chemical class of herbicides deserving of particular attention is the bipyridyl group, specifically paraquat (1,1'-dimethyl-4,4'-bipyridylium dichloride, methyl viologen) and diquat (1,1'-ethylene-2,2'-bipyridylium dibromide) (Fig. 22-23). Paraquat was first synthesized in 1882, but its pesticidal properties were not discovered until 1959 (Haley, 1979). This agent, a nonselective contact herbicide, is one of the most specific pulmonary toxicants known and has been the subject of intensive investigation because of the startling toxicity observed in humans. A high mortality rate is encountered in poisoning cases. Many countries have banned or severely restricted the use of paraquat because of the debilitating or life-threatening hazards from occupational exposure and the large number of reported accidental and suicidal fatalities (Campbell, 1968; Davies et al., 1977; Haley, 1979; Tinoco et al., 1993). However, paraquat is still used in some 130 countries and, in third-world nations, is available to 98 percent of the agricultural workers (WHO, 1984; Ramasamy et al., 1988). In Taiwan, paraquat accounted for 54 percent of the pesticide-related poisonings in the years 1985 to 1993 (Yang et al., 1996). The toxicology of this class of herbicides should not be ignored.

Figure 22-23. The chemical structures of paraquat and diquat, marketed as the dichloride and dibromide salts, respectively.

In animals, paraquat shows moderate acute toxicity, the oral LD_{50} values for various species ranging from 22 to 262 mg/kg. Intoxication involves a combination of signs and symptoms that include lethargy, hypoxia, dyspnea, tachycardia, hyperpnea, adipsia, diarrhea, ataxia, hyperexcitability, and convulsions, depending on the dosage and the species studied (Smith and Heath, 1976; Haley, 1979). Necropsy reveals hemorrhagic and edematous lungs, intraalveolar hemorrhage, congestion and pulmonary fibrosis, centrilobular hepatic necrosis, and renal tubular necrosis. Lung weights of intoxicated animals increase significantly despite marked losses in body weight. From a catalog of all the signs and symptoms, it is obvious that the lung is the most susceptible target organ, and the same histopathologic picture of pulmonary lesions is observed in mice, rats, dogs, and humans (Clark et al., 1966). In poisonings, immediate effects are usually not seen in animals; within 10 to 14 days, however, respiration becomes impaired, rapid, and shallow and the morphologic changes seen include degeneration and vacuolization of pneumocytes, damage to type I and type II alveolar epithelial cells, destruction of the epithelial membranes, and proliferation of fibrotic cells.

Paraquat, a highly polar compound, is poorly absorbed from the gastrointestinal tract (5 to 10 percent) (Haley, 1979). Experiments in rats showed that 52 percent of the administered oral dose was still localized in the intestine some 32 h postadministration, although 45 percent of the dose had been excreted in the urine and feces within 48 h, with some detected in urine for up to 21 days (Murray and Gibson, 1974). Intoxication by the ingestion of formulation concentrates may be enhanced by increased absorption due to the presence of emulsifiers and cosolvents. Metabolism by mammalian tissue is not extensive, although intestinal microflora may account for 30 percent of the excreted metabolites in animal studies (Daniel and Gage, 1966). Elevated levels of paraquat in renal tissue suggest the kidney as a primary route of excretion (Rose et al., 1976).

Pulmonary tissue, both in vivo and in vitro, acquires much higher concentrations of paraquat than other tissues with the exception of the kidney. Over a 30-h posttreatment period, disproportionately high levels are found in the lung (Sharp et al., 1972; Rose et al., 1976). Acquisition is due to a unique diamine/ polyamine transport system in the alveolar cells. Upon uptake, paraquat undergoes a NADPH-dependent one-electron reduction to a free radical that reacts with molecular oxygen to regenerate the paraquat cation plus a reactive superoxide anion ($O_2^{-\bullet}$), which is converted into hydrogen peroxide (H_2O_2) by the enzyme superoxide dismutase. Both O_2 and H_2O_2 can attack polyunsaturated lipids, forming lipid hydroperoxides that, in turn, react with unsaturated lipids to form more lipid-free radicals, perpetuating the destructive reaction (Smith, 1987). Alveolar cell membrane damage results in alveolitis, the destruction of alveolar cells, invasion of the space by fibrotic cells accompanied by a loss of pulmonary elasticity and respiratory impairment, with an inefficient gas (O_2, CO_2) exchange. Cellular events can be modulated by the availability of oxygen, animals kept in air with only 10% oxygen faring better than those kept in room air (Rhodes, 1974).

Paraquat poisonings in children and adults have been described in detail in the literature (Almog and Tal, 1967; Davies et al., 1977; Haley, 1979; Hayes, 1982; Tinoco et al., 1993). Paraquat is a favored agent in suicide attempts in many parts of the world (Wesseling et al., 1993 , 1997; Yang et al., 1996). Paraquat-induced intoxications should be divided into two categories: (1) poisonings by accidental or intentional ingestion, usually involving formulation concentrates containing up to 20 percent active ingredient, and (2) functional intoxications, associated with dermal and/or inhalation exposure of diluted spray formulations.

The ingestion of commercial paraquat concentrates is invariably fatal and runs a time course of 3 to 4 weeks. The initial irritation and burning of the mouth and throat, the necrosis and sloughing of the oral mucosa, severe gastroenteritis with esophageal and gastric lesions, abdominal and substernal chest pains, and bloody stools give way to the characteristic dominant pulmonary symptoms, including dyspnea, anoxia, opacity in the lungs seen in chest x-rays, progressive fibrosis, coma, and death. While the pulmonary lesions are the most life-threatening, paraquat induces multiorgan toxicity with necrotic damage to the liver, kidneys, and myocardial muscle plus extensive hemorrhagic incidents throughout the body.

Survivors of moderate-to-severe paraquat poisonings showed significant impairment in respiratory function tests, which improved dramatically or partially with time (Lin et al., 1995). However, it is as yet unknown whether long-term respiratory health effects occur with repeated and/or seasonal inhalation and/or dermal exposure to diluted paraquat aerosols (Wesseling et al., 1997). Swan (1969) found no detectable changes in workers exposed to sprays 6 days per week for 12 weeks. Senanayake et al. (1993) found no changes in standard spirometric tests in Sri Lankan tea plantation workers continually exposed to paraquat aerosols. More recent studies have confirmed that no correlation exists between exposure and parameters such as $FEV_{1.0}$, FVC, etc. (Castro-Gutierrez et al., 1997; Dalvie et al., 1999). However, in one study, severity of dyspnea and a threefold increase in episodic wheezing accompanied by shortness of breath was found among the most highly exposed workers (Castro-Gutierrez et al., 1997). Perhaps the standard, spirometric, functional tests are not sensitive enough since, in the second study, there was a significant relationship between long-term exposure and arterial oxygen desaturation measured by oximetry during an exercise test (Dalvie et al., 1999). More sensitive tests may be needed to assess long-term respiratory disabilities.

Treatment of paraquat poisoning should be vigorous and initiated as quickly as possible. Gastric lavage should be followed by the administration of mineral adsorbents such as Fuller's earth (kaolin), bentonite clay, or activated charcoal to bind any unabsorbed paraquat remaining in the gastrointestinal tract. Purgatives may be given. Absorbed paraquat may be removed from the bloodstream by aggressive, lengthy hemoperfusion through charcoal or by hemodialysis. To avoid excessive pulmonary damage, supplemental oxygen should be reduced to a level just sufficient to maintain acceptable arterial oxygen tension (>40 to 50 mmHg) (Haley, 1979; Hayes, 1982). Even though these patients may suffer from hypoxia and respiratory insufficiency, hyperbaric oxygen is contraindicated because it

appears to promote cellular toxicity.

Diquat is a rapid-acting contact herbicide used as a desiccant, for the control of aquatic weeds, and to destroy potato halums before harvesting. Diquat is slightly less toxic than paraquat; the oral LD_{5C} values in various species are on the order of 100 to 400 mg/kg. Part of the reduced toxicity may be related to the fact that it is poorly absorbed from the gastrointestinal tract; only 6 percent of an ingested dose is excreted in the urine, whereas 90 to 98 percent of the dose is eliminated via the urine following subcutaneous administration (Daniel and Gage, 1966). A latency period of 24 h is seen prior to visible toxic effects.

Following acute, high-dose exposure or chronic exposure of animals to diquat, the major target organs were the gastrointestinal tract, the liver, and the kidneys (Hayes, 1982; Morgan, 1982). Chronic feeding studies resulted in an increased incidence of cataracts in both dogs and rats (Clark and Hurst, 1970). It is considered that diquat can form free radicals and that the tissue necrosis is associated with the same mechanism(s) of superoxide-induced peroxidation as observed with paraquat. Unlike paraquat, diquat shows no special affinity for the lung and does not appear to involve the same mechanism that selectively concentrates paraquat in the lung (Rose and Smith, 1977).

Few diquat-related human intoxications have been reported to date (Schonborn et al., 1971; Narita et al., 1978; Hayes, 1982). In the few cases of suicidal intent described, ulceration of mucosal membranes, gastrointestinal symptoms, acute renal failure, hepatic damage, and respiratory difficulties were observed. CNS effects were more severe. Interestingly, no fibrosis was evident in the lungs. One individual died of cardiac arrest.

Chloroacetanilides

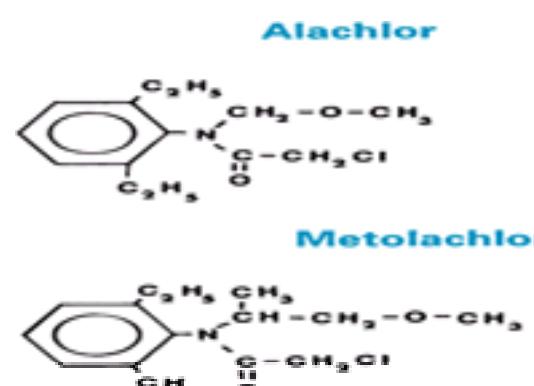
Alachlor (Lasso) (Fig. 22-24) is an aniline herbicide used to control annual grasses and broad-leaf weeds in a number of crops (corn, soybeans, peanuts) as a systemic herbicide absorbed by the germinating shoots and roots by interfering with protein synthesis and root elongation. It is a slightly toxic (EPA class III) herbicide, the oral LD_{5C} (rat) being 930 to 1350 mg/kg, and is a slight-to-moderate skin irritant (WSSA, 1994; Kamrin, 1997). Subchronic studies in rats and dogs, with doses of 1 to 100 mg/kg/day, showed no adverse effects, but a 6-month dog study showed hepatic toxicity at all doses above 5 mg/kg/day, while a year-long study revealed hepatic, renal, and splenic effects above a dosage of 1 mg/kg/day. In reproductive studies, maternal and fetal toxicity was observed at the high oral doses used (150 and 400 mg/kg/day), but there was no effect on reproduction. Neither were teratogenic effects seen in rats and rabbits, confirming the negative results in microbial mutagenicity studies. Revisiting the toxicity database and providing replacement studies for carcinogenicity revealed thyroid tumors and adenocarcinomas of the stomach and nasal turbinates of Long-Evans rats and in the lungs of CD-1 mice receiving relatively high doses (126 and 260 mg/kg/day for rats and mice, respectively (Alachlor Review Board, 1987). Alachlor is considered to be a category 2B (probable) human carcinogen by the U.S. EPA, a risk to agricultural workers during mixing and loading, with levels of exposure ranging from 0.00038 to 2.7 mg/kg/day depending on the exposure model used. The putative carcinogen metabolite, 2.6-diethylbenzoquinonimine (DEBQ1), is formed by oxidative and nonoxidative reactions in mice, rats, and monkeys but not in humans (Coleman et al., 1999). However, the human may form DEBQ1 via another route. Studies of thyroid tumors in rats suggest that alachlor-induced follicular cell tumors were related to increased metabolism of thyroxine via hepatic enzyme conjugation (Wilson et al., 1996). To date, there has been no evidence of an appreciable effect of alachlor exposure on worker mortality or cancer rates (Acquavella et al., 1996).


Figure 22-24. The chemical structures of alachlor (2-chloro-2', 6'-diethyl- N-(methoxymethyl)acetanilide) and metolachlor (2-chloro-6'-ethyl-ethyl-N-(2-methoxy-1-methylethyl) acet-o-toluidide.

The discovery of alachlor in well water at levels of 0.11 to 2.11 µg/L, the highest being 9.1 µg/L, led to the cancellation of its registration in Canada in 1985. Concerns about one analog of a series has led to the examination of other chloracetanilides and closely related agents—e.g., acetochlor, amidochlor, butachlor, metalaxyl, metolachlor (Fig. 22-24), propachlor, etc.—all of the agents showing a consistent pattern of mutagenic activity mediated via metabolites, possibly even species-specific intermediates (Dearfield et al., 1999). One example acetochlor is converted into a rat-specific metabolite that may be related to the nasal tumors, thus posing no genetic or carcinogenic hazard to humans (Ashby et al., 1996). However, changes in leopard frog metamorphosis by acetochlor appears to be related to an interaction with thyroid hormone via a nonthyroid receptor mechanism (Cheek et al., 1999). No doubt, detailed mechanistic studies will reveal one or more modes of action.

Phosphonomethyl Amino Acids

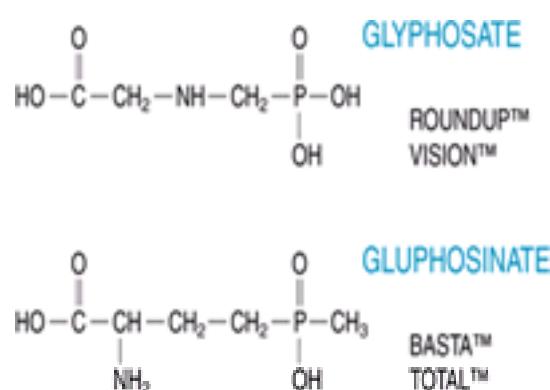
Two agents, Λ-phosphonomethyl glycine (glyphosate, Roundup, Vision) and Λ-phosphonomethyl homoalanine (glufosinate, Basta) must be considered because of their use in attempted suicides in southeastern Asia (Fig. 22-25). Both agents are broad-spectrum nonselective systemic herbicides for postemergent control of annual and perennial plants (grasses, sedges, broad-leaf weeds) and woody plants. While they exist as free acids, these agents are marketed as the isopropylamine or trimethylsulfonium salts of glyphosate and the ammonium salt of glufosinate in formulation concentrates of 41 percent and 18.5 percent, respectively. In considering any toxicity data, one must make the distinction whether the data pertain to the acid, the salt, or the complete formulation(s) containing what appear to be biologically active surfactants (Kamrin, 1997; Watanabe and Sano, 1998).


Figure 22-25. The chemical structures of glyphosate (N-phosphonomethyl glycine) and glufosinate (N-phosphonomethyl homoalanine).

Glyphosate Glyphosate binds to and inhibits the enzyme 5-enolpyruvyl-shikimate-3-phosphate synthetase (EPSPS), an enzyme of the aromatic amino acid biosynthesis pathway essential for protein synthesis in plants (Haslam, 1993). In mammals, ingestion, with oral LD_{5C} values in the rat being 5600 mg/kg, although that of the trimethylsulfonium salt is 750 mg/kg (WSSA, 1994). Formulations of glyphosate show moderate toxicity, LD_{5C} values being between 1000 and 5000 mg/kg (Monsanto, 1985; WSSA, 1994). Glyphosate is nontoxic by the dermal route, with dermal LD_{5C} values being in excess of 5000 mg/kg for the acid and the

isopropylamine salt. While glyphosate is not a dermal irritant in animals and does not induce photosensitization, formulations can cause severe occupational contact dermatitis, although patch testing in humans resulted in no visible skin changes or sensitization (WSSA, 1994; Maibach, 1986). Glyphosate is an ocular irritant in the rabbit and human (Acquavella et al., 1999). Chronic studies with rats, dogs, and rabbits resulted in no glyphosate-related effects up to the highest doses tested (400 to 500 mg/kg/day) (WSSA, 1994). Reproductive problems were observed in test animals only at very high (150 mg/kg/day) doses that elicited maternal toxicity. Glyphosate was not teratogenic at elevated doses in rabbits (350 mg/kg/day) or rats (175 mg/kg/day), although other signs of toxicity in dams and fetuses were observed. Glyphosate was not mutagenic in standard tests (Ames and other bacterial assays, dominant lethal test in mouse) (Li and Long, 1998; WSSA, 1994). However, one study, with glyphosate isopropylamine salt and Roundup formulation, showed weak mutagenic activity in the Ames test and a significant increase in chromosomal aberrations in the *Allium* root cell when Roundup was tested (Rank et al., 1993). Carcinogenicity was not observed in mice, rats or dogs, glyphosate being classified by the U.S. EPA as a class E agent. Moses (1989) has reported tumors in the pituitary and mammary glands in glyphosate-treated rats. Glyphosate does not inhibit cholinesterases.

Unfortunately, glyphosate has become the agent of choice to replace paraquat as a suicidal agent in many countries, the incidence of such poisonings increasing as paraquat is banned or is more tightly controlled (Talbot et al., 1991; Tominack et al., 1991; Mendes et al., 1991; Leveridge, 1996; Yang et al., 1996). The formulation concentrate is used. Mild intoxications are characterized by gastrointestinal symptoms (nausea, vomiting, diarrhea, abdominal pain) due to mucosal irritation and injury, with resolution within 24 h (Talbot et al., 1991). In moderate intoxications, more severe and persistent intestinal symptoms (ulceration, esophagitis, hemorrhage) are seen, along with hypotension, some pulmonary dysfunction, acid-base disturbance, and evidence of hepatic and renal damage. Severe poisoning is characterized by pulmonary dysfunction requiring intubation, renal failure requiring dialysis, hypotension and vascular shock, cardiac arrest, repeated seizures, coma, and death (Talbot et al., 1991; Tominack et al., 1991). A reasonable dose-effect relationship was established by Talbot et al. (1991), who estimated the volume(s) of formulation (concentrate) ingested causing asymptomatic, mild, moderate or severe poisoning in humans to be 17, 58, 128 and 184 mL, respectively. This could be converted to glyphosate concentrations of 87, 298, 658, and 946 mg/kg based on the formulation containing 360 g/L of free glyphosate and a 70-kg body weight.

Several reviews of intoxication cases, particularly the Japanese and Taiwanese series, have raised suspicions about the toxicity of the surfactant polyoxyethyleneamine (POEA) in the formulations used currently (Sawada and Nagai, 1987; Sawada et al., 1988; Talbot et al., 1991; Tominack et al. 1991). The median lethal dose of POEA is less than one-third that of the formulation or glyphosate (Sawada et al., 1988). Tai et al. (1990) found that POEA was responsible for the hypotensive effect in dogs. This class of surfactants has been associated with hemolysis and with gastrointestinal and CNS effects (Grugg et al., 1960; Sawada et al., 1988). As of 1999, efforts were being made to reformulate the Roundup product to replace POEA (personal communication).

Glufosinate *N*-phosphonomethyl homoalanine acts as a suicide substrate, interfering with glutamate synthesis in plants by irreversibly inhibiting the enzyme glutamine synthetase, which plays an important role in ammonia detoxification and amino acid metabolism (Ebert et al., 1990). The herbicidal effect is caused by cytotoxicity from increased ammonia levels and impairment of photorespiration and photosynthesis (Hack et al., 1994).

The acute oral toxicity of glufosinate in mice, rats, and rabbits was low, the oral LD_{50} lying between 1500 and 2000 mg/kg (Ebert et al., 1990; Hack et al., 1994). In subchronic feeding studies in rats, no agent-related deaths occurred, although body weight gains in males were retarded in the 5000-ppm group. Food consumption was reduced and water consumption increased and, at this high dose, signs of CNS excitation and hypothermia were noted (Hack et al., 1994). Glufosinate was not considered to be mutaginic, teratogenic, or carcinogenic in animal studies, although in more recent studies using whole-embryo culture, teratogenic effects in mice have been observed, the effect being induced apoptosis in the neuroepithelium of developing embryos (Watanabe and Iwase, 1996; Watanabe, 1997). While glufosinate did not inhibit brain cholinesterase, reductions in erythrocytic and serum cholinesterases have been seen in 7 of 16 patients affected by this herbicide (Watanabe and Iwase, 1998). In contrast to plant metabolism, glufosinate ammonium inhibited glutamine synthetase in animals, but this did not lead to a problem in ammonia metabolism, the mammal obviously compensating by using other metabolic pathways (Hack et al., 1994).

Glufosinate ammonium has been involved in a number of poisoning cases, particularly in Japan (Koyama et al., 1994; Watanabe and Sano, 1998; Tanaka et al., 1998). Early clinical symptoms included nausea, vomiting, and diarrhea associated with intestinal mucosal irritation but were followed in 24 h by neurologic signs, including impaired respiration, seizures, muscle weakness (post–status epileptic myopathy), convulsions, and death within 4 days in 6 of 31 patients (Koyama, 1995). Some survivors showed either a brief loss of memory or amnesia for 7 to 10 days after intoxication (Koyama, 1995). Any significant role of glutamate in the neurologic events has not been confirmed. Limited information is available regarding glufosinate persistence in vivo, but urinary levels higher than concomitant blood levels have been reported and urinary excretion persisted for 3 to 5 days after ingestion (Watanabe and Iwase, 1998).

Once again, concerns have been raised about the role of the surfactant. The direct cause of death seemed to be circulatory disturbance, especially cardiac insufficiency, possibly related to the surfactant in the formulation involved in the intoxications (Koyama et al., 1995; Watanabe and Sano, 1998). The absorption of glufosinate in animals was 25 to 30 percent higher than the absorption rate of the agent when given alone (Watanabe and Sano, 1998). This suggested that the glufosinate-related effects might be enhanced by surfactant-induced penetration of the CNS, while the cardiovascular system effects were surfactant-related.

Many herbicides representative of several chemical classifications and diverse structures have recently been introduced into agricultural practice (Table 22-11). In general, these chemicals have relatively low acute toxicity, the oral LD_{50} values in rats being of the order of 100 to 10,000 mg/kg, and they are toxicologically uninteresting, since—in subchronic and chronic studies—large doses can be administered without eliciting significant biological effects. Many of these newer chemicals are applied to crops or soil at exceedingly low application rates, minimizing nontarget species toxicity and avoiding environmental contamination. Present concerns focus on groundwater contamination and closer scrutiny of minor contaminants for mutagenic, teratogenic, and carcinogenic effects. Poisonings in humans have usually been associated with occupational exposure or with a few atypical but sometimes well-publicized incidents (Stevens and Sumner, 1991).

FUNGICIDES

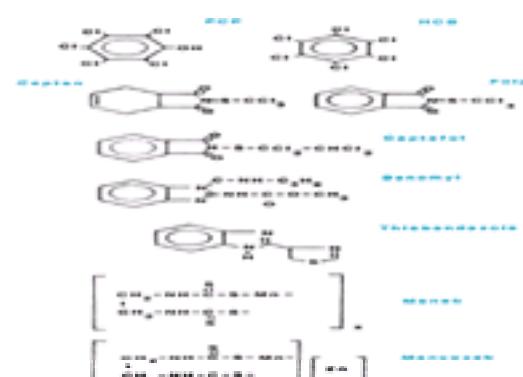
Fungicidal chemicals are derived from a variety of structures ranging from simple inorganic compounds, such as sulfur and copper sulfate, through the aryl- and alkyl-mercurial compounds and chlorinated phenols to metal-containing derivatives of thiocarbamic acid (Fig. 22-26). The chemistry of fungicides and their properties have been discussed by Cremlyn (1978), Kramer (1983), and Edwards et al. (1991). *Foliar fungicides* are applied as liquids or powders to the aerial green parts of plants, producing a protective barrier on the cuticular surface and systemic toxicity in the developing fungus. *Soil fungicides* are applied as liquids, dry powders, or granules, acting either through the vapor phase or by systemic properties. *Dressing fungicides* are applied to the postharvest crop (cereal grains, tubers, corms, etc.) as liquids or dry powders to prevent fungal infestation of the crop, particularly if it may be stored under less than optimum conditions of temperature and humidity. The postharvest loss of food crops to disease is a serious worldwide problem (Table 22-1). Fungicides may be described as protective, curative, or eradicative, according to their mode of action. *Protective fungicides,* applied to the plant before the appearance of any phytopathic fungi, prevent infection by either sporicidal activity or by changing the physiologic environment on the leaf surface. *Curative fungicides* are used when an infestation has already begun to invade the plant, and these chemicals function by penetrating the plant cuticle and destroying the young fungal mycelium (the hyphae) growing in the epidermis of the plant, preventing further development. *Eradicative fungicides* control fungal development following the appearance of symptoms, usually after sporulation, by killing both the new spores and the mycelia and by penetrating the cuticle of the plant to the subdermal level (Kramer, 1983).


Figure 22-26. Chemical structures of fungicides representative of various chemical classifications.

An effective fungicide must possess the following properties: (1) low toxicity to the plant but high toxicity to the particular fungus; (2) activity per se or ability to convert itself (by plant or fungal enzymes) into a toxic intermediate; (3) ability to penetrate fungal spores or the developing mycelium to reach a site of action; and (4) formation of a protective, tenacious deposit on the plant surface that will be resistant to weathering by sunlight, rain, and wind (Cremlyn, 1978). This list of properties is never fulfilled entirely by any single fungicide, and all commercially available compounds show some phytotoxicity, lack of persistence due to environmental degradation, and so forth. Thus, the timing of the application is critical in terms of the development of the plant as well as the fungus.

The topic of fungicidal toxicity has been extensively reviewed by Hayes (1982) Edwards et al. (1991), and Kamrin (1997). With a few exceptions, most of these chemicals have a low order of toxicity to mammals (Table 22-12). However, all fungicides are cytotoxic and most produce positive results in the usual in vitro microbial mutagenicity test systems. Such results are not surprising because the microorganisms (Salmonella, coliforms, yeasts, and fungi) used in these test systems are not dissimilar from those cell systems that fungicides are designed to kill, either through a direct lethal effect or via lethal genetic mutations (Lukens, 1971). A safe fungicide (nonmutagenic in test cell systems) would be useless for the protection of food and health. Public concern has focused on the positive mutagenicity tests obtained with many fungicides and the predictive possibility of both teratogenic and carcinogenic potential. The fact that nearly 90 percent of all agricultural fungicides are carcinogenic in animal models has not reassured the public, especially when this is translated into the fact that some 75 million pounds of the fungicides used annually fall into this category (NAS, 1987). An evaluation of 11 fungicides concluded that, although the areas treated with these chemicals represented only 10 percent of the acreage treated annually with pesticides, they could account for 60 percent of the total estimated dietary carcinogenic risk.

Table 22-12 Acute Toxicity of Fungicides

While a number of different chemicals are shown in Fig. 22-26 to illustrate the diversity of structures, agents such as pentachlorophenol (PCP), hexachlorobenzene (HCB), captafol, and folpet have been deregistered or banned in many countries but still see some use in other, less regulated parts of the world. Other fungicides are undergoing reevaluation because of suspected toxicity, particularly as teratogens or carcinogens and incomplete or outdated toxicity databases.

Hexachlorobenzene

From the 1940s through the 1950s, HCB saw extensive use as a fungicidal dressing applied to seed grain as a dry powder. Between 1955 and 1959, an epidemic of poisoning occurred in Turkey, ultimately involving some 4000 individuals who consumed treated grain during times of crop failure. The syndrome, called black sore, was characterized by dermal blistering and epidermolysis, pigmentation and scarring, alopecia, photosensitivity, hepatomegaly, porphyria, suppurative arthritis, osteomyelitis, and osteoporosis of the bones of the hands (Cam and Nigogosyan, 1963). Both adults and children were afflicted, young children and nursing infants being at particular risk (Schmid, 1960; Wray et al., 1962; Hayes, 1982). While this agent has largely fallen by the wayside, it is still being used in developing countries and still presents a health hazard.

The mammalian toxicity of HCB has been reviewed by Hayes (1982) and Hayes and Laws (1991). Like other organochlorine compounds, HCB possesses all of the properties of chemical stability, slow degradation and biotransformation, environmental persistence, bioaccumulation in adipose tissue and organs containing a high content of lipid membranes, and the ability to induce a range of tissue cytochrome-P450 as well as conjugative enzymes. Repeated exposure of animals results in hepatomegaly and porphyria as well as focal alopecia with itching and eruptions, followed by pigmented scars, anorexia, and neurotoxicity expressed as irritability, ataxia, and tremors. Immunosuppression was observed in both mice and rats and a dose-dependent increase in hepatic and thyroid tumors was observed in hamsters (Lambrecht et al., 1982). While not mutagenic in microbial test systems and negative in dominant lethal studies, HCB was teratogenic in mice (renal and palate malformations) and in rats (increased incidence of 14th rib). Hexachlorobenzene was particularly toxic to developing perinatal animals, acquisition transplacentally and via the milk causing hepatomegaly, enlarged kidneys, hydronephrosis, and possible effects on the immune system.

Pentachlorophenol

Once used in tremendous volumes as a biocide in leather tanning, wood preservation, the paper and cellulose industry, and in paints, this chemical has been phased out of use because many commercial products were contaminated by polychlorinated dibenzodioxins and dibenzofurans, predominantly by hexachlorinated, heptachlorinated, and octachlorinated congeners. While these congeners are considerably less toxic than TCDD, evidence from animal studies has pointed to the fact that the contaminants in commercial- or technical-grade PCP were responsible for the toxicity observed. Technical-grade PCP fed to rats caused altered plasma enzymes, increased hepatic and renal weights, and caused hepatocellular degeneration in addition to changes in blood biochemistry (decreased erythrocyte count, decreased hemoglobin and serum albumin). The administration of purified PCP resulted only in increased liver and kidney weight. Prolonged treatment of female rats with technical PCP caused hepatic porphyria, increased microsomal monooxygenase activity, and increased liver weight, whereas purified PCP caused no changes over the dosage range studied (Goldstein et al., 1977). Pentachlorophenol was not teratogenic in rats and is not considered to be carcinogenic in mice or rats (Innes et al., 1969; Johnson et al., 1973; Schwetz et al., 1977). A number of environmental problems have been associated with PCP (Eisler, 1989).

Human poisoning by commercial PCP has occurred, usually associated with occupational exposure and instances of sloppy handling and neglect of hygienic principles (Jorens and Schepens, 1993). The chemical is absorbed readily through the skin, the most usual route of acquisition, with several products, including PCP, detected in the urine.

High-level exposure can result in death, preceded by an elevated body temperature (42°C or 108°F), profuse sweating and dehydration, marked loss of appetite, decrease in body weight, tightness in the chest, dyspnea following exercise, rapid pulse, nausea and vomiting, headache, incoordination, generalized weakness, and early coma (Hayes, 1982). Pentachlorophenol acts cellularly to uncouple oxidative phosphorylation, the target enzyme being Na^+,K^+-ATPase (Desaiah, 1977). Survivors frequently display dermal irritation and exfoliation, irritation of the upper respiratory tract, and possible impairment of autonomic function and circulation.

Phthalimides

Of this class of chemicals, folpet and captofol, true phthalimides, have been deregistered and only captan, being structurally different with a cyclohexene ring (Fig. 22-26), sees any use today. All of the agents were embroiled in a prolonged controversy concerning mutagenic and possible teratogenic and carcinogenic properties. All three chemicals were recognized as effective, persistent foliar fungicides for rusts and smut, for Botrytis mold on soft fruit, apple and pear scab, black spot on roses, and as seed dressings (Cremlyn,1978). All three chemicals have high oral LD_{50} values of approximately 10,000 mg/kg in the rat. Mutagenicity associated with these agents was confirmed, but—because of the exceptionally high doses (up to 500 mg/kg) required to elicit biological effects—teratogenicity was not proven or was masked by maternal toxicity and possible nutritional deficits.

Although the mechanism(s) by which captan and its analogs exerted their cellular toxicity has never been established, captan is known to react with cellular thiols to produce thiophosgene, a potent and unstable chemical capable of reacting with sulfhydryl-, amino-, or hydroxyl-containing enzymes (Cremlyn, 1978). Thiols reduce the potency of captan. A volatile breakdown product of captan was responsible for mutagenic activity, the intermediate being short-lived and forming more quickly at higher levels at an alkaline pH. It is possible that there may be several mechanisms by which these chemicals can induce cellular toxicity.

Dithiocarbamates

Dimethyl- and ethylene-bisdithiocarbamate (EBDC) compounds have been employed since the early 1950s as fungicides, and the EBDC chemicals saw widespread use on a large variety of small fruits and vegetables. The nomenclature of these agents arises from the metal cations with which they are associated; for instance, dimethyldithio-carbamic acid bound to iron or zinc are ferbam and ziram, respectively, whereas EBDC compounds associated with sodium, manganese, or zinc are nabam, maneb, and zineb, respectively. As is shown in Fig. 22-24, these chemicals are polymeric structures that possess environmental stability and yield good foliar protection as well as a low order of acute toxicity, with LD_{50} values in excess of 6000 mg/kg with the exception of nabam (395 mg/kg). Mancozeb is a polymeric mixture of a zinc salt and the chemical maneb.

Although toxicity is negligible in animal feeding trials even at high doses, acceptance of these agents has been marred by reported adverse health effects. Maneb, nabam, and zineb have been reported to be teratogenic (Petrova-Vergieva and Ivanova-Chemischanka, 1973). Mancozeb has not been demonstrated to be teratogenic in the rat but has been associated with abnormally shaped sperm (Hemavathi and Ratiman, 1993). Maneb has been associated with adverse reproductive outcomes (embryotoxicity: changes in usual number of offspring per litter, pregnancy rate, estrous cycle, and fetal development) (Lu and Kennedy, 1986). Maneb caused pulmonary tumors in mice, but studies in the rat have been equivocal (IARC, 1976). Environmental and mammalian degradation of the EBDC compounds into ethylene thiourea (ETU), a known mutagen, teratogen, and carcinogen, as well as an antithyroid compound, has raised suspicions about these agents and fostered requests for more in-depth studies (IARC, 1976). Recent chronic studies of mancozeb administered to rats at high (500 to 1500 mg/kg/day) doses demonstrated increased thyroid weight, reduced iodine uptake, reduced protein-bound iodine and thyroxine, as well as a dose-related decrease in thyroid peroxidase activity (Kackar et al., 1997). Significant histopathologic changes were observed, including thyroid hyperplasia and hypertrophy of the follicular mass with a loss of colloid mass. A study of EBDC fungicide–exposed backpack sprayers in Mexico demonstrated that ETU was formed in vivo and excreted in the urine and that thyroid-stimulating hormone levels were increased, although there was a nonsignificant reduction in thyroxine and significant increases in sister chromatic exchanges and chromosomal translocations in blood lymphocytes (Steenland et al., 1997).

Neurotoxicity has not been attributed to EBDC fungicides in either experimental animals or humans except at excessively high doses (Ecobichon, 1994c). A double (within 2 weeks) acute occupational, dermal exposure to Mandizan (mixture of maneb and zineb) resulted in initial complaints of muscle weakness, dizziness, and fatigue, with disorientation, slurred speech, muscle incoordination, loss of consciousness, and tonic/clonic convulsions appearing rapidly following the second exposure (Israeli et al., 1983). A recent report from Brazil on two apparent Parkinson patients revealed that, as sprayers, they had experienced significant annual exposure to maneb over 4 to 5 years (Ferraz et al., 1988). Signs and symptoms included inability to walk, difficulty in talking, tremors in hands and feet, a short-stepped gait with cogwheeling, and bradykinesia. An extended study of 50 rural workers, 84 percent of whom admitted to using maneb improperly or carelessly, revealed milder but similar signs and symptoms. It was suggested that the effects might be related to the manganese content, although blood manganese levels were not elevated. Other evidence might point to breakdown products of EBDC, such as carbon disulfide, as the neurotoxicant, although it is hard to accept such a high level of absorption. It is also known that dithiocarbamates can bind various divalent metals to form more lipophilic complexes capable of entering the CNS (Ecobichon, 1994c).

FUMIGANTS

Such agents are used to kill insects, nematodes, weed seeds, and fungi in soil as well as in silo-stored cereal grains, fruits and vegetables, clothes, and other consumables, generally with the treatment carried out in enclosed spaces because of the volatility of most of the products. Fumigants range from acrylonitrile and carbon disulfide to carbon tetrachloride, ethylene dibromide, chloropicrin, and ethylene oxide; their toxicologic properties are discussed under other headings because many have other uses. Attention in this section is directed only to a very few agents, although all of the chemicals mentioned have the potential for inhalation exposure and, for some of them, dermal and ingestion exposure.

Fumigants may be liquids (ethylene dibromide, dibromochloropropane, formaldehyde) that readily vaporize at ambient temperature, solids that can release a toxic gas on reacting with water (Zn_2P_3, AlP) or with acid [NACN, $Ca(CN)_2$], or gases (methylbromide, hydrogen cyanide, ethylene oxide). These chemicals are nonselective, highly reactive, and cytotoxic. The physicochemical properties of these agents and hence their pattern(s) of use vary considerably (Cremlyn, 1978). With proper attention to use and appropriate safety precautions, there should be little effect other than occasional occupational exposure, because the volatility of the agents is such that, when the enclosed space is opened, the gas or vapor escapes readily. However, reports in the literature have indicated the presence of low residual levels of ethylene dibromide, methylbromide, and other chemicals in various samples of treated foods. More extensive descriptions of fumigant toxicity can be found in Hayes (1982), Morgan (1982), and Hayes and Laws (1991).

Phosphine

Used extensively as a grain fumigant, phosphine (PH_3) is released from aluminum phosphide (AlP) by the natural moisture in the grain over a long period of time, giving continual protection during transhipment of the grain. One serious accident with this chemical has been reported, in which this author played a small role in identifying the causative agent, as the problem originated in the port of Montreal, Canada (Wilson et al., 1980). Grain leaving Canada for European destinations is fumigated by adding a certain number of sachets of AlP per ton of grain in the hold of the ship while loading. Phosphine (PH_3), being heavier than air, sinks slowly through the grain. The particular ship in question ran into a bad storm off Nova Scotia and began to leak, hastening the breakdown of the AlP to form PH_3. The toxicant penetrated the quarters of the crew and officers, where 29 out of 31 crew members became acutely ill and two children, family members of one of the officers, were seriously affected, one dying before reaching a hospital in Boston. Symptoms of PH_3 intoxication in the adults included shortness of breath, cough and pulmonary irritation, nausea, headache, jaundice, and fatigue. The highest concentrations of PH_3 (20 to 30 ppm) were measured in a void space on the main deck near the air intake for the ship's ventilation system. In some of the living quarters, PH_3 levels of 0.5 ppm were detected. Although this could be considered a bizarre situation, it does illustrate an apparent problem with the use of this type of agent in an atmosphere of excess moisture.

Ethylene Dibromide/ Dibromochloropropane

When inhaled at relatively high (>200 ppm) concentrations, ethylene dibromide can cause pulmonary edema and inflammation in the exposed animals. As one might expect, repeated exposures to lower concentrations produced hepatic and renal damage visualized as morphologic changes. Centrolobular hepatic necrosis and proximal tubular damage in the kidneys were observed in one fatal poisoning in which the individual ingested 4.5 ml of ethylene dibromide. This chemical, along with 1,2-dibromo-3-chloropropane (DBCP), was found to elicit malignant gastric squamous cell carcinomas in mice and rats (IARC, 1977). DBCP was also found to cause sterility in male animals, and concentrations as low as 5 ppm had an adverse effect on testicular morphology and spermatogenesis. However, these results in animals came to light only when a similar situation was detected in workers who manufactured the agent. Equivocal results have been reported for the mutagenicity of DBCP, the agent that causes base-pair substitution but not a frame-shift mutation in *Salmonella* strains. In animal studies of the dominant lethal assay, DBCP was positive (mutagenic) in rats but not in mice. DBCP was a reproductive toxicant in rabbits and rats but not in mice (IARC, 1977).

RODENTICIDES

Many vertebrates—including rats, mice, squirrels, bats, rabbits, skunks, monkeys, and even elephants—on occasion can be considered to be pests. Rodents, the most important of which are the black rat (*Rattus rattus*), the brown or Norway rat (*Rattus norvegicus*), and the house mouse (*Mus musculus*), are particularly serious problems because they act as vectors for several human diseases. They can consume large quantities of postharvest stored food and/or foul or contaminate even greater amounts of foodstuffs with urine, feces, hair, and bacteria that cause diseases.

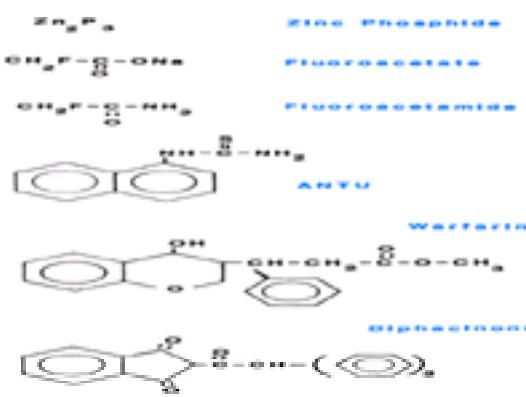
To be effective yet safe, a rodenticide must satisfy the following criteria: (1) it must not be unpalatable to the target species and therefore must be potent; (2) it must not induce bait shyness, so that the animal will continue to eat it; (3) death should occur in a manner that does not raise the suspicions of the survivors; (4) it should make the intoxicated animal go out into the open to die (otherwise the rotting corpses create health hazards); and (5) it should be species-specific, with considerably lower toxicity to other animals that might inadvertently consume the bait or eat the poisoned rodent (Cremlyn, 1978). The agents used constitute a diverse range of chemical structures having a variety of mechanisms of action for at least partially successful attempts to attain species selectivity (Fig. 22-27). With some chemicals, advantage has been taken of the physiology and biochemistry unique to rod-ents. With other rodenticides, the sites of action are common to most mammals but advantage is taken of the habits of the pest animal and/or the dosage, thereby minimizing toxicity to nontarget species.


Figure 22-27. Representative structures of inorganic and organic rodenticides from various chemical classifications.

Although most rodenticides are formulated in baits that are unpalatable to humans, thereby minimizing the potential hazard, there are surprising numbers of rodenticide intoxications each year. With only a few exceptions, the accidental or intentional ingestion of most rodenticides poses a serious, acute toxicologic problem because the dosage ingested is invariably high and the signs and symptoms of intoxication are generally well advanced and severe when the patient is seen by a physician. As with other household products, rodenticide poisoning is more frequently seen in children, whose added hazard is a small body weight in relation to the dosage ingested. The toxicology of the various classes of rodenticides has been extensively reviewed and the reader is referred to Hayes and Laws (1991) and to Ellenhorn and Barceloux (1988) for in-depth coverage of the subject.

A number of inorganic compounds—including thallium sulfate, arsenious oxide, other arsenic salts, barium carbonate, yellow phosphorus, aluminum phosphide, and zinc phosphide—have been used as rodenticides. A mixture of sodium cyanide with magnesium carbonate and anhydrous magnesium sulfate has been used in rabbit and mole burrows, causing hydrogen cyanide gas to be liberated slowly on contact with moisture. Natural or synthetic organic chemicals, including strychnine, red squill (scillaren glycosides), and DDT have been used in the past. All of these agents are nonselective, highly toxic, and hazardous to other forms of life and, with the exception of zinc phosphide, have been abandoned in favor of target-specific, selective chemicals.

Zinc Phosphide

This agent is used in developing nations because it is both cheap and effective. The toxicity of the chemical can be accounted for by the phosphine (PH_3) formed following a hydrolytic reaction with water in the stomach on ingestion. Phosphine causes widespread cellular toxicity with necrosis of the gastrointestinal tract and injury to other organs, such as the liver and kidneys. Although moist zinc phosphide emits an unpleasant, rotten-fish odor, it is accepted by rodents at concentrations of 0.5 or 1.0 percent in baits.

Accidental poisonings are rare in adults but a definite problem in children. Hayes (1982) recounts a poisoning attributed to the inhalation of zinc phosphide dust from treated grain, with signs of intoxication that included vomiting, diarrhea, cyanosis, tachycardia, rhales, restlessness, fever, and albuminuria several hours following exposure. It is a favorite chemical in suicides in Egypt (A. Amr, personal communication). The signs and symptoms include nausea, vomiting, headache, light-headedness, dyspnea, hypertension, pulmonary edema, dysrrhythmias, and convulsions. Doses of the order of 4000 to 5000 mg have been fatal, but other individuals have survived doses of 25,000 to 100,000 mg if early vomiting has occurred. The usual decontamination measures and supportive therapy are often successful if initiated early.

Fluoroacetic Acid and Derivatives

Sodium fluoroacetate (compound 1080) and fluoroacetamide (compound 1081) are white in color, odorless, and tasteless. The extreme toxicity of these two chemicals has restricted their use to prepared baits. Both agents are well absorbed from the gastrointestinal tract. Acute oral toxicity of fluoroacetate in the rat is of the order of 0.2 mg/kg, whereas that of fluoroacetamide is 4 to 15 mg/kg. The mechanism of action involves the incorporation of the fluoroacetate into fluoroacetyl–coenzyme A, which condenses with oxaloacetate to form fluorocitrate, which inhibits the enzyme aconitase and prevents the conversion of citrate to isocitrate in the tricarboxylic (Krebs) cycle. Inhibition of this system by fluorocitrate results in reduced glucose metabolism and cellular respiration and affects tissue energy stores. These chemicals are uniquely effective in mice and rats because of the high metabolic rate in the tissues susceptible to inhibition.

Estimates of the lethal dose of fluoroacetate in humans lie in the range of 2 to 10 mg/kg. Gastrointestinal symptoms are seen initially at some 30 to 100 min following ingestion. Initial nausea, vomiting, and abdominal pain are replaced by sinus tachycardia, ventricular tachycardia or fibrillation, hypotension, renal failure, muscle spasms, and such CNS symptoms as agitation, stupor, seizures, and coma. Histopathologic examination of postmortem samples has revealed cerebellar degeneration and atrophy. There are no known antidotes to fluoroacetate intoxication, although glycerol monoacetate has proved beneficial in the treatment of poisoned monkeys.

a-Naphthyl Thiourea

Following the discovery that phenylthiourea was lethal to rats but not toxic to humans, a-naphthyl thiourea (ANTU) was introduced as a relatively selective rodenticide (Richter, 1946). A wide range of acute oral LD_{50} values has been reported for different species, the rat being the most sensitive at 3 mg/kg and the monkey the least susceptible at 4 g/kg. The exact mechanism of action is not known, but it is suspected that ANTU must be biotransformed in vivo into a reactive intermediate. Young rats are resistant to the chemical, whereas older rats become tolerant to it, suggesting that perhaps microsomal monooxygenases in young rats metabolize the agent too rapidly into nontoxic products, whereas in older rats either the lower levels of monooxygenases or the inhibition of these enzymes results in less activation and affords protection (Boyd and Neal, 1976). ANTU causes extensive pulmonary edema and pleural effusion as a consequence of action on the pulmonary capillaries. Studies with [35]S- and ^{14}C-labeled ANTU revealed that covalent binding to macromolecules in the lung and liver occurred following treatment (Boyd and Neal, 1976). Following exposure to ANTU, there are a number of biochemical effects, such as alterations in carbohydrate metabolism, adrenal stimulation, and interaction of the chemical with sulfhydryl groups, but none of these appear to bear any relationship to the observed signs of toxicity.

Although it would appear that the human is very resistant to ANTU intoxication, probably because insufficient quantities are ingested, poisonings have occurred, with tracheobronchial hypersecretion of a white, nonmucous froth containing little protein, pulmonary edema, and respiratory difficulty (Hayes, 1982).

Anticoagulants

With the discovery that coumadin [3-(a-acetonylbenzyl)-4-hydroxycoumarin, warfarin), isolated from spoiled sweet clover, acted as an anticoagulant by antagonizing the actions of vitamin K in the synthesis of clotting factors (factors II, VII, IX, and X), it was introduced as a rodenticide. The onset of anticoagulation is delayed 8 to 12 h after the ingestion of warfarin, with this latent period of onset dependent on the half-lives of the various clotting factors (Katona and Wason, 1986). The safety of warfarin as a rodenticide rests with the fact that multiple doses are required before toxicity develops and that single doses have little effect. However, the development of resistance to warfarin in rats in the 1950s prompted research into newer compounds, and the exploration of structure-activity relationships led to the development of the superwarfarins (brodifacoum, bromadiolone, coumachlor, diphencoumarin) and the indanediones (diphacinone, chlorophacinone, pindone), a new class of anticoagulant compounds that are more water-soluble. All of these newer agents differ from one another in terms of acute toxicity, rapidity of action, and acceptance by the rodent.

Human poisonings by these agents are rare because they are dispensed in grain-based baits. However, there are sufficient numbers of suicide attempts, attempted murders, and a famous classic case of the inadvertent consumption of warfarin-laden cornmeal bait by an unsuspecting Korean family to provide adequate documentation of the signs and symptoms of poisoning (Lange and Terveer, 1954; Hayes, 1982; Jones, 1984; Lipton, 1984; Katona and Wason, 1986). Following consumption over a period of days, bleeding of the gingiva and nose occurs, with bruising and hematomas developing at the knee and elbow joints and on the buttocks, gastrointestinal bleeding with dark tarry stools, hematuria accompanied by abdominal or low back (flank) pain, epistaxis, and cerebrovascular accidents. The signs and symptoms will persist for many days after cessation of exposure, particularly so in the case of the superwarfarins, which have prolonged biological half-lives (e.g., brodifacoun with 156 h compared to 37 h for warfarin) (Katona and Wason, 1986). In the Korean episode, consumption of warfarin was estimated to be on the

order of 1 to 2 mg/kg/day for a period of 15 days, and signs and symptoms appeared 7 to 10 days after initial exposure; 2 out of the 14 affected individuals died as a consequence of not receiving any treatment (Lange and Terveer, 1954).

CONCLUSIONS

With the advent of the chemical pesticides with their diverse nature, structures, and biological activity, the problem of ranking the hazard that each one poses to health has arisen. Should a classification system be based on acute toxicity alone or should some numerical scoring system be used to evaluate other endpoints of toxicity? Should the classification scheme be based on the oral, dermal, or inhalation routes of exposure to the active ingredient or to a formulation concentrate? If one chooses acute toxicity and a definitive endpoint expressed as the LD_{50}, one must be cognizant of the fact that the LD_{50} is an estimate, with the range and confidence limits for any particular chemical possibly overlapping a class boundary. To establish a classification system on the basis of other toxicologic endpoints would be impossible given the variability of biological effects, the dosages required to attain them, and the significance of such results in terms of human exposure.

In 1972, the WHO Expert Committee on Insecticides recommended the preparation of a classification of pesticides that would serve as a guide for developing countries (WHO, 1973). The classification was to distinguish between the more and the less hazardous forms of each pesticide and was meant to permit formulations to be classified according to the percentage of the active ingredient and its physical state. Only acute hazards to health were considered, meaning those resulting from single or multiple exposures over a relatively short period of time, from handling the product in accordance with the manufacturer's directions. In 1975, the categories of the classification were established and, with only one modification to class 111, they are essentially the same as those that appear in Table 22-13. It is important to appreciate that the LD_{50} value quoted for any pesticide is not the median value but the lower confidence limit value for the most sensitive sex, thereby ensuring that a large safety factor has been built into the classification. A recent paper by Copplestone (1988) discusses the advantages and disadvantages of the system and the placement of problem chemicals such as rodenticides (highly toxic to rats but not presenting the same hazard to humans) and paraquat (having a low dermal toxicity but causing fatal effects if ingested).

| | | LD_{50} FOR THE RAT (mg/kg body weight) | | | |
| | | ORAL | | DERMAL | |
CLASS		SOLIDS	LIQUIDS	SOLIDS	LIQUIDS
Ia	Extremely hazardous	≤5	≤20	≤10	≤40
Ib	Highly hazardous	5-50	20-200	10-100	40-400
II	Moderately hazardous	50-500	200-2000	100-1000	400-4000
III	Slightly hazardous	>500	>2000	>1000	>4000
III+	Unlikely to present hazard in normal use	>2000	>3000	—	—

Table 22-13 The WHO Recommended Classification of Pesticides by Hazard

From experience, the WHO is of the opinion that this classification scheme has worked well in practice, faithfully reflecting the toxicity of these chemicals for humans. Only a few changes in classification have been made for chemicals and/or their formulations since the introduction of the scheme, signifying that the system functions effectively. It would appear that acute toxicity is the most effective parameter by which to judge the hazard to human health. With the move away from animal experimentation to in vitro testing, this classification system can be modified to reflect other endpoints of toxicity if they can be quantitated, correlated, and validated to be equivalent to the LD_{50} results. As Dr. Copplestone described it, "the classification has been a meeting point between science and administration and a useful tool in the armamentarium of preventive medicine" (Copplestone, 1988).

TOXIC EFFECTS OF METALS

Robert A. Goyer and Thomas W. Clarkson

INTRODUCTION

Metals differ from other toxic substances in that they are neither created nor destroyed by humans. Nevertheless, their utilization by humans influences the potential for health effects in at least two major ways: first, by environmental transport, that is, by human or anthropogenic contributions to air, water, soil, and food, and second, by altering the speciation or biochemical form of the element (Beijer and Jernelov, 1986).

Metals are probably the oldest toxins known to humans. Lead usage may have begun prior to 2000 B.C., when abundant supplies were obtained from ores as a by-product of smelting silver. Hippocrates is credited in 370 B.C. with the first description of abdominal colic in a man who extracted metals. Arsenic and mercury are cited by Theophrastus of Erebus (370–287 B.C.) and Pliny the Elder (A.D. 23–79). Arsenic was obtained during the melting of copper and tin, and an early use was for decoration in Egyptian tombs. In contrast, many of the metals of toxicologic concern today are only recently known to humans. Cadmium was first recognized in ores containing zinc carbonate in 1817. About 80 of the 105 elements in the periodic table are regarded as metals, but less than 30 have been reported to produce toxicity in humans. The importance of some of the rarer or lesser known metals such as indium or gallium might increase with new applications in microelectronics, antitumor therapy, or other new technologies.

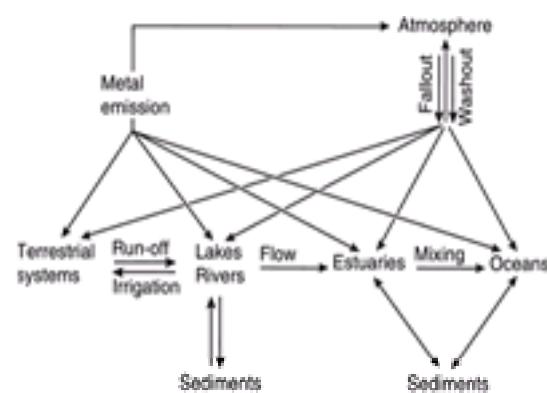
Metals are redistributed naturally in the environment by both geologic and biological cycles (Fig. 23-1). Rainwater dissolves rocks and ores and physically transports material to streams and rivers, depositing and stripping materials from adjacent soil and eventually transporting these substances to the ocean to be precipitated as sediment or taken up in rainwater to be relocated elsewhere on earth. The biological cycles include bioconcentration by plants and animals and incorporation into food cycles. These natural cycles may exceed the anthropogenic cycle, as is the case for mercury. Human industrial activity, however, may greatly shorten the residence time of metals in ore, may form new compounds, and may greatly enhance worldwide distribution not only by discharge to land and water but also to the atmosphere. When discharged in gaseous or fine particulate forms, metal may be transported in the atmosphere over global distances. The role of human activity in the redistribution of metals is demonstrated by the 200-fold increase in lead content of Greenland ice, beginning with a natural low level (about 800 B.C.) and continuing with a gradual rise in lead content of ice through the evolution of the industrial age and finally a nearly precipitous rise in lead corresponding to the period when lead was added to gasoline in the 1920s (Ng and Patterson, 1981). Metal contamination of the environment therefore reflects both natural sources and a contribution from industrial activity.


Figure 23-1. Routes for transport of trace elements in the environment. [From Beijer and Jernelõv (1986).]

The conceptual boundaries of what is regarded as the toxicology of metals continue to broaden. Historically, metal toxicology largely concerned acute or overt effects, such as abdominal colic from lead toxicity or the bloody diarrhea and suppression of urine formation from ingestion of corrosive (mercury) sublimate. There must continue to be knowledge and understanding of such effects, but they are uncommon with present-day occupational and environmental standards. There is, however, growing interest in, and inquiry into, subtle, chronic, or long-term effects in which cause-and-effect relationships are not obvious or may be subclinical. These might include a level of effect that causes a change in an important index of affected individuals' performance—that is, lower than expected IQs due to childhood lead exposure. Assigning responsibility for such toxicologic effects is extremely difficult and sometimes impossible, particularly when the endpoint in question lacks specificity, in that it may be caused by a number of agents or even combinations of substances. The challenges for the toxicologist, therefore, are many. The major ones include the need for quantitative information regarding dose and tissue levels as well as greater understanding of the metabolism of metals, particularly at the tissue and cellular levels, where specific effects may occur. Depending on the dose, most metals affect multiple organ systems; but at the lowest dose where effects occur, each metal tends to effect first a specific organ or tissue.

There is increasing emphasis on the use of biomarkers of exposure, toxicity, and suseptiblity to toxic metals. Biomarkers of exposure, also called biological monitors, such as metal concentrations in blood, and urine, have a long history of use, but the advent of molecular biology has greatly expanded the possiblities for all three types of biomarkers. Thus in the case of chromium, DNA-protein complexes may serve as a biomarker of both exposure and carcinogenic potential. The induction of genes known to play a protective role against metal toxicity—for example, the metallothionein and heme oxygenase genes—show promise as markers of both effect and susceptiblity. The use of such biomarkers provides guidelines for preventive measures or therapeutic intervention.

DOSE–EFFECT RELATIONSHIPS

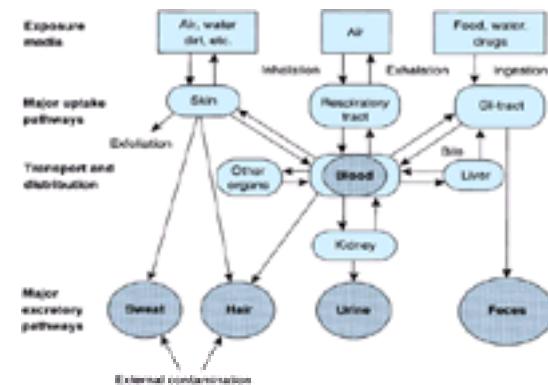
Estimates of the relationship of dose or level of exposure to toxic effects for a particular metal are in many ways a measure of the dose–response relationships discussed in greater detail in Chap. 2. Relationships between sources of exposure, transport, and distribution to various organs and excretory pathways are shown in Fig. 23-2. The dose or estimate of exposure to a metal may be a multidimensional concept and is a function of time as well as the concentration of metal. The most precise definition of dose is the amount of metal within cells of organs manifesting a toxicologic effect. Results from single measurements may reflect recent exposure or longer-term or past exposure, depending on retention time in the particular tissue.


Figure 23-2. Metabolism after exposure to metals via skin absorption, inhalation and ingestion.

The arrows indicate how the metals are transported and distributed. Tissues that are particularly useful for biological monitoring are identified in shaded areas. [From Elinder et al. (1994), with permission.]

A critical determinant of retention of a metal is its biological half-life, that is, the time it takes for the body or organ to excrete half of an accumulated amount. The biological half-life varies according to the metal as well as the organ or tissue; in the case of many metals, more than one half-life is needed to fully describe the retention time. For example, the biological half-lives of cadmium in kidney and lead in bone are 20 to 30 years, whereas for some metals, such as arsenic or lithium, they are only a few hours or days. The half-life of lead in blood is only a few weeks, as compared to the much longer half-time in bone. After inhalation of mercury vapor, at least two half-lives describe the retention in brain—one of the order of a few weeks and the other measured in years.

Blood, urine, and hair are the most accessible tissues in which to measure an exposure or dose; they are sometimes referred to as *indicator tissues.* In vivo, the quantitation of metals within organs is not yet possible, although techniques such as neutron activation and x-ray fluorescence spectroscopy are emerging technologies. Indirect estimates of quantities of toxic metals in specific organs may be calculated from metabolic models derived from autopsy data. Blood and urine concentrations usually reflect recent exposure and correlate best with acute effects. An exception is urinary cadmium, which may reflect renal damage related to an accumulation of cadmium in the kidney. Partitioning of metal between cells and plasma and between filterable and nonfilterable components of plasma should provide more precise information regarding the presence of biologically active forms of a particular metal. For example, most of the methyl mercury in blood is protein-bound, whereas the transportable species—believed to be a complex with low-molecular-weight thiol amino acids—accounts for a tiny fraction. Such partitioning is now standard laboratory practice for blood calcium; ionic calcium is by far the most active form of the metal. Other specific metal complexes, such as chromate and arsenate anions, have now been shown to be the species transported into cells. Speciation of toxic metals in urine may also provide diagnostic insights. For example, cadmium metallothionein in plasma or urine may be of greater toxicologic significance than total cadmium.

Hair might be useful in assessing variations in exposure to metals over the long term. Analyses may be performed on segments of the hair, so that metal content of the newest growth can be compared with past exposures. Hair levels of mercury have been found to be a reliable measure of exposure to alkyl or methyl mercury. For most other metals, however, hair is not a reliable tissue for measuring exposure because of metal deposits from external contamination that complicate analyses, in spite of washing.

Cellular targets for toxicity are specific biochemical processes (enzymes) and/or receptors on membranes of cells and organelles. The proximate toxic action of the metal may involve an interaction between the free metal ion and the toxicologic target—for example, in the case of alkali and alkaline earth metals such as lithium and barium. Other metals that bind with high affinities to cellular ligands may transfer from a ligand involved in transport of the metal directly to the target ligand. For example, methyl mercury is believed to transfer from one thiol group to another without any intermediary free mercury ion.

Toxicity is determined by dose at the cellular level as well as such factors as valence state and ligand binding. Hexavalent chromium is highly toxic, whereas the trivalent form functions as an essential trace element. Ligand binding is probably the most fundamental chemical process in metal toxicity and in cellular defense against metals. The thiol ligands of metallothionein avidly bind a number of toxic metals as part of a defense system. Lead attaches to thiol ligands on enzymes involved in heme synthesis, trivalent arsenic to the thiol groups of alpha lipoic acid, and uranium to phosphate groups on glucose transporters, all metal ligand interactions underlying toxic action.

Certain metals can form organometallic compounds involving covalent metal-carbon bonds. These "organic" forms differ in toxic properties from the inorganic counterparts. Nonionized alkyl compounds such as tetraethyl lead and dimethyl mercury are lipid soluble and pass readily across biological membranes unaltered by their surrounding medium. They are dealkylated or transformed ultimately to inorganic species. Hence, the patterns of disposition and toxicity of organic forms tend to differ from those of inorganic forms. For example, alkyl mercury is primarily a neurotoxin, whereas mercuric chloride is toxic to the kidneys.

HOST FACTORS INFLUENCING THE TOXICITY OF METALS

Recognition of factors that influence toxicity of a particular level of exposure to a toxic metal are important in determining the risk of toxicity, particularly in susceptible populations. A number of factors influencing the toxicity of metals are shown in Table 23-1. The interaction of toxic with essential metals occurs when the metabolism of a toxic metal is similar to that of the essential element (Goyer, 1995). Absorption of toxic metals from the lung or gastrointestinal tract may be influenced by an essential metal, particularly if the toxic metal shares or influences a homeostatic mechanism, as occurs for lead and calcium and iron, and for cadmium and iron. There is an inverse relationship between the protein content of the diet and cadmium and lead toxicity. Vitamin C reduces lead and cadmium absorption, probably because of increased absorption of ferrous ion. Toxic metals may influence the role of essential metals as cofactors for enzymes or other metabolic processes (e.g., lead interferes with the calcium-dependent release of neurotransmitters). Lead, calcium, and vitamin D have a complex relationship affecting mineralization of bone, and they have a more direct one involving impairment of 1-25-dihydroxy vitamin D synthesis in the kidney.

Immune status of host

Table 23-1 Factors Influencing Toxicity of Metals

Metalloprotein complexes involved in detoxification or protection from toxicity have now been described for a few metals (Goyer, 1984). Morphologically discernible cellular inclusion bodies are present with exposures to lead, bismuth, and a mercury-selenate mixture. Metallothioneins form complexes with cadmium, zinc, copper, and other metals, and ferritin and hemosiderin are intracellular iron-protein complexes. None of these proteins or metal-protein complexes have any known enzymatic activity. The nature and influences of these complexes are discussed below (this chapter) in the discussion of the toxicology of the particular metals involved.

Persons at either end of the life span, whether they are young children or elderly people, are believed to be more susceptible to toxicity from exposure to a particular

level of metal than most adults (NRC, 1993). The major pathway of exposure to many toxic metals in children is food, and children consume more calories per pound of body weight than adults. Moreover, children have higher gastrointestinal absorption of metals, particularly lead. Experimental studies have extended these observations to many metals, and a milk diet, probably because of its lipid content, seems to increase metal absorption. The rapid growth and rapid cell division that children's bodies experience represent opportunities for genotoxic effects. Intrauterine toxicity to methyl mercury is well documented. There is no impediment to the transplacental transport of lead, so that fetal blood lead levels are similar to maternal levels.

Lifestyle factors such as smoking or alcohol ingestion may have indirect influences on toxicity. Cigarette smoke by itself contains some toxic metals, such as cadmium, and cigarette smoking may also influence pulmonary effects. Alcohol ingestion may influence toxicity indirectly by altering diet and reducing essential mineral intake.

For metals that produce hypersensitivity reactions, the immune status of an individual becomes an additional toxicologic variable. Metals that provoke immune reactions include mercury, gold, platinum, beryllium, chromium, and nickel. Clinical effects are varied but usually involve any of four types of immune responses. In anaphylactic or immediate hypersensitivity reactions, the antibody IgE reacts with the antigen on the surface of mast cells, releasing vasoreactive amines. Clinical reactions include conjunctivitis, asthma, urticaria, or even systemic anaphylaxis. Cutaneous, mucosal, and bronchial reactions to platinum have been attributed to this type of hypersensitivity reaction. Cytotoxic hypersensitivity is the result of a complement-fixing reaction of IgG immunoglobulin with antigen or hapten bound to the cell surface. The thrombocytopenia sometimes occurring with exposure to organic gold salts may be brought about in this manner. Immune complex hypersensitivity occurs when soluble immune complex forms deposits (antigen, antibody, and complement) within tissues, producing an acute inflammatory reaction. Immune complexes are typically deposited on the epithelial (subepithelial) side of glomerular basement membrane, resulting in proteinuria following exposure to mercury vapor or gold therapy. Cell-mediated hypersensitivity, also known as the *delayed hypersensitivity reaction,* is mediated by thymus-dependent lymphocytes and usually occurs 24 to 48 h after exposure. The histologic reaction consists of mononuclear cells and is the typical reaction seen in the contact dermatitis following exposure to chromium or nickel. The granuloma formation occurring with beryllium and zirconium exposure may be a form of cell-mediated immune response.

METAL-BINDING PROTEINS

Protein binding of metals has been the subject of a recent major review on the molecular biology of metal toxicology (Zalups and Koropatnick, 2000). Several kinds of metal-protein interactions may be considered. A protein may be the target of toxicity. Enzymes are the best-documented targets. The protein may play a protective role, reducing the activity (toxicity of the metal). The metallothioneins are the best-known example.

Many different classes of proteins are known to play a role in the disposition of metals in the body. Nonspecific binding to proteins, such as serum albumin or hemoglobin, plays a role in metal transport in the bloodstream and in the distribution of metals between red cells and plasma. Metals bound to albumin may be carried into cells by endocytotic mechanisms. The distribution of methyl mercury between red cells and plasma depends upon genetically determined species of hemoglobin molecules differing in their content of cysteine residues. In addition, proteins with specific metal binding properties play a special role in both the transport of metals from plasma to tissues and in the transport of metals across cell membranes and within the cell.

Specific Metal-Binding Proteins

The metallothioneins, discovered over 40 years ago, may have several diverse functions, including essential metal homeostasis and protection against metal toxicity. They have low molecular weights (about 6000 Da) and are rich in thiol ligands. These ligands provide the basis for high-affinity binding of several essential and nonessential but toxic metals such as Cd, Cu, Hg, Ag, and Zn. In most cases but not all, the metallothioneins are highly inducible by a number of metals and other stimulants. Metallothioneins can interact with metals in complex physiologic and biochemical pathways, as illustrated in the discussion of cadmium, below.

Transferrin is a glycoprotein that binds most of ferric iron in plasma. Transport of iron across cell membranes occurs by receptor-mediated endocytosis of ferric transferrin. The receptor is a disulfide-linked membrane glycoprotein whose affinity for apotransferrin is two orders of magnitude lower than that for ferric transferrin. Once inside the cell, iron is separated from transferrin by an acidification process within the endosomes. This protein also transports Al^{3+} and Mn^{2+}.

Ferritin is primarily a storage protein for iron in the reticuloendothelial cells of liver, spleen, and bone. It plays a major role in hepatic turnover of iron. Kupffer cells release iron acquired from the phagocytosis of red cells in the form of ferritin, which is efficiently internalized by hepatocytes via their ferritin receptors. It has been suggested that ferritin may serve as a general metal detoxicant, since it binds a variety of toxic metals including Cd, Zn, Be and Al.

Ceruloplasmin is a copper-containing glycoprotein oxidase in plasma that converts ferrous to ferric iron, which then binds to transferrin. This protein also stimulates iron uptake by a transferrin-independent mechanism.

Membrane Carrier Proteins

In addition to the cases discussed above, a rapidly increasing number of carrier proteins are being discovered that transport metals across cell membranes and organelles inside the cells. Although certain metals may be transported in the free ionic forms, as through calcium channels, many metals are transported as complexes with endogenous ligands on transport systems intended for the ligand itself. This is made possible because many of these carriers are generally multispecific, accepting substrates that differ considerably in their chemical structure and are not able to discriminate between substrates whose only modification is the attachment of a metal ion.

The phosphate and sulfate transporters can carry a number of metal oxyanions across the plasma membrane. Vanadate and arsenate are structurally similar to phosphate and can compete with phosphate for transport as well as intracellular binding sites. In fact, their toxicity may be related to this competition. Similarly, chromate, molybdate, and selenate are structurally similar to sulfate and are carried on the sulfate transporter.

Amino acid and peptide transporters and organic solute carriers also accept metals as complexes with endogenous molecules such as amino acids, peptides, and bicarbonate. Cellular uptake of copper or zinc may occur as complexes with the amino acid histidine. Methyl mercury crosses cell membranes as a complex with cysteine on the large neutral amino acid carrier and is exported from hepatocytes into bile as a complex with glutathione. Zinc appears to be taken up into red blood cells as an anionic complex with bicarbonate, $Zn(HCO_3)_2$, through the anion exchanger. Bicarbonate complexes of lead may follow a similar route.

Other examples of metal transporters have been the subject of a recent review (Ballatori, 2000a). These include divalent cation transporters and ATP-activated membrane pumps. For example, Wilson's and Menke's diseases are due to genetic errors in copper metabolism related to ATP-activated copper carriers. It has been estimated (Ballatori, 2000b) that the human genome may contain upwards of 9000 genes coding for transporter proteins, of which 2000 are concerned with the transport of drugs and other xenobiotics. This rapidly expanding field is still not sufficiently developed to identify polymorphisms of these protein carriers. The future holds promise that identification and measurement of expression of these carriers in cells and tissues will result in valuable biomarkers of metal effects and of individual susceptibility to metal toxicity.

COMPLEXATION AND CHELATION THERAPY

Treatment of poisoning from toxic metals is sometimes warranted to prevent or reverse toxicity and therefore remains an important topic, particularly for those metals that are cumulative and persistent (e.g., lead). It must be emphasized, however, that treatment is only a secondary alternative to reduction or prevention of exposures to toxic metals.

Complexation is the formation of a metal ion complex in which the metal ion is associated with a charged or uncharged electron donor, referred to as a *ligand.* The ligand may be monodentate, bidentate, or multidentate; that is, it may attach or coordinate using one, two or more donor atoms. *Chelation* occurs when bidentate ligands form ring structures (*chelate* comes from the Greek word for claw) that include the metal ion and the two ligand atoms attached to the metal (Williams and Halstead, 1982). Metals may react with O-, S-, and N-containing ligands present in the form of OH, COOH, SH, NH_2, NH, and N. A resultant metal complex is formed by coordinate bonds (coordination compound), in which both electrons are contributed by the ligand (Klaassen, 1990).

Chelating[1] agents (drugs) vary in their specificity for toxic metals. Ideal chelating agents should be water-soluble, resistant to biotransformation, able to reach sites of metal storage, capable of forming nontoxic complexes with toxic metals, and of being excreted from the body; they should also have a low affinity for essential metals, particularly calcium and zinc (Klaassen, 1990). The challenge in the development of safer and more effective chelating agents is to design all of the desirable

chemical, physiologic, and pharmacologic properties into the drug (Jones, 1992).

The general properties of chelating agents that are of current interest are briefly described below. Additional details and comments are provided later in the chapter with discussions of specific metals.

BAL (British Anti-Lewisite)

BAL (2,3-dimercaptopropanol) was the first clinically useful chelating agent. It was developed during World War II as a specific antagonist to vesicant arsenical war gases, based on the observation that arsenic has an affinity for sulfhydryl-containing substances. BAL, a dithiol compound with two sulfur atoms on adjacent carbon atoms, competes with the critical binding sites responsible for the toxic effects. These observations led to the prediction that the "biochemical lesion" of arsenic poisoning would prove to be a thiol with sulfhydryl groups separated by one or more intervening carbon atoms. This prediction was borne out a few years later with the discovery that arsenic interferes with the function of 6,8-dithiooctanoic acid in biological oxidation (Gunsalus, 1953).

BAL has been found to form stable chelates in vivo with many toxic metals, including inorganic mercury, antimony, bismuth, cadmium, chromium, cobalt, gold, and nickel. However, it is not necessarily the treatment of choice for toxicity to these metals. BAL has been used as an adjunct in the treatment of the acute encephalopathy of lead toxicity. It is a potentially toxic drug, and its use may be accompanied by multiple side effects. Although treatment with BAL will increase the excretion of cadmium, there is a concomitant increase in renal cadmium concentration, so that its use in case of cadmium toxicity is to be avoided. It does, however, remove inorganic mercury from the kidney, but it is not useful in the treatment of alkyl mercury or phenyl mercury toxicity. BAL also enhances the toxicity of selenium and tellurium, so it is not to be used to remove these metals from the body.

DMPS

DMPS (2,3-dimercapto-1-propanesulfonic acid) is a water-soluble derivative of BAL developed in response to BAL's toxicity and unpleasant side effects. DMPS has been shown to reduce blood lead levels in children (Chisholm and Thomas, 1985). It has the advantage over ethylene diamine tetraacetic acid (EDTA) in that it is administered orally and does not appear to have toxic side effects. It has been widely used in the former Soviet Union to treat many different metal intoxications. DMPS has been used experimentally to estimate the renal burden of lead (Twarog and Cherian, 1984) and inorganic mercury (Cherian et al., 1988). Its effectiveness in mobilizing metals from the kidney may be due to the fact that it is transported into kidney cells on the organic anion transport system (Zalups et al., 1998). It increases the urinary excretion of mercury in persons with an increased body burden from industrial exposure, from dentists and dental technicians, from persons with dental amalgams, from those exposed to mercurous chloride in skin creams (Aposhian et al., 1992; Gonzalez-Ramirez et al., 1998). This agent has also been used to assess body burdens of inorganic mercury from dental amalgams and of arsenic ingested from drinking water (Aposhian, 1998).

DMSA

DMSA (meso-2.3.-dimercaptosuccinic acid; succimer), like DMPS, is a chemical analog of BAL. More than 90 percent of DMSA is in the form of a mixed disulfide in which each of the sulfur atoms is in disulfide linkage with a cysteine molecule (Aposhian and Aposhian, 1992). The drug is of current interest clinically because of its ability to lower blood lead levels. It has advantages over EDTA because it is given orally and has greater specificity for lead. It may be safer than EDTA in that it does not enhance excretion of calcium and zinc to the same degree. Studies in rodents showed that a single dose of DMSA primarily removes lead from soft tissues (Smith and Flegal, 1992). A lead mobilization test with DMSA does not appear to give better information on body burden than measurements of lead in blood, plasma, or urine (Gerhardsson et al., 1999).

The drug has been licensed recently by the U.S. Food and Drug Administration (FDA) specifically for the treatment of lead poisoning in children whose blood lead levels are ³45 µg/dL, and it has been used in Europe. However its effectiveness in improving long-term blood lead levels in children has been questioned (O'Connor and Rich, 1999), nor, according to studies on primates, does it appear effective in removing lead from the brain (Cremin et al., 1999). Its ability to reverse some of the toxic outcomes of lead poisoning, such as negative effects on cognitive and behavioral development, has not been demonstrated.

EDTA

Calcium salt of ethylene diamine tetraacetic acid (EDTA) must be used for clinical purposes because the sodium salt has greater affinity for calcium and will produce hypocalcemic tetany. However, the calcium salt will bind lead, with displacement of calcium from the chelate. EDTA is poorly absorbed from the gastrointestinal tract so it must be given parenterally, which distributes it rapidly throughout the body. It has long been the method of choice for the treatment of lead toxicity. The peak excretion point is within the first 24 h and represents the excretion of lead from soft tissues. Removal of lead from the skeletal system occurs more slowly, with the restoration of equilibrium with soft tissue compartments. Animal experiments indicate that EDTA is not effective in reducing total brain lead (Seaton et al., 1999). Calcium EDTA does have the potential for nephrotoxicity, so it should be administered only when clinically indicated (EPA, 1986). Combination therapy of EDTA with other chelating agents, such as BAL and DMSA, has been used to reduce the risk of side effects from either agent alone, as each agent can be given at a lower dose in combined therapy. Whether BAL or DMSA is used as the second agent, the results are equally effective in reducing blood lead in children (Besunder et al., 1997).

DTPA

DTPA, or diethylenetriaminepentaacetic acid, has chelating properties similar to those of EDTA. The calcium salt ($CaNa_2DTPA$) must be used clinically because of DTPA's high affinity for calcium. It has been used for the chelation of plutonium and other actinide elements, but with mixed success. Experimental studies have shown that various multidentate hydroxypyridinonate ligands are more effective than $CaNa_2DTPA$ for promoting excretion of Pu and other actinides (Durbin et al., 2000).

Desferrioxamine

Desferrioxamine is a hydroxylamine isolated as the iron chelate of *Streptomyces pilosus* and is used clinically in the metal-free form (Keberle, 1964). It has a remarkable affinity for ferric iron and a low affinity for calcium, and it competes effectively for iron in ferritin and hemosiderin but not in transferrin and not for the iron in hemoglobin or heme-containing enzymes. It is poorly absorbed from the gastrointestinal tract, so it must be given parenterally. Clinical usefulness is limited by a variety of toxic effects, including hypotension, skin rashes, and possibly cataract formation. It seems to be more effective in hemosiderosis due to blood transfusion but is less effective in treatment of hemochromatosis. A high-molecular-weight derivative in which desferrioxamine is chemically coupled to hydroxyethyl starch shows promise in human tests as an effective iron chelator, with lower toxicity than the parent compound (Dragsten et al., 2000).

Dithiocarbamate (DTC)

Dithiocarb (diethyldithiocarbamate), or DTC, has been recommended as the drug of choice in the treatment of acute nickel carbonyl poisoning. The drug may be administered orally for mild toxicity and parenterally for acute or severe poisoning (Sunderman, 1979). However, no adequately controlled clinical studies have been performed (Bradberry and Vale, 1999).

DTC has also been used experimentally for removal of cadmium bound to metallothionein (Kojima et al., 1990). A number of DTC compounds with various substitutions of nonpolar, nonionizing groups have been synthesized by Jones and Cherian (1990). Sodium, *N*-(4-methoxybenzyl)-D-glucamine dithiocarbamate (MeOBGDTC), is among the most effective in removing cadmium from tissues. The CdMeOBGDTC complex is excreted in the bile rather than by the kidney, avoiding the nephrotoxicity characteristic of cadmium chelates. To date the use of this compound has been limited to experimental studies in rodents.

Penicillamine and *N*-Acetylcysteine

Penicillamine (b, b-dimethylcysteine), a hydrolytic product of penicillin, has been used for the removal of copper in persons with Wilson's disease and for the removal of lead, mercury, and iron (Walshe, 1964). It is also important to note that penicillamine removes other physiologically essential metals, including zinc, cobalt, and manganese. Attached to its use is the risk of inducing a hypersensitivity reaction with a wide spectrum of undesirable immunologic effects, including skin rash, blood dyscrasia, and possibly proteinuria and nephrotic syndrome. It has cross-sensitivity with penicillin, so it should be avoided by persons with penicillin hypersensitivity. For persons who have developed a sensitivity to penicillamine, an orally active chelating agent, triethylene tetramine 2HCl (Trien), is an alternative for the removal of

copper (Walshe, 1983). Reducing the commonly used dose from 25 to 30 mg/kg/day to 15 mg/kg/day maintains the efficacy of d-penicillamine at reducing blood lead with reduced side effects in lead-exposed children (Shannon and Townsend, 2000).

N-acetylcysteine has been widely used clinically as a mucolytic agent (e.g., for cystic fibrosis) and to protect against the toxic effects of a number of chemicals. It is a free-radical scavenger, a precursor to glutathione, and it can form stable water-soluble complexes with mercury and other metals. Its ease of administration (oral), low toxicity, and wide availability in the clinical setting makes it an attractive therapeutic agent. It is effective in accelerating the removal of methyl mercury in animal tests (Ornaghi et al., 1993; Ballatori et al., 1998). It was also effective in extracorporeal complexation hemodialysis (see below) in one case of human exposure to methyl mercury (Lund et al., 1984).

Hemodialysis with Chelation

Hemodialysis is usually not effective in removing metals from the bloodstream because many metals are associated with red blood cells and/or bound to plasma proteins (for example, Sauder et al., 1988). However a chelating agent may transform the metal into a diffusible form amenable to removal by hemodialysis (Kostyniak and Clarkson, 1981). The chelating agent may be given systemically, as in the application of desferrioxamine to remove aluminum in conjunction with hemodialysis (Nakamura et al., 2000). Extracorporeal complexation hemodialysis avoids systemic application of the complexing agent by introducing the agent into the blood as it enters the dialyzer. Hemodialysis then removes the metal chelate and as well as the excess chelating agent. The method was first successfully used to remove methyl mercury from intoxicated patients (Al-Abbasi et al., 1978), and it has subsequently been applied to a case of inorganic poisoning (Kostyniak et al., 1990). The most effective complexing agent appears to be DMSA for mercury removal with hemodialysis (Kostyniak, 1982). The method has been successfully tested in dogs to remove cadmium using a combination of EDTA and glutathione as complexing agents (Sheabar et al., 1989).

MAJOR TOXIC METALS WITH MULTIPLE EFFECTS

Arsenic (As)

Arsenic[1] is particularly difficult to characterize as a single element because its chemistry is so complex and there are many different arsenic compounds. It may be trivalent or pentavalent and is widely distributed in nature. The most common inorganic trivalent arsenic compounds are arsenic trioxide, sodium arsenite, and arsenic trichloride. Pentavalent inorganic compounds are arsenic pentoxide, arsenic acid, and arsenates, such as lead arsenate and calcium arsenate. Organic compounds may also be trivalent or pentavalent, such as arsanilic acid, or may even occur in methylated forms as a consequence of biomethylation by organisms in soil, fresh water, and seawater.

A summary of environmental sources of arsenic as well as their potential health effects is contained in the National Research Council's is report on arsenic in drinking water (NRC, 1999). Inorganic arsenic is released into the environment from a number of anthropogenic sources, which include primary copper, zinc, and lead smelters, glass manufacturers that add arsenic to raw materials, and chemical manufacturers. The National Air Sampling Network tests conducted by the EPA indicate that in areas not influenced by copper smelters, maximum 24-h concentrations do not exceed 0.1 µg/m^3.

Drinking water usually contains a few micrograms per liter or less. Most major U.S. drinking water supplies contain levels lower than 5 µg/L. It has been estimated that about 350,000 people might drink water containing more than 50 µg/L (Smith et al., 1992). While seafoods contain several times the amount of arsenic in other foods, about 90 percent or more is organic arsenic that is unabsorbed (NRC, 1999). According to the 1991–1997 FDA Total Diet Market Basket Study conducted by the FDA for the 1991–1997 period, daily intake of arsenic from food is less than 10 µg/day (Tao and Bulger, 1998). Assuming consumption of 2000 mL/day of drinking water containing as much as 5 µg/L of arsenic, drinking water also contributes 10 µg/day for a total of 20 µg/day from food and water. Youst et al. (1998) estimated that daily dietary intake of inorganic arsenic ranges from 8.3 to 14 µg/day in the United States and 4.8 to 12.7 µg/day in Canada. Major sources of occupational exposure to arsenic in the United States include the manufacture of pesticides, herbicides, and other agricultural products. High exposure to arsenic fumes and dust may occur in the smelting industries; the highest concentrations most likely are among roaster workers.

Toxicokinetics About 80 to 90 percent of a single dose of arsenite [As(III) or arsenate As(V)] has been shown to be absorbed from the gastrointestinal tract of humans and experimental animals. Arsenic compounds of low solubility (e.g., arsenic selenide, lead arsenide, and gallium arsenide) are absorbed less efficiently than dissolved arsenic. Skin can be a route of exposure to arsenic, and systemic toxicity has been reported in persons having extensive acute dermal contact with solutions of inorganic arsenic (Hostynek et al., 1993). Airborne arsenic is largely trivalent arsenic oxide, but deposition in airways and absorption from lungs is dependent on particle size and chemical form (Morrow et al., 1980). Excretion of absorbed arsenic is mainly via urine. The biological half-life of ingested inorganic arsenic is about 10 h, and 50 to 80 percent is excreted in about 3 days. The biological half-life of methylated arsenic is about 30 h. Arsenic has a predilection for skin and is excreted by desquamation of skin and in sweat, particularly during periods of profuse sweating. It also concentrates in nails and hair. Arsenic in nails produces Mees' lines (transverse white bands across fingernails), which appear about 6 weeks after the onset of symptoms of toxicity. The time of exposure may be estimated from measuring the distance of the line from the base of the nail and the rate of nail growth, which is about 0.3 cm per month or 0.1 mm per day. Arsenic in hair may also reflect past exposure, but intrinsic or systematically absorbed arsenic in hair must be distinguished from arsenic that is deposited from external sources.

Biotransformation The metabolism and potential for toxicity of arsenic is complicated by in vivo transformation of inorganic forms by methylation to monomethyl arsenic (MMA) and dimethyl arsenic (DMA). The methylation of arsenic compounds involves both oxidation states of the element. The liver is the major site for methylation. A substantial fraction of absorbed As(V) is rapidly reduced to AS(III), most of which is then methylated to MMA or DMA. The probable mechanisms of in vivo methylation involve a two-electron process that probably involves thiol oxidation. As(V) is reduced to As(III). The resulting As(III) then reacts with *S*-adenosylmethionine (SAM) in an oxidative addition resulting in the transfer of a methyl group from sulfur to arsenic (Abernathy et al., 1999). Compared with inorganic arsenic, the methylated metabolites are less reactive with tissue constituents, less acutely toxic, less cytotoxic, and more readily excreted in the urine (NRC, 1999). This is presumed to be a process of detoxification of the more toxic inorganic forms, and dimethyl arsenic appears to be a terminal metabolite, which is rapidly formed and rapidly excreted. The liver is the major site for methylation of inorganic arsenic. Studies using primary cultures of normal human hepatocytes have shown that the total methylation yield (MMA and DMA) increased in a dose-dependent manner, but the methylation process is saturable. DMA production was inhibited by As(III) in a concentration-dependent manner and DMA/MMA ratio decreased. At higher concentrations of As(III), both methylated forms of arsenic decreased (Styblo et al., 1999). There are major differences in the biotransformation of inorganic arsenic in different mammalian species (Vahter, 1994; Vahter et al., 1995). For most animal species, DMA is the main metabolite. Studies of marmoset monkeys and chimpanzees show no methylation of inorganic arsenic.

A number of studies in humans in which metabolites of inorganic arsenic in urine have been speciated consistently show average values of 10 to 30 percent inorganic arsenic, 10 to 20 percent MMA, and 55 to 76 percent DMA. Those results were found in human subjects in the general environment and in those exposed at work. However, there are variations in arsenic methylation due to such factors as possible genetic polymorphisms, age, and sex. Studies of native peoples and people of Spanish descent in northern Argentina and Chile exposed to arsenic in drinking water showed that urinary arsenic consisted of only 2 to 4 percent MMA on average (Concha et al., 1998a). On the other hand, a study of exposure to arsenic in drinking water in northeastern Taiwan showed 27 percent MMA in urine—an unusually high percentage (Chiou et al., 1997).

Mechanisms of Toxicity It has been known for some years that trivalent compounds of arsenic are the principal toxic forms and that pentavalent arsenic compounds have little effect on enzyme activity. A number of sulfhydryl-containing proteins and enzyme systems have been found to be altered by exposure to arsenic. Some of these can be reversed by addition of an excess of a monothiol such as glutathione. Effects on enzymes containing two thiol groups can be reversed by dithiols such as 2,3-dimercaptopropanol (British anti-Lewisite, or BAL) but not by monothiol. Arsenic affects mitochondrial enzymes and impairs tissue respiration (Brown et al., 1976), which seems to be related to the cellular toxicity of arsenic. Mitochondria accumulate arsenic, and respiration mediated by NAD-linked substrates is particularly sensitive to arsenic; this is thought to result from a reaction between the arsenite ion and the dihydrolipoic acid cofactor, which is necessary for oxidation of the substrate. Arsenite also inhibits succinic dehydrogenase activity and uncouples oxidative phosphorylation, which results in stimulation of mitochondrial ATPase activity. Arsenic inhibits energy-linked functions of mitochondria in two ways: competition with phosphate during oxidative phosphorylation and inhibition of energy-linked reduction of NAD. Inhibition of mitochondrial respiration results in decreased cellular production of ATP and increased production of hydrogen peroxide, which might cause oxidative stress, and production of reactive oxygen species (ROS). Intracellular production of ROS results in observed induction of major stress protein families (NRC, 1999).

Arsenic compounds induce metallothionein in vivo. Potency is dependent on the chemical form of arsenic. As(III) is most potent, followed by As(V), monomethylarsenate, and dimethylarsenate (Kreppel et al., 1993). Metallothionein is thought to have a protective effect against arsenic toxicity and may be responsible at least in part for its self-induced tolerance. Metallothionein-null mice are more sensitive than wild-type mice to the hepatotoxic and nephrotoxic effects of chronic or injected inorganic arsenicals (Liu et al., 1998). The role of asenical-induced oxidative stress and ROS may play a role in mediating DNA damage and

initiating the carcinogenic process (NRC, 1999).

Toxicology Ingestion of large doses (70 to 180 mg) of arsenic may be fatal. Symptoms of acute illness, possibly leading to death, consist of fever, anorexia, hepatomegaly, melanosis, and cardiac arrhythmia, with changes in electrocardiograph results that may point to eventual cardiovascular failure. Other features include upper respiratory tract symptoms, peripheral neuropathy, and gastrointestinal, cardiovascular, and hematopoietic effects. Acute ingestion may be suspected from damage to mucous membranes, such as irritation, vesicle formation, and even sloughing. Sensory loss in the peripheral nervous system is the most common neurologic effect, appearing 1 or 2 weeks after large exposures and consisting of wallerian degeneration of axons, a condition that is reversible if exposure is stopped. Anemia and leukopenia, particularly granulocytopenia, occur a few days following exposure and are reversible. The hematologic consequences of chronic exposure to arsenic are similar to effects from acute exposure. There may also be disturbances in heme synthesis, with an increase in urinary porphyrin excretion.

Chronic exposure to inorganic arsenic compounds may lead to neurotoxicity of both the peripheral and central nervous systems. Neurotoxicity usually begins with sensory changes, paresthesia, and muscle tenderness followed by weakness, progressing from proximal to distal muscle groups. Peripheral neuropathy may be progressive, involving both sensory and motor neurons leading to demyelination of long axon nerve fibers, but effects are dose-related. Acute exposure to a single high dose can produce the onset of paresthesia and motor dysfunction within 10 days. More chronic occupational exposures producing more gradual, insidious effects may occur over a period of years, and it has been difficult to establish dose–response relationships (Murphy et al., 1981; Donorio et al., 1987).

Liver injury, characteristic of longer-term or chronic exposure, manifests itself initially in jaundice and may progress to cirrhosis and ascites. Toxic effects on hepatic parenchymal cells result in the elevation of liver enzymes in the blood, and studies in experimental animals show granules and alterations in the ultrastructure of mitochondria as well as nonspecific manifestations of cell injury, including loss of glycogen.

The relationship between the prevalence of ingestion of inorganic arsenic in drinking water and cardiovascular disease has been shown in studies in the United States (Engel and Smith, 1994) and in Taiwan (Chiou et al., 1997). Peripheral vascular disease has been observed in persons with chronic exposure to arsenic in drinking water in Taiwan and Chile; it is manifest by acrocyanosis and Raynaud's phenomenon and may progress to endarteritis obliterans and gangrene of the lower extremities (blackfoot disease). This specific effect seems to be related to the cumulative dose of arsenic, but the prevalence is uncertain because of difficulties in separating arsenic-induced peripheral vascular disease (NRC, 1999). Recent studies in southwestern Taiwan (Lai et al., 1994) and cohorts with occupational exposure in Sweden (Rahman and Axelson, 1995) were associated with chronic arsenic ingestion in drinking water and an increase risk of diabetes mellitus. Immunomodulating and immunotoxic effects of arsenic have been suggested from studies in experimental animals, while human studies have shown some effect on lymphocyte replicating ability (Gonsebatt et al., 1994).

Reproductive Effects and Teratogenicity High doses of inorganic arsenic compounds given to pregnant experimental animals produced various malformations, somewhat dependent on time and route of administration, in fetuses and offspring. However, no such effects have been noted in humans with excessive occupational exposures to arsenic compounds. Arsenic readily crosses the placenta in women without known exposure to arsenic. In a fetus and suckling infant in an Andean village where the arsenic content of drinking water was about 200 µg/L, the concentration of arsenic in cord blood was almost as high as that in maternal blood (Concha et al., 1998b). However, more than 90 percent of the arsenic in plasma and urine was in the form of DMA, a percentage that is higher than the percentage in nonpregnant women, suggesting that there is increased methylation during pregnancy. Animal data indicate that less developmental toxicity is caused by the methylated metabolites than by arsenite (NRC, 1999).

Carcinogenicity The potential carcinogenicity of arsenic compounds was recognized over 100 years ago by Hutchinson (1887), who observed an unusual number of skin cancers occurring in patients treated with arsenicals. The IARC (1987) and EPA (1988) classify arsenic as a carcinogen, for which there is sufficient evidence from epidemiologic studies to support a causal association between exposure and skin cancer and lung cancer via inhalation. There is now evidence that arsenic causes cancer of internal organs from oral ingestion (Bates et al., 1992). In humans, chronic exposure to arsenic induces a series of characteristic changes in skin epithelium, proceeding from hyperpigmentation to hyperkeratosis. Diffuse or spotted hyperpigmentation, the initial nonmalignant cutaneous effect, can first appear within 6 months to 3 years of chronic ingestion at concentrations in excess of approximately 0.4 mg/kg/day. Lower exposure rates, on the order of 0.01 mg/kg/day or longer, can result in pigmentation after intervals as long as 5 to 15 years. Palmar-plantar hyperkeratosis usually follows the initial appearance of arsenical hyperpigmentation within a period of years. There may actually be two cell types of arsenic-induced skin cancer—basal cell carcinomas and squamous cell carcinomas—arising in keratotic areas. The basal cell cancers are usually only locally invasive, but squamous cell carcinomas may have distant metastases. The skin cancers related to arsenic differ from ultraviolet light–induced tumors in that they generally occur on areas of the body not exposed to sunlight (e.g., on palms and soles), and they occur as multiple lesions.

The NRC report (1999), utilizing various statistical approaches, cites lifetime cancer risks for bladder cancer from exposure at different levels of arsenic in drinking water. The current EPA maximum contaminant level for arsenic in drinking water is under revision.

Occupational exposure to airborne arsenic may also be associated with lung cancer, usually a poorly differentiated form of epidermoid bronchogenic carcinoma. The time period between initiation of exposure and occurrence of arsenic-associated lung cancer has been found to be on the order of 35 to 45 years. Enterline and Marsh (l980) report a latency period of 20 years in their study of copper smelter workers.

In contrast to most other human carcinogens, it has been difficult to confirm the carcinogenicity of arsenic in experimental animals. Intratracheal installations of arsenic trioxide produced an increased incidence of pulmonary adenomas, papillomas, and adenomatoid lesions, suggesting that arsenic trioxide can induce lung carcinomas (Pershagan et al., 1984), but other studies testing As(III) and As(V) compounds by oral administration or skin application have not shown potential for either promotion or initiation of carcinogenicity. Similarly, experimental studies for carcinogenicity of organic arsenic compounds have been negative.

The mode of action of arsenic carcinogenicity has not been established. Inorganic arsenic and its metabolites have been shown to induce deletion mutations and chromosomal aberrations but not point mutations. Arsenic has also been shown to be comutagenic. Other modes of action that have been suggested include effects on DNA methylation, oxidative stress, and cell proliferation, but that data are not sufficient to draw firm conclusions (NRC, 1999).

Arsine

Arsine gas (AsH$_3$) is formed by the reaction of hydrogen with arsenic and is generated as a by-product in the refining of nonferrous metals. Arsine is a potent hemolytic agent, producing acute symptoms of nausea, vomiting, shortness of breath, and headache accompanying the hemolytic reaction. Exposure may be fatal and may be accompanied by hemoglobinuria and renal failure and even jaundice and anemia in nonfatal cases when exposure persists (Fowler et al., 1989).

Biomarkers Biomarkers of arsenic exposure are arsenic concentrations in urine, blood, and hair (Table 23-2). Urinary arsenic is the best indicator of exposure because it is the main route of excretion for most arsenic compounds. The half-time of inorganic arsenic in humans is about 4 days. Urine arsenic level in persons in the general population without seafood intake is usually in the range of 10 µg/L (5 to 50 µg/L). Some marine organisms may contain very high concentrations of organoarsenicals, which do not have significant toxicity and are rapidly excreted in urine without transformation. One serving of seafood might give rise to urinary arsenic concentrations of 1000 µg/L (Norin and Vahter, 1981). Individuals should be advised not to ingest seafood for a day or two before measurement of urinary arsenic. Most of the absorbed inorganic or organic arsenic has a short half-time in blood, so that arsenic concentrations in blood are increased only a short time following absorption. Like lead, arsenic is measured in whole blood, not serum, because most of the arsenic is in red blood cells. Levels are usually very low and expressed per liter of whole blood. High levels of arsenic in drinking water (wells) will increase urine and blood arsenic. In studies carried out in California and Nevada, a water concentration of 400 µg/L corresponded to about 75 µg/L in the urine and about 14 µg/L in the blood (Valentine et al., 1979). Compared with urine, blood is a much less sensitive indicator of arsenic exposure. Hair or even fingernail concentrations of arsenic may be helpful in evaluating past exposures, but interpretation is made difficult because of the problem of differentiating external contamination.

	NORMAL	EXCESSIVE EXPOSURE
Urine µg/L	5–50	>100 (without seafood)
Blood µg/L	1–4	50
Hair µg/kg	<1	

Table 23-2 Biomarkers of Arsenic Exposure

There are no specific biomarkers of arsenic toxicity, and evaluation of clinical effects must be interpreted with knowledge of exposure history.

Treatment For acute toxicity, treatment is symptomatic, with particular attention to fluid volume replacement and support of blood pressure with pressor agents. For acute symptoms, dimercaprol may be given (3 mg/kg intramuscularly every 4 hours) until symptoms subside, followed by oral penicillamine. Succimer (2,3-dimercaptosuccinic acid) is also thought to be effective. For chronic exposures, dimercaprol and/or penicillamine may also be used (Klaassen, 1990).

Beryllium (Be)

Beryllium[1] is an uncommon metal with a few specific industrial uses. Environmental sources and toxicologic effects of beryllium are reviewed in detail in health criteria documents (EPA, 1987; WHO, 1990). Release of beryllium to the environment largely results from coal combustion. The combustion of coal and oil contributes about 1250 or more tons of beryllium to the environment each year (mostly from coal), which is about five times the annual production from industrial use. The major industrial processes that release beryllium into the environment are beryllium extraction plants, ceramic plants, and beryllium alloy manufacturers. These industries also provide the greatest potential for occupational exposure. Currently, the major use for beryllium is as an alloy, but about 20 percent of world production is for applications utilizing the free metal in nuclear reactions, x-ray windows, and other special applications related to space optics, missile fuel, and space vehicles. It is also present in cigarette smoke (Smith et al., 1997). The mean urinary levels of beryllium in the general population are reported as 0.26 µg/L (Apostoli et al., 1989).

Toxicokinetics Knowledge of the toxicokinetics of beryllium has largely been obtained from experimental animals, particularly the rat. Clearance of inhaled beryllium is multiphasic; half is cleared in about 2 weeks, the remainder is removed slowly, and a residuum becomes fixed in the tissues probably within fibrotic granulomata. Gastrointestinal absorption of ingested beryllium probably occurs only in the acidic milieu of the stomach, where it is in the ionized form, but beryllium passes through the intestinal tract as precipitated phosphate. Removal of radiolabeled beryllium chloride from rat blood is rapid, whereas beryllium has a half-life of about 3 h. It is distributed to all tissues, but most goes to the skeleton. High doses go predominantly to the liver, but it is gradually transferred to the bone. The half-life in tissues is relatively short except in the lungs, and a variable fraction of an administered dose is excreted in the urine, where it has a long biological half-life.

Skin Effects Contact dermatitis is the commonest beryllium-related toxic effect. Exposure to soluble beryllium compounds may result in papulovesicular lesions on the skin, which is a delayed-type hypersensitivity reaction. The hypersensitivity is cell-mediated, and passive transfer with lymphoid cells has been accomplished in guinea pigs. If contact is made with an insoluble beryllium compound, a chronic granulomatous lesion develops, which may be necrotizing or ulcerative. If insoluble beryllium-containing material becomes embedded under the skin, the lesion will not heal and may progress in severity. Use of a beryllium patch test to identify beryllium-sensitive individuals may in itself be sensitizing, so any use of this procedure as a diagnostic test is discouraged.

Pulmonary Effects *Acute Chemical Pneumonitis* Acute pulmonary disease from inhalation of beryllium is a fulminating inflammatory reaction of the entire respiratory tract, involving the nasal passages, pharynx, tracheobronchial airways, and the alveoli; in the most severe cases, it produces an acute fulminating pneumonitis. This occurs almost immediately following inhalation of aerosols of soluble beryllium compounds, particularly fluoride, an intermediate in the ore extraction process. Severity is dose-related. Fatalities have occurred, although recovery is generally complete after a period of several weeks or even months.

Chronic Granulomatous Disease, Berylliosis Chronic beryllium disease (CBD) was first described among fluorescent lamp workers exposed to insoluble beryllium compounds, particularly beryllium oxide. CBD is an antigen-stimulated, cell-mediated immune response that leads to granulomatous lung disease (Tinkle and Newman, 1997). The major symptom is shortness of breath, which in severe cases may be accompanied by cyanosis and clubbing of fingers (hypertrophic osteoarthropathy, a characteristic manifestation of chronic pulmonary disease). Chest x-rays show miliary mottling. Histologically, the alveoli contain small interstitial granulomas resembling those seen in sarcoidosis. In the early stages, the lesions are composed of fluid, lymphocytes, and plasma cells. Multinucleated giant cells are common. Later, the granulomas become organized with proliferation of fibrotic tissue, eventually forming small fibrous nodules. As the lesions progress, interstitial fibrosis increases, with loss of functioning alveoli, impairment of effective air–capillary gas exchange, and increasing respiratory dysfunction. CD4+ cells are believed to be involved in the pathogenesis of CBD (Fontenot et al., 1999). The alpha subunit of the soluble IL-2 receptor is elevated in serum and bronchiolar lavage cells of individuals with CBD and correlates with the degree of clinical severity. This soluble receptor may be a useful biomarker for progression of the disease (Tinkle et al., 1997).

Carcinogenicity Evidence for the carcinogenicity of beryllium was first observed in experimental studies beginning in 1946, before the establishment of carcinogenicity in humans. Epidemiologic confirmation in humans has been evolving. Studies of humans with occupational exposure to beryllium prior to 1970 were negative. However, reports of two worker populations and a registry of berylliosis cases studied earlier show a small excess of lung cancer, although the total number of cases is small. These findings of excess cancer risk in humans are supported by a clear demonstration of carcinogenicity in animals (Hayes, 1997). The IARC (1994) states there is sufficient evidence in humans and animals for the carcinogenicity of beryllium and its compounds. In vitro studies of genotoxicity have shown that beryllium will induce morphologic transformation in mammalian cells (Dipaolo and Casto, 1979). Beryllium will also decrease the fidelity of DNA synthesis but is negative when tested as a mutagen in bacterial systems.

Cadmium (Cd)

Cadmium[1] is a modern toxic metal. It was discovered as an element only in 1817, and industrial use was minor until about 50 years ago. But now it is a very important metal with many applications. Because of its noncorrosive properties, its main use is in electroplating or galvanizing. It is also used as a color pigment for paints and plastics and as a cathode material for nickel-cadmium batteries. Cadmium is a by-product of zinc and lead mining and smelting, which are important sources of environmental pollution. The toxicology of cadmium is extensively reviewed by Friberg et al. (1986), WHO (1992), EPA (1997), and ATSDR (1998).

Exposure For persons in the general population, the major source of cadmium is food. Plants readily take up cadmium from soil contaminated by fallout from the air, cadmium-containing water used for irrigation and cadmium-containing fertilizers. Another source of concern about potential sources of cadmium toxicity is the use of commercial sludge to fertilize agricultural fields. Commercial sludge may contain up to 1500 mg of cadmium per kilogram of dry material. Studies from Sweden have shown a slow but steady increase in the cadmium content of vegetables over the years. Shellfish, such as mussels, scallops, and oysters, may be a major source of dietary cadmium and contain 100 to 1000 µg/kg. Shellfish accumulate cadmium from the water in the form of cadmium-binding peptides. Meat, fish, and fruit contain 1 to 50 µg/kg, grains contain 10 to 150 µg/kg, and the greatest concentrations are in the liver and kidney of animals. Total daily intake of cadmium from food, water, and air in North America and Europe varies considerably but is estimated to be about 10 to 40 µg/day.

Workplace exposure to cadmium is particularly hazardous in the presence of cadmium fumes or airborne cadmium. Airborne cadmium in the present-day workplace environment is generally 0.05 or µg/m^3 or less. Occupations at risk include electrolytic refining of lead and zinc and other industries that employ thermal processes—e.g., iron production, fossil fuel combustion, and cement manufacture—all of which release airborne cadmium, the metal being a constituent of the natural raw material. Other occupations include the manufacture of paint pigments, cadmium-nickel batteries, and electroplating (WHO, 1992). A major nonoccupational source of respirable cadmium is cigarettes.

Toxicokinetics Gastrointestinal absorption of cadmium is about 5 to 8 percent. Absorption is enhanced by dietary deficiencies of calcium and iron and by diets low in

protein. Low dietary calcium stimulates synthesis of calcium-binding protein, which enhances cadmium absorption. In general, women have higher blood cadmium concentrations than men. This is most likely due to increased gastrointestinal absorption because of low iron stores in women of childbearing age. Women with low serum ferritin levels have been shown to have twice the normal absorption of cadmium (Flanagan et al., 1978; Berglund et al., 1994). Respiratory absorption of cadmium is greater than gastrointestinal absorption and independent on solubility of cadmium compound, but it ranges from about 15 to 30 percent. As much as 50 percent of cadmium fumes, as in cigarette smoke, may be absorbed. One cigarette contains 1 to 2 µg of cadmium, and 10 percent of the cadmium in a cigarette is inhaled (0.1 to 0.2 µg). Smoking one or more packs of cigarettes a day may double the daily absorbed burden of cadmium.

Absorbed cadmium is excreted in urine. While gastrointestinal excretion is possible, particularly in bile as a glutathione complex, there are no available data to indicate net gastrointestinal excretion in humans. Cadmium excretion in urine increases proportionally with body burden (Friberg et al., 1986; ATSDR, 1998).

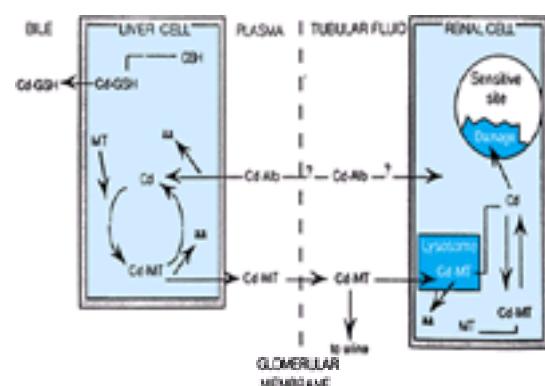
Cadmium is transported in blood by binding to red blood cells and high-molecular-weight proteins in plasma, particularly albumin; it is distributed primarily to liver and kidney (Fig. 23-3).


Figure 23-3. A schematic representation of the role of metallothionein in the disposition of cadmium in the liver and kidney. [Adapted from   Jarup et al. (1998).]

In the liver, cadmium induces the synthesis of metallothionein and is then either stored in the liver as Cd-MT complex or transported via blood to the kidney, where it may accumulate in lysosomes. cd-MT complex in lysosomes is slowly catabolized to non-metallothionein-bound cadmium but may again be complexed with metallothionein or may induce renal toxicity (see "Nephrotoxicity," below).

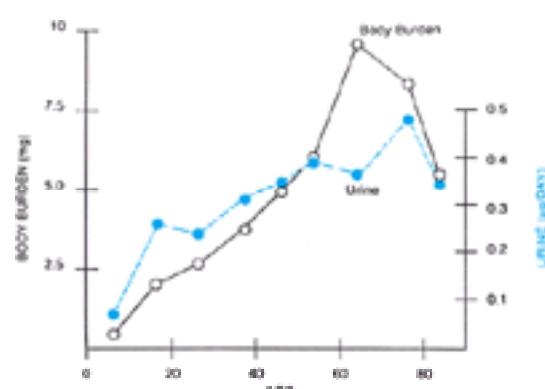
Blood cadmium levels in adults without excessive exposure is usually less than 1 µg/dL. Newborns have a low body content of cadmium, usually less than 1 mg total body burden. The placenta synthesizes metallothionein and may serve as a barrier to maternal cadmium, but the fetus may be exposed with increased maternal exposure. Human breast milk and cow's milk are low in cadmium, with less than 1 µg/kg of milk. About 50 to 75 percent of the body burden of cadmium is in the liver and kidneys; its half-life in the body is not known exactly, but it may be as long as 30 years. With continued retention, there is progressive accumulation in the soft tissues, particularly in the kidneys, through ages 50 to 60, when the cadmium burden in soft tissues begins to decline slowly (Fig. 23-4).


Figure 23-4. Illustration of the accumulation of cadmium with age.

Because of the potential for renal toxicity, there is considerable concern about the levels of dietary cadmium intake for the general population (Nordberg, 1984).

Acute Toxicity Acute toxicity may result from the ingestion of relatively high concentrations of cadmium, as may occur from contaminated beverages or food. Nordberg (1972) relates an instance in which nausea, vomiting, and abdominal pain occurred from consumption of drinks containing approximately 16 mg/L cadmium. Recovery was rapid, without apparent long-term effects. Inhalation of cadmium fumes or other heated cadmium-containing materials may produce an acute chemical pneumonitis and pulmonary edema. Inhalation of large doses of cadmium compounds may be lethal for humans and experimental animals (ATSDR, 1998). Experimental studies have shown that the chemical form of cadmium can affect its toxicity, probably related to solubility. In acute exposures, the relatively more soluble cadmium chloride, cadmium oxide fume, and cadmium carbonate are more toxic that than the relatively less soluble cadmium sulfide (Klimisch, 1993).

Chronic Toxicity The principal long-term effects of low-level exposure to cadmium are chronic obstructive pulmonary disease and emphysema and chronic renal tubular disease. There may also be effects on the cardiovascular and skeletal systems.

Chronic Pulmonary Disease Toxicity to the respiratory system is proportional to the time and level of exposure. Obstructive lung disease results from chronic bronchitis, progressive fibrosis of the lower airways, and accompanying alveolar damage leading to emphysema. The lung disease is manifest by dyspnea, reduced vital capacity, and increased residual volume. The pathogenesis of the lung lesion is the turnover and necrosis of alveolar macrophages. Released enzymes produce irreversible damage to alveolar basement membranes, including the rupture of septa and interstitial fibrosis (Davison, 1988). It has been found that cadmium reduces a_1-antitrypsin activity, perhaps enhancing pulmonary toxicity. However, no difference in plasma a_1-antitrypsin activity could be found between cadmium-exposed workers with and without emphysema (Lauwerys et al., 1979).

Nephrotoxicity Cadmium is toxic to renal tubular cells and glomeruli as reflected by impairment of renal tubular and glomerular function. Morphologic changes are nonspecific and consist of tubular cell degeneration in the initial stages, progressing to an interstitial inflammatory reaction and fibrosis. Analysis of kidney cadmium levels by in vivo neutron activation analysis and x-ray fluorescence has made it possible to study the relationship between renal cadmium levels and the occurrence of effects (Skerfving et al., 1987). The critical concentration of cadmium in the renal cortex that produces tubular dysfunction in 10 percent of the population is about 200 µg/g and about 300 µg/g in 50 percent of the population. There is a pattern in which liver and kidney cadmium levels increase simultaneously until the average cadmium concentration in the renal cortex is about 300 µg/g and the average level in the liver is about 60 µg/g. At higher cadmium liver levels, the level in the renal cortex is disproportionately low, as cadmium is lost from the kidney (Ellis et al., 1984). Daily intake in food of 140 to 260 µg of cadmium per day for more than 50 years or exposure in workroom air of 50 µg/m³ for more than 10 years has produced renal dysfunction (Thun et al., 1989; WHO, 1992). An epidemiologic study of the dose–response relationship of cadmium intake from historical data, rice consumption, and b $_2$-microglobulin as an index of renal tubular dysfunction, found that the total cadmium intake over a lifetime that produced an adverse health effect was 2000 mg for both men and women (Nogawa et al., 1989).

Renal tubular dysfunction is reflected by proteinuria. The proteinuria is principally tubular, consisting of low-molecular-weight proteins whose tubular reabsorption has been impaired by cadmium injury to proximal tubular lining cells. The predominant protein is a b $_2$-microglobulin (b$_2$-m), but a number of other low-molecular-weight proteins have been identified in the urine of workers with excessive cadmium exposure, such as retinol-binding protein (RBP), lysozyme,

N-acetyl-b-D-glucosaminidase (NAG), ribonuclease, a$_1$-microglobulin, and immunoglobulin light chains (Lauwerys et al., 1980; Buchet et al., 1990). The presence of high-molecular-weight proteins in the urine, such as albumin and transferrin, indicates that some workers may actually have a mixed proteinuria and suggests a glomerular effect as well. The pathogenesis of the glomerular lesion in cadmium nephropathy is not presently understood.

Role of Metallothionein The accumulation of cadmium in the kidneys to some extent without apparent toxic effect is possible because of the formation of cadmium-thionein or metallothionein, a metal–protein complex with a low molecular weight (see " Metal-Binding Proteins," above). Metallothionein is primarily a tissue protein and is ubiquitous in most organs, but it exists in the highest concentration in the liver, particularly following recent exposure to cadmium, and in the kidneys, where it accumulates with age in proportion to cadmium concentration. Cadmium bound to metallothionein within tissues is thought to be nontoxic. However, when the levels of cadmium exceed the critical concentration, it becomes toxic. The protective role of metallothionein is supported by an experiment showing that metallothionein-null mice are more sensitive to cadmium nephrotoxicity than control mice (Liu et al., 1998).

The factors that determine the level of cadmium or of cadmium-metallothionein complex that is toxic are not clear, but experimental studies have shown that repeated injections of low levels of cadmium-metallothionein over several weeks result in a chronic and irreversible nephrotoxicity with renal accumulations of cadmium of only 40 µg/g, less than the 200 µg/g in the renal cortex, which is suggested as the critical level in humans (Wang et al., 1993). Also, renal tubular necrosis occurs in non-cadmium-exposed rats following transplantation of livers from cadmium-toxic animals (Chan et al., 1993). These studies suggest that cadmium nephrotoxicity follows the slow release and renal excretion of cadmium-metallothionein from liver and other soft tissues. Cadmium-metallothionein is toxic when taken up by the proximal tubular cell complex, whereas cadmium chloride at even greater concentrations in proximal tubular cells is not toxic (Dorian et al., 1995).

Skeletal Effects Cadmium toxicity affects calcium metabolism, and individuals with severe cadmium nephropathy may have renal calculi and excess excretion of calcium, probably related to increased urinary loss. With chronic exposure, however, urinary calcium may be less than normal. Associated skeletal changes are probably related to calcium loss and include bone pain, osteomalacia, and/or osteoporosis. Bone changes are part of Itai-Itai disease, a syndrome recognized in postmenopausal multiparous women living in the Fuchu area of Japan prior to and during World War II. The syndrome consists of severe bone deformities and chronic renal disease. Excess cadmium exposure has been implicated in the pathogenesis of the syndrome, but vitamin D and perhaps other nutritional deficiencies are thought to be cofactors. Itai-Itai translates to "ouch-ouch," reflecting the accompanying bone pain. Also, cadmium can affect calcium, phosphorus, and bone metabolism in both industrial workers and people exposed in the general environment. These effects may be secondary to the cadmium effects on the kidneys and/or the direct toxic effect of cadmium on bone metabolism, but there has been little study of calcium metabolism in people with excess exposure to cadmium (Friberg, 1986).

Whether the skeletal effects from cadmium exposure are a product of cadmium toxicity per se or the result of cadmium toxicity plus renal disease and nutritional deficiencies, particularly calcium deficiency, has been debated (Nogawa et al., 1999). Cadmium in bone may interfere with calcification, decalcification, and bone remodeling. Anderson and Danylchuk (1979) found that exposure of beagle dogs for 6 months to cadmium (25 mg/wL) reduced bone turnover rate, consistent with calcium deficiency or osteomalacia. Wang and Battachharyya (1993) showed that cadmium increased release of ^{45}Ca from skeletons of mice and dogs as early as 72 h after the start of dietary cadmium.

A proposed mechanism for the decreased calcium absorption and negative calcium balance in cadmium-exposed rats is that cadmium inhibits activation of vitamin D in the renal cortex (Feldman and Cousins, 1974). Nogawa and colleagues (1987) reported that serum 1,25(OH)$_2$ vitamin D levels were lower in Itai-Itai disease patients and in cadmium-exposed subjects with renal damage than in nonexposed subjects. A decrease in serum 1,25(OH)$_2$ vitamin D levels was closely related to serum concentrations of parathyroid hormone, b$_2$-microglobulin, and the percentage of tubular reabsorption, suggesting that cadmium-induced bone effects were mainly due to a disturbance in vitamin D and parathyroid hormone metabolism. Friberg et al. (1986) suggest that cadmium in the proximal tubular cells depresses cellular functions, which may be followed by the depressed conversion of 25(OH) vitamin D to 1,25(OH)$_2$ vitamin D. This is likely to lead to decreased calcium absorption and mineralization of bone, which in turn may lead to osteomalacia. Bhattacharyya and coworkers (1988) found, in studies of mice, that multiparity enhanced cadmium's toxicity to bone. Hypercalciuria is a sensitive indicator for cadmium exposure (Buchet, 1990).

Hypertension and Cardiovascular Effects Epidemiologic studies suggest that cadmium is an etiologic agent for essential hypertension. A study of blood pressures in cadmium workers found an increase in systolic but not diastolic blood pressure (Thun et al., 1989). Studies from Japan have found that the rate of cerebrovascular disease mortality among people who had cadmium-induced renal tubular proteinuria was twice as high as among people in cadmium-polluted areas without proteinuria (Nogawa et al., 1979). Although the population-based U.S. NHANES II study and studies in Belgium (Staessen et al., 1995) have not supported a role for cadmium in the etiology of hypertension and cardiovascular disease in humans, animal studies indicate that cadmium may be toxic to myocardial function. Rats exposed to cadmium in drinking water (Kopp et al., 1983) developed electrocardiographic and biochemical changes in the myocardium and impairment of the functional status of the myocardium. These effects may be related to (1) decreased high-energy phosphate stored in the myocardium, (2) reduced myocardial contractility, and (3) diminished excitability of the cardiac conduction system. Jamall and Sprowls (1987) found that rats whose diets were supplemented with copper, selenium, and cadmium had a marked reduction in heart cytosolic glutathione peroxidase, superoxide dismutase, and catalase. They suggest that heart mitochondria may be the site of the cadmium-induced biochemical lesion in the myocardium.

Neurologic Disorders Epidemiologic studies in humans have suggested a relationship between abnormal behavior and/or decreased intelligence in children and adults exposed to cadmium. However such studies are typically complicated by exposure to other toxic metals. Furthermore, the blood-brain barrier and circumventricular epithelial cells with tight junctions limit the pathways of entrance for cadmium into the central nervous system. In addition, the choroid plexus epithelium accumulates high levels of toxic metals from the blood or cerebrospinal fluid (Murphy, 1997). Metallothionein in glial cells and ependymal cells near circumventricular organs also serves to minimize cadmium diffusion into other parts of the brain.

Carcinogenicity Epidemiologic studies have shown a relationship between occupational (respiratory) exposure to cadmium and lung cancer and possibly prostate cancer. An increase in respiratory cancers was also found in a restudy of a cohort in a U.S. cadmium recovery plant (Thun et al., 1985). Concern has been expressed regarding the influence of confounding factors in the work environment, particularly coexposure to arsenic (Sorahan and Lancashire, 1997). Cadmium has recently been accepted by the International Agency for Research on Cancer as a category 1 (human) carcinogen, based primarily on its relationship to pulmonary tumors (IARC, 1994). There are few studies that examine a relationship between oral intake of cadmium and cancer in humans. A study of cancer incidence among inhabitants with renal tubular dysfunction in a cadmium-polluted area of Japan was negative. The potential relationship between cadmium exposure and prostate cancer in humans remains controversial (Waalkes, 1995).

Cadmium chloride exposure by inhalation produced a dose-dependent increase in the incidence of lung carcinomas in rats (Takenaka et al., 1983; Oldiges, 1989). In rats, cadmium will produce a variety of tumors, including malignant tumors at the site of injection and in the lungs after inhalation. Cadmium chloride, oxide, sulfate, and sulfide produced local sarcomas in rats after their subcutaneous injection, and cadmium powder and cadmium sulfide produced local sarcomas in rats following their intramuscular administration. Other studies have found that oral cadmium exposure was associated with tumor of the prostate, testes, and hematopoietic system in rats. The incidence of lesions was less in zinc-deficient rats, but there was no dose–response relationship (Waalkes, 1995). Other studies have produced cancer in the ventral lobe of the rat prostate by oral or parenteral exposures as well as by direct injection. The lobular structure of the prostate is absent in humans; it is thought that the ventral prostate in rats has no human analog and that tumors of the dorsolateral lobe are more comparable to the human disease (Waalkes and Rehm, 1994). However, subcutaneous injection of cadmium in a particularly cancer-sensitive strain of rat (Noble/Cr) did produce proliferative lesions of the dorsolateral prostate as well as tumors of the testes, pituitary adenomas, and injection-site sarcomas (Waalkes et al., 1999).

Biomarkers of Cadmium Effects Urinary Beta$_2$-microglobulin (b$_2$m), retinal-binding protein (RBP), *N*-acetyl-b-glucosaminidase (NAG), and metallothionein have been used in conjunction with urinary cadmium levels as a measure of cadmium exposure to cadmium renal tubular dysfunction. Other sensitive indicators include a$_1$-m, trehalase, and calcium (ATSDR, 1998). The relationship of these indicators to urine cadmium levels were determined in a large population study in Belgium (Buchet, 1990). It was estimated that more than 10 percent of values would be abnormal when urine cadmium excretion rate exceeded 2.87 µg/24 h for RBP, 3.05 µg/24 h for b$_2$-m, 4.29 µg/24 h for amino acids, and 1.92 µg/24 h for calcium.

Increased excretion of b$_2$-m is an early indicator of tubular proteinuria, but samples must be controlled for pH. RBP measurements may be a more practical and reliable test of proximal tubular function than b$_2$-m because sensitive immunologic analytic methods are now available, and b$_2$-m is less stable in urine (Lauwerys et al., 1984). Activity of the enzyme NAG in urine may be a sensitive indicator of cadmium-induced renal tubular dysfunction, but a dose–response relationship has not been established (Kawada et al., 1998). None of the biomarkers of tubular dysfunction are specific indicators of cadmium effects and their levels must be interpreted in association with a corresponding increase in urinary cadmium. Minor increases in excretion of biomarkers of renal tubular dysfunction may not in themselves

indicate an adverse health effect but are indicators of likely possible progression of renal disease if cadmium exposure is continued.

Increase in urinary calcium excretion is a sensitive effect of cadmium-induced renal tubular dysfunction and may contribute to the age-related decline in bone mass (Aoshima et al., 1997). Roels et al. (1993) identified three main groups of thresholds for increased excretion of biomarkers of cadmium effect on the kidney. When calcium levels are at around 2 µg/g creatinine, there was increased excretion 6-keto prostaglandin and sialic acid; at around 4 µg/g creatinine, there were increases in NAG, albumin, and transferrin; and at around 10 µg/g creatinine, there were increases in excretion of b_2-m, RBP, and antiglomerular basement membrane antibodies.

Biomarkers of Cadmium Exposure The most important measure of excessive cadmium exposure is increased cadmium excretion in urine. In persons in the general population without excessive cadmium exposure, urinary cadmium excretion is both small and constant. Ninety-five percent of U.S. residents excrete less than 2 µg/L in urine and less than 1 percent excrete 4 µg/L (Gunter, 1997). With excessive exposure to cadmium, as might occur in workers, an increase in urinary cadmium may not occur until all of the available cadmium binding sites are saturated. However, when the available binding sites (e.g., metallothionein) are saturated, increased urinary cadmium reflects recent exposure, body burden, and renal cadmium concentration, so that urinary cadmium measurement does provide a good index of excessive cadmium exposure. Most of the cadmium in urine is bound to metallo-thionein, and there is good correlation between metallothionein and cadmium in urine in cadmium workers with normal or abnormal renal function (Shaikh et al., 1989). Therefore, the measurement of metallothionein in urine provides the same toxicologic information as the measurement of cadmium, and it does not have the problem of external contamination. Radioimmunoassay techniques for measurement of metallothionein are available (Chang et al., 1980) but are not as practical as other biomarkers of cadmium effect.

There is debate as to whether the threshold for preventing cadmium nephropathy is 5 µg/g or 10 µg/g creatinine. Changes in urinary excretion of low-molecular-weight proteins were consistently observed in workers excreting more than 10 µg cadmium per gram of creatinine (Buchet et al., 1980). The American Conference of Governmental Industrial Hygienists biological exposure indexes for cadmium are 5 µg/g creatinine in the urine and 5 µg/L cadmium in the blood (ACGIH, 1996). Roels et al. (1999), recommends that, on the basis of increased excretion of a number of biomarkers (cited above) at urinary cadmium levels ranging from 2.4 to 11.5 µg/g creatinine, occupational exposure to cadmium should not exceed 5 µg of cadmium per gram of creatinine.

Blood cadmium levels generally reflect recent exposure rather than accumulated body burden and are usually in the range of 0.4 to 1.0 µg/L for nonsmokers and somewhat higher for smokers (Lauwerys et al., 1994). Workers with cumulative cadmium exposure equivalent to a blood cadmium concentration of 10 µg/L for 20 years have been shown to have a 14 percent incidence of renal dysfunction (Jarup et al., 1988).

Reversibility of Renal Effects Follow-up studies of persons with renal tubular dysfunction (b_2-microglobulinuria) from occupational exposure to cadmium have shown that the proteinuria is irreversible and that there is a significant increase of creatinine in serum with time, suggesting a progressive glomerulopathy (Roels et al., 1989). Also, persons with renal tubular dysfunction from excess dietary ingestion of cadmium (cadmium-polluted rice) do not have a reversal of the defect as long as 10 years after reduced exposure in cases when the b_2-m exceeds 1000 µg/g of creatinine (Kido et al., 1988). Ellis (1985) has shown, however, that liver cadmium in workers no longer exposed to cadmium gradually declines. Persistence of renal tubular dysfunction after cessation of exposure may reflect the level of body burden and the shifting of cadmium from liver to kidney.

Treatment At the present time, there is no chelation therapy for cadmium toxicity approved for clinical use in humans. Experimentally, DMSA and CaEDTA best reduce acute mortality from cadmium exposure in combination with glutathione. Some DMSA analogs acutely increase biliary excretion of cadmium. However, each of these therapies may result in significant adverse effects (Angle, 1995).

Chromium (Cr)

Chromium[1] is a generally abundant element in the earth's crust and occurs in oxidation states ranging from Cr^{2+} to Cr^{6+}, but only trivalent and hexavalent forms are of biological significance. The trivalent is the more common form. However, hexavalent forms such as chromate compounds are of greater industrial importance. Sodium chromate and dichromate are the principal substances for the production of all chromium chemicals. The major source of chromium is from chromite ore. Metallurgic-grade chromite is usually converted into one of several types of ferrochromium or other chromium alloys containing cobalt or nickel. Ferrochrome is used for the production of stainless steel. Chromates are produced by a smelting, roasting, and extraction process. The major uses of sodium dichromate are for the production of chrome pigments; for the production of chrome salts used for tanning leather, mordant dying, wood preservatives; and as an anticorrosive in cooking systems, boilers, and oil-drilling muds. Overviews of chromium exposures and health effect have been reviewed (Fishbein, 1981; WHO, 1988; O'Flaherty, 1995).

Chromium in ambient air originates from industrial sources, particularly ferrochrome production, ore refining, chemical and refractory processing, the manufacture of cement, and combustion of fossil fuels. Chromium precipitates and fallout are deposited on land and water; land fallout is eventually carried to water by runoff, where it is deposited in sediments. A controllable source of chromium is wastewater from chrome-plating and metal-finishing industries, textile plants, and tanneries. Cobalt-chromium alloy hip replacements lead to elevated blood levels of chromium (Habbab et al., 2000). The daily intake by humans is under 100 µg, mostly from food, with trivial quantities from most water supplies and ambient air.

Human Body Burden Tissue concentrations of chromium in the general population have considerable geographic variation; concentrations as high as 7µg/kg occur in the lungs of persons in New York or Chicago, with lower concentrations in liver and kidney. In persons without excess exposure, blood chromium concentration is between 20 and 30 µg/L and is evenly distributed between erythrocytes and plasma. With occupational exposure, an increase in blood chromium is related to increased chromium in red blood cells. Chromates readily cross cell membranes on anion carriers as they are isostructural with sulfate and phosphate anions. Urinary excretion is independent of the oxidation state of chromium administered to animals and is less than 10 µg/day for humans in the absence of excess exposure.

Essentiality See the discussion of trivalent chromium—Cr(III)—under "Essential Metals with Potential for Toxicity," below.

Toxicity Systemic toxicity to chromium compounds occurs largely from accidental exposures, occasional attempts to use chromium as a suicidal agent, and from previous therapeutic uses. The major effect from ingestion of high levels of Cr(VI) is acute tubular and glomerular damage. Evidence of kidney damage from lower-level chronic exposure is equivocal (Wadeen 1991). Animal studies of chronic exposure to Cr(VI) have not shown evidence of toxicity (O'Flaherty, 1995). Cr(VI) is corrosive and causes chronic ulceration and perforation of the nasal septum. It also causes chronic ulceration of other skin surfaces, which is independent of hypersensitivity reactions on skin. Allergic chromium skin reactions readily occur with exposure and are independent of dose (Proctor et al., 1998). Occupational exposure to chromium may be a cause of asthma (Bright et al., 1997). The known harmful effects of chromium in humans have been attributed to the hexavalent form, and it has been speculated that the biological effects of Cr(VI) may be related to the reduction to Cr(III) and the formation of complexes with intracellular macromolecules. Cr(III) compounds are considerably less toxic than the hexavalent compounds and are neither irritating nor corrosive. Nevertheless, nearly all industrial workers are exposed to both forms of chromium compounds, and at present there is no information as to whether there is a gradient of risk from predominant exposure to hexavalent or insoluble forms of chromium to exposure to soluble trivalent forms.

Carcinogenicity Exposure to chromium, particularly in the chrome production and chrome pigment industries, is associated with cancer of the respiratory tract (Langard and Norseth, 1986). The mechanism of Cr(VI) carcinogenicity in the lung is believed to be its reduction to Cr(III) and its generation of reactive intermediates.

Animal studies support the notion that the most potent carcinogenic chromium compounds are the slightly soluble hexavalent compounds. Studies on in vitro bacterial systems, however, show no difference between soluble and slightly soluble compounds. Trivalent chromium salts have little or no mutagenic activity in bacterial systems. Because there is preferred uptake of the hexavalent form by cells and it is the trivalent form that is metabolically active and binds with nucleic acids within the cell, it has been suggested that the causative agent in chromium mutagenesis is trivalent chromium bound to genetic material after reduction of the hexavalent form. The intracellular reduction of Cr(VI) involves the oxidation of both small (acorbate and glutathione) and large (macromolecules—DNA and protein) forms and probably plays a role in the carcinogenic process. In fact chromium elicits a variety of effects: (1) at the biochemical level, the formation of coordination covalent interaction of Cr(V) and Cr(III) with DNA and of DNA-DNA and DNA-protein complexes; (2) at the genomic level, the induction of gene expression (oxidant stress and metallothionein and tumor supressor genes), gene mutations, DNA lesions, and inhibition of protein synthesis and arrest of DNA replication; (3) at the cellular level, cell cycle arrest, apoptosis, and neoplastic transformation (Bridgewater et al., 1998; Singh et al., 1998; Klatreider et al., 1999; Dubrovskaya and Wetterhahn, 1998; Solis-Heredia et al., 2000).

Costa and coworkers (1993) have shown that detection of DNA-protein complexes may serve as a biomarker of exposure and of carcinogenic potential from occupational exposure to chromium. There is suggestive evidence that chromium compounds cause cancer at sites other than the respiratory tract (Costa 1997).

Lead (Pb)

If we were to judge of the interest excited by any medical subject by the number of writings to which it has given birth, we could not but regard the poisoning by lead as the most important to be known of all those that have been treated of, up to the present time (Orfila, 1817).

Lead[1] is a ubiquitous toxic metal and is detectable in practically all phases of the inert environment and in all biological systems. Because it is toxic to most living things at high exposures and there is no demonstrated biological need for it, the major issue regarding lead is determining the dose at which it becomes toxic. Specific concerns vary with the age and circumstances of the host, and the major risk is toxicity to the nervous system. The most susceptible populations are children, particularly toddlers, infants in the neonatal period, and the fetus. Several reviews and multiauthored books on the toxicology of lead are available (Goyer and Rhyne, 1973; EPA, 1986; Goyer, 1993; NRC, 1993; ATSDR, 1999).

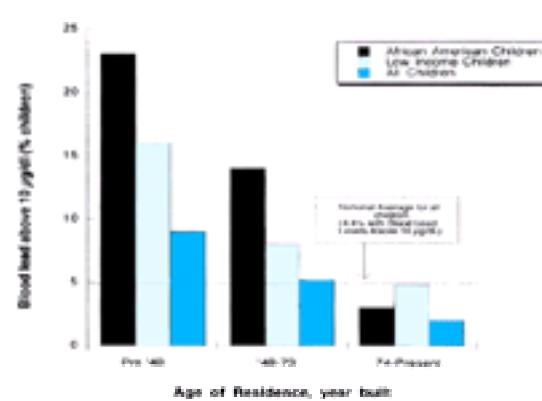
Exposure The principal route of exposure for people in the general population is food, and sources that produce excess exposure and toxic effects are usually environmental and presumably controllable. These sources include lead-based indoor paint in old dwellings, lead in dust from environmental sources, lead in contaminated drinking water, lead in air from combustion of lead-containing industrial emissions, hand-to-mouth activities of young children living in polluted environments, lead-glazed pottery, and—less commonly—lead dust brought home by industrial workers on their shoes and clothes. Dietary intake of lead has decreased since the 1940s, when estimates of intake were 400 to 500 µg/day for U.S. populations to present levels of under 20 µg/day. One factor reducing the lead content of food has been a reduction in the use of lead-soldered cans for food and beverages. Most municipal water supplies measured at the tap contain less than 0.05 µg/mL, so that daily intake from water is usually about 10 µg; it is unlikely to be more than 20 µg. Corrosive water (pH 6.4) will leach lead from soldered joints and lead-containing brass fittings (NRC, 1993). The introduction of lead-free gasoline and awareness of the hazards of indoor leaded paint has been credited with a decline in blood lead levels for persons ages 1 to 74 from 12.8 to 2.8 µg/day for 1988 to 1991 (Pirkle et al., 1994). Blood lead levels among people in the general population have continued to decline in the United States to <5 µg/dL (Pirkle, 1998). Nevertheless, the most current national survey (N-HANES IV) shows that nearly a million U.S. children are at risk from lead poisoning (blood lead levels >10 µg/dL) and that specific groups of children are at greatest risk (Fig. 23-5).


Figure 23-5. National blood lead levels. National Health and Nutrition Examination Survey. Phase 2, 1991–1994. [Adapted from   CDC (2000).]

The geometric mean blood lead level of African-American children living in central portions of cities with more than 1 million people is 13.9 µg/dL, and about 35 percent of these children have blood lead levels greater than 10 µg/dL—that is, above the guideline recommended by the U.S. Centers for Disease Control (CDC, 1991). Major risk factors for these children are housing containing lead-based paint and exposure to urban dust (CDC, 1997). Utilizing radioisotope techniques, Manton et al. (2000) determined that major environmental sources of lead for infants and toddlers up to 4 years of age were hand-to-mouth transfer from floors, the lead being derived from dust sills and exterior surfaces. Seasonal influences, or increases in childhood lead exposure during the hot summer months, were previously thought to be due to effect of sunlight and mobilization of lead from bone. It has now been shown that seasonal variation in blood lead levels in children is related to dust lead levels in the home (Yin et al., 2000).

Other potential sources of exposure to lead are recreational shooting on indoor ranges, hand-loading of ammunition, soldering, jewelry making, pottery making, gunsmithing, glass polishing, painting, and stained glass crafting, all of which involve some exposure to lead. Workplace exposure is gradually being reduced. Overt or clinical lead poisoning among workers in lead industries was common in the 1930s, 1940s, and even in the early 1950s, but it is far less frequently observed today (Wegman and Fine, 1990). Nevertheless, lead continues to be one of the metals presenting a hazardous occupational exposure. Children of workers with occupational exposure to lead may have higher blood lead levels than children in the general population (Whelan et al., 1997). In addition, there are several nutritional and dietary factors that influence lead toxicity (Mahaffey, 1985). In a study of effects of lifestyle factors on blood lead levels, alcohol consumption has been shown to account for the large proportion of variability in blood lead levels, followed by age and smoking (Weyermann and Brenner, 1997). Wine had a greater effect on blood lead levels than beer. Other significant contributing factors were gender, hematocrit, calcium intake, and consumption of milk products.

Toxicokinetics Toxicokinetics of lead are reviewed in reports by the NRC (1993), and ATSDR (1999). Adults absorb 5 to 15 percent of ingested lead and usually retain less than 5 percent of what is absorbed. Children are known to have a greater absorption of lead than adults; one study found an average net absorption of 41.5 percent and 31.8 percent net retention in infants on regular diets. Lead absorption in children is related to age and development of the gastrointestinal tract (Ziegler et al., 1978). Nutritional problems—such as low dietary iron and calcium—enhance lead absorption (Wassermann et al., 1994; Bruening et al., 1999). Lead in water and other beverages is absorbed to a greater degree than lead in food. Lead ingested between meals is absorbed more than lead with meals, and increasing frequency of food intake minimizes lead absorption.

Concentrations of lead in air vary due to point-source emissions but are now usually less than 1.0 µg/m^3. Since the introduction of lead-free gasoline in the United States, airborne lead is only a minor component of total daily lead exposure. Lead in the atmosphere exists either in solid forms, dust or particulates of lead dioxide, or in the form of vapors. Lead absorption by the lungs also depends on a number of factors in addition to concentration. These include volume of air respired per day, whether the lead is in particle or vapor form, and size distribution of lead-containing particles. Only a very minor fraction of particles over 0.5 µm in mean maximal external diameter are retained in the lung, but they are then cleared from the respiratory track and swallowed. However, the percentage of particles less than 0.5 µm retained in the lung increases with reduction in particle size. About 90 percent of lead particles in ambient air that are deposited in the lungs are small enough to be retained. Absorption of retained lead through alveoli is relatively efficient and complete.

More than 90 percent of the lead in blood is in red blood cells. There seem to be at least two major compartments for lead in the red blood cell, one associated with the membrane and the other with hemoglobin and other blood cell components. Blood lead is in equilibrium between plasma and erythrocytes with 1 percent or less in the plasma, for blood lead levels up to 100 µg/dL. The relationship between blood and plasma lead is stable and nearly linear for blood lead levels up to 50 µg/dL. Above this level the relationship becomes curvilinear, with rapid increase in plasma levels (Manton et al., 1984). Because of analytic difficulties in the accurate measurement of the low levels of lead in plasma and the complicating potential of lead from hemolysis, measurement of plasma lead seems to be of limited usefulness for monitoring persons with occupational exposure.

The total body burden of lead may be divided into at least two kinetic pools, which have different rates of turnover (O'Flaherty, 1998). The largest and kinetically slowest pool is the skeleton, with a half-life of more than 20 years; the soft tissue pool is much more labile. Lead in trabecular bone is more labile than that in cortical bone, and trabecular bone has a shorter turnover time. Lead in bone may contribute as much as 50 percent of blood lead, so that it may be a significant source of internal exposure to lead. Lead in maternal bone is of particular concern during pregnancy and lactation, and it may be mobilized in later years in persons with osteoporosis (Silbergeld et al., 1988). The fraction of lead in bone increases with age from about 70 percent of body lead in childhood to as much as 95 percent of the body burden with advancing years. The total lifetime accumulation of lead may be as much as 200 mg to over 500 mg for a worker with heavy occupational exposure. The largest soft tissue accumulations of lead are in liver and kidney, but lead is present in most tissues of the body. Animal studies have shown that lead in the central nervous system tends to concentrate in gray matter and certain nuclei.

The major route of excretion of absorbed lead is the kidney. Renal excretion of lead is usually with glomerular filtrate with some renal tubular absorption. With elevated blood lead levels, excretion may be augmented by transtubular transport. Lead is also excreted to a lesser degree with other body fluids, including milk

during lactation (Gulson et al., 1998). Lead crosses the placenta, so that cord blood lead levels generally correlate with maternal blood lead levels but are slightly lower. Maternal blood lead decreases slightly during pregnancy, probably due to hemodilution. Lead accumulation in fetal tissues, including brain, is proportional to maternal blood lead levels (Goyer, 1996).

Toxicity The toxic effects from exposures to inorganic lead form a continuum from subtle or biochemical effects to clinical or overt effects (Goyer, 1990). These effects involve several organ systems and biochemical activities. The critical effects or most sensitive effects in infants and children involve the nervous system (NRC, 1993; ATSDR, 1999). For adults with excess occupational exposure or even accidental exposure, the concerns are peripheral neuropathy and/or chronic nephropathy. However, the critical effect or most sensitive effect for adults in the general population may be hypertension. Effects on the heme system provide biochemical indicators of lead exposure in the absence of chemically detectable effects, but anemia due to lead exposure is uncommon without other detectable effects or other synergistic factors. Other target organs are the gastrointestinal, reproductive, and skeletal systems.

Neurologic, Neurobehavioral, and Developmental Effects in Children Clinically overt lead encephalopathy may occur in children with high exposure to lead, probably at blood lead levels of 80 µg/dL or higher. Symptoms of lead encephalopathy begin with lethargy, vomiting, irritability, loss of appetite, and dizziness progressing to obvious ataxia and a reduced level of consciousness, which may progress to coma and death. The pathologic findings at autopsy are severe edema of the brain due to extravasation of fluid from capillaries in the brain. This is accompanied by the loss of neuronal cells and an increase in glial cells. Recovery is often accompanied by sequelae including epilepsy, mental retardation, and, in some cases, optic neuropathy and blindness (Perlstein and Attala, 1966).

Over the past 20 or more years there have been a number of cross-sectional and prospective epidemiologic studies relating blood lead levels at the time of birth, during infancy, and through early childhood with measures of psychomoter, cognitive, and behavioral outcomes. These studies have been summarized by NRC (1993) and ATSDR (1999). Despite differences in the ranges of blood lead represented in a cohort, most studies report a 2- to 4-point IQ deficit for each 10 microgram-per-deciliter increase in blood lead within the range of 5 to 35 µg/dL. A threshold is not evident from these studies.

It has been difficult to discern whether there are specific neuropsychological deficits associated with increased lead exposures. To date there are no specific indicators of the neurologic effects of lead. The most sensitive indicators of adverse neurologic outcomes are psychomotor tests or mental development indices, such as the Bayley Scales for infants, and broad measures of IQ, such as full-scale WISC-R IQ scores for older children. Blood lead levels at 2 years of age are more predictive of a longer-term adverse neurologic outcome than umbilical cord blood lead concentration. Children in the lower socioeconomic strata may begin to manifest language deficits by the second year of life, which may be prevented in children with greater academic advantages. Increased blood lead levels in infancy and early childhood may be manifest in older children and adolescents as decreased attention span, reading disabilities, and failure to graduate from high school (Needleman et al., 1990).

The public health significance of small deficits in IQ may be considerable. When the actual cumulative frequency distribution of IQ between high- and low-lead subjects are plotted and compared, there is an increase in the number of children with a severe deficit, that is, IQ scores below 80. Also, the same shift truncates the upper end of the curve, where there is a 5 percent reduction in children with superior function (IQ 125 or greater). There is presently no estimate of the cost of this effect at the high end of the curve, but it may be of considerable importance to both society and to the individual. Small changes in IQ have been associated with differences in measures of socioeconomic status, such as income and educational achievement (Needleman, 1989).

An association between hearing thresholds and blood lead greater than 20 µg/dL has been found in teenagers (Schwartz et al., 1991).

Adults with occupational exposure may demonstrate abnormalities in a number of measures in neurobehavior, with cumulative exposures resulting from blood lead levels <40 µg/dL (Lindgren et al. 1996). Payton et al. (1998) performed a number of cognitive tests and measured tibial lead concentration on a cohort of men with mean age of 66.8 years and mean blood lead level of 55 µg/dL. They found those men with higher blood lead levels performed less well than men with lower blood lead levels. They also found that men with higher blood lead and tibeal lead showed a slower response for pattern memory.

Mechanisms of Effects on the Developing Nervous System Studies to date suggest that the primary anatomic site for lead effect on the brain is the endothelial cell of the blood-brain barrier leading to entry of lead into the brain, followed by morphologic and pharmacologic effects (summarized by Goyer, 1996). Possible mechanisms for lead effects on the nervous system are summarized in Table 23-3.

Morphologic effects (neurodevelopmental)
  Impairment of timed programming of cell–cell
    connections
  Interference with neural cell adhesion molecules
  Altered migration of neurons during development
Pharmacologic effects (functional)
  Interferes with neurotransmitter function
Disrupts calcium metabolism
  Blocks voltage-dependent calcium membrane
    channels
  Substitutes for calcium in calcium-sodium ATP pump
  Competes for uptake by mitochondria
  Binds to second messenger calcium receptors (e.g.,
    calmodulin, protein kinase C)

SOURCE: Modified from Goyer (1996).

Table 23-3 Mechanisms for Lead Effects on the Nervous System

A highly significant morphologic effect during development is the result of lead impairment of timed programming of cell:cell connections, resulting in modification of neuronal circuitry. Lead also induces precocious differentiation of the glia, whereby cells migrate to their eventual positions during structuring of the central nervous system. Within the catecholaminergic nervous system, lead exposure causes alterations in the concentrations of the transmitters noradrenaline and dopamine in addition to changes in the activities of the enzymes tyrosine hydroxylase and phenyl-ethanolamine- *N*-methyl transferase. The activity of the cholinergic biosynthetic enzyme choline acetyltransferase is also affected (McIntosh et al., 1987).

Calcium is a critical component of numerous biochemical and metabolic functions in the brain, and lead may act as a surrogate for calcium, resulting in subtle disruptions of essential functions. Lead impairs normal calcium homeostasis and uptake by calcium membrane channels and substitutes for calcium in calcium-sodium ATP pumps. Lead also blocks entry of calcium into nerve terminals; it inhibits calcium uptake in brain mitochondria, with a decrease in energy production to perform brain functions. Probably the most critical interaction between lead and calcium is in cells where lead interferes with calcium receptors that are coupled with second-messenger functions. Intracellular calcium signals are received by a variety of calcium receptor proteins. The two that have received the most attention are calmodulin and protein kinase C. Calmodulin serves as a sensor for the concentration of calcium within cells. Lead acts by displacing calcium ions bound to calmodulin. Protein kinase C–mediated responses include cell division and proliferation, cell-cell communications, and organization of the cytoskeleton. Markovac and Goldstein (1988) found that lead activates protein kinase C in microvessels which may be a factor in altering the normally tight blood-brain barrier.

Peripheral Neuropathy Peripheral neuropathy is a classic manifestation of lead toxicity, particularly the footdrop and wristdrop that characterized the house painter and other workers with excessive occupational exposure to lead more than a half-century ago. Segmental demyelination and possibly axonal degeneration follow lead-induced Schwann cell degeneration. Wallerian degeneration of the posterior roots of sciatic and tibial nerves is possible, but sensory nerves are less sensitive to lead than motor nerve structure and function. Motor nerve dysfunction, assessed clinically by electrophysiologic measurement of nerve conduction velocities, has been shown to occur with blood lead levels as low as 40 µg/dL (ATSDR, 1999).

Hematologic Effects Lead has multiple hematologic effects. In lead-induced anemia, the red blood cells are microcytic and hypochromic, as in iron deficiency, and there are usually increased numbers of reticulocytes with basophilic stippling. The anemia results from two basic defects: shortened erythrocyte life span and impairment of heme synthesis. Shortened life span of the red blood cell is thought to be due to increased mechanical fragility of the cell membrane. The biochemical basis for this effect is not known, but the effect is accompanied by inhibition of sodium- and potassium-dependent ATPases.

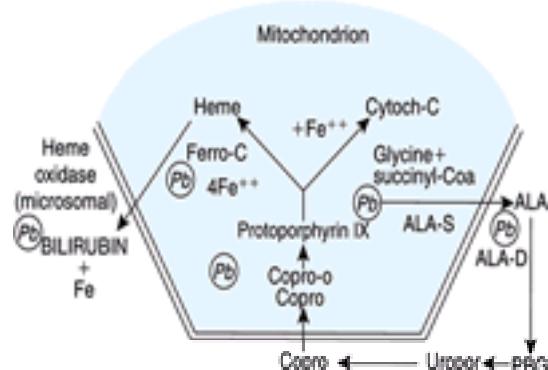
A schematic presentation of the effects of lead on heme synthesis is shown in Fig. 23-6.


Figure 23-6. Scheme of heme synthesis showing sites where lead has an effect.

Probably the most sensitive effect is inhibition of d-aminolevulinic acid dehydratase (ALA-D), resulting in a negative exponential relationship between ALA-D and blood lead. There is also depression of coproporphyrinogen oxidase, resulting in increased coproporphyrin activity. Lead also decreases ferrochelatase activity. This enzyme catalyzes the incorporation of the ferrous ion into the porphyrin ring structure. Failure to insert iron into protoporphyrin results in depressed heme formation. The excess protoporphyrin takes the place of heme in the hemoglobin molecule and, as the red blood cells containing protoporphyrin circulate, zinc is chelated at the center of the molecule at the site usually occupied by iron. Red blood cells containing zinc-protoporphyrin are intensely fluorescent and may be used to diagnose lead toxicity. Depressed heme synthesis is thought to be the stimulus for increasing the rate of activity of the first step in the heme synthetic pathway. Delta-aminolevulinic acid synthetase is subject to negative feedback control. As a consequence, the increased production of d-aminolevulinic acid (ALA) and decreased activity of ALA-D result in a marked increase in circulating blood levels and urinary excretion of ALA. Prefeeding of lead to experimental animals also raises heme oxygenase activity, resulting in some increase in bilirubin formation. The change in rates of activity of these enzymes by lead produces a dose-related alteration in the activity of the affected enzymes, but anemia only occurs in very marked lead toxicity. The changes in enzyme activities, particularly ALA-D in peripheral blood and excretion of ALA in urine, correlate very closely with actual blood lead levels and serve as early biochemical indices of lead exposure (ATSDR, 1999).

A genetic polymorphism for the heme pathway enzyme was identified by Granick et al. in 1973, but the molecular characteristics and potential clinical implications have received attention only recently. Battistuzzi et al. (1981) identified two common alleles, ALAD-1 and ALAD-2, with frequencies of 0.9 and 0.1 in European-based populations, giving rise to three phenotypes, 1-1, 1-2, and 2-2. Heterozygotes have ALAD-2 activity that is 50 percent normal, whereas severely deficient homozygous (2-2) people have ALA-D activity that is approximately 2 percent of homozygous normal. Doss et al. (1982) reported that those workers with moderate workplace exposure to lead and high free erythrocyte protoporphyrin (FEP) concentrations were heterozygous for ALAD deficiency. Fleming and coworkers (1998) found that lead workers with the ALAD-2 allele had higher blood serum levels than ALAD-1 homozygotes and that the cumulative blood lead index based on blood lead histories and in vivo x-ray fluorescent (XRF) measurements of bone lead was greater in workers homozygous for ALAD-1. This finding suggested a greater transfer of blood lead to bone in this group than in workers with the ALAD-1/2 genotype. It is suggested, therefore, that the ALAD-2 allele affects the metabolism of lead, possibly leaving workers with this genotype more susceptible to soft tissue accumulation of lead. Smith et al. (1998) suggests a potential link between the ALAD variant and the subclinical indices of renal function (elevated BUN, uric acid, and creatinine).

Renal Toxicity Lead nephropathy is one of the oldest recognized health effects of lead (Oliver, 1902). It has been a major hazard from industrial exposure. However, with progressive reduction of exposure in the workplace and more sensitive biological indicators of renal toxicity, lead nephropathy should be a vanishing disease. The pathogenesis of lead nephropathy is described in stages, or as acute (reversible) or chronic (irreversible). Lead is a renal carcinogen in rodents, but whether it is carcinogenic to people is unclear. Acute lead nephrotoxicity is limited to functional and morphologic changes in proximal tubular cells (Goyer and Rhyne, 1973). It is manifest clinically by decrease in energy-dependent transport functions, including aminoaciduria, glycosuria, and ion transport. The functional changes are thought to be related to a lead effect on mitochondrial respiration and phosphorylation. In experimental models and biopsies from children with lead toxicity, there are ultrastructural changes in mitochondria consisting of swelling with distorted cristae. Mitochondria isolated from lead-poisoned rats show decreased state III respiration. These changes are reversible by treatment with a chelating agent.

A characteristic microscopic change is the formation of a lead–protein complex which appears in renal tubular cells as inclusion bodies. By light microscopy the inclusions are dense, homogeneous eosinophilic bodies. The bodies are composed of a lead–protein complex. The protein is acidic and contains large amounts of aspartic and glutamic acids and little cystine. It is suggested that lead binds loosely to the carboxyl groups of the acidic amino acids (Moore et al., 1973). Lead will form inclusion bodies in the cytoplasm of kidney cells grown in culture and tends to migrate into nuclei secondarily (McLaughlin et al., 1980). Renal biopsies from a group of shipwreckers with heavy exposure to lead have shown that the histologic features of early and chronic exposure to lead are similar in experimental animals and humans, suggesting similar pathogenetic mechanisms. Nuclear inclusion bodies become less common as renal tubules atrophy and as interstitial fibrosis increases in severity.

Proximal tubular dysfunction is usually not demonstrable in the chronic phase of lead nephropathy, but interstitial fibrosis is usually associated with asymptomatic renal azotemia and reduced glomerular filtration rate. In workers without azotemia but with decreased inulin clearance, there is decreased maximum reabsorption of glucose. Although progression from acute reversible to chronic irreversible lead nephropathy has not been clearly shown to occur in humans, this progression has been demonstrated in rodent models.

There is no specific biomarker for lead-induced renal disease. Lead may produce a chronic interstitial nephropathy, most commonly with prolonged exposure to blood lead levels greater than 60 μg/dL, but biochemical indicators may respond as low as 40 μg/dL. In a mortality study of 4519 battery plant workers and 2300 lead production workers by Cooper and coworkers (1985), there was excess mortality from chronic nephritis. The mean blood concentration of 1326 of the battery workers in this study with three or more analyses was 62.7 μg/100 g. Gennart and colleagues (1992), found that none of the indicators of renal function, including red blood plasma (RBP), b$_2$-microglobulin, albumin and NAG in urine, and creatinine differed from controls and did not correlate with blood lead levels (mean 51 μg/dL, range 40 to 75) or duration of exposure. This finding is consistent with the observation of Buchet and coworkers (1980) that workers who do not have recorded blood lead levels over 62 or 63 μg/dL for up to 12 years do not have lead nephropathy. However, depressed glomerular filtration rates have been reported in a group of lead-exposed workers whose blood lead levels were as low as 40 μg/dL. Some studies report correlations of blood lead levels as low as 30 μg/dL with urinary levels of NAG and urinary and serum b$_2$-microglobulin, but these findings are not confirmed by others (Buchet et al., 1980; Gennart et al., 1992). Increase in urinary b$_2$-microglobulin is not a characteristic finding in lead-induced nephropathy and there is no meaningful correlation with blood lead levels (Bernard and Lauwerys, 1989). Also, Ong et al. (1987) were not able to find a dose–response relationship between blood lead levels and urinary excretion of NAG. Urinary excretion of NAG might occur at an early stage of lead nephropathy, perhaps reflecting increased urinary leakage from damaged renal tubular epithelium. There is evidence that lead impairs heme-containing enzyme systems in the kidney that are involved in vitamin D metabolism. Vitamin D synthesis requires a heme-containing hydroxylase enzyme in the kidney for the hydroxylation of 25-hydroxyvitamin D to 1,25-dehydroxy-vitamin D, which is important in the gastrointestinal absorption of calcium. These effects may occur with lead levels as low as 30 μg/dL, below the levels of lead that alters other biomarkers for nephrotoxicity (Rosen et al., 1985).

Lead and Gout The relationship between chronic lead exposure and gouty nephropathy was suggested more than a hundred years ago. The tubular or metabolic mechanism for the elevated blood uric acid levels is not known. However, patients with gout and renal disease have a greater chelate-provoked lead excretion than do renal patients without gout (Batuman et al., 1981).

Effects on Cardiovascular System There is considerable debate regarding the causal relationship between lead exposure and hypertension. Many of the studies are summarized in review literature (NRC, 1993; WHO, 1995; ATSDR, 1999). Epidemiologic studies on the effects of lead on blood pressure are inconclusive or contradictory and the WHO (1995) and ATSDR (1999) reviews conclude that the evidence to date is not sufficient to support causal relationship between blood lead levels and increases in blood pressure. Hu et al. (1996) related lead accumulation in bone with blood pressure in a cohort of 590 men, mean age 66.6 years, with hypertension (BP>160/90 mmHg). Results indicated an increase in odds ratio of 1.5 for hypertension for individuals with elevated bone lead.

The largest populations have been studied in the second National Health and Nutrition Examination Survey (NHANES II) for the U.S. population, performed during the years 1976 to 1980. These studies included blood lead levels and blood pressure measurements in a general population sample of 5803 men and women aged 12 to 74. Analysis of the data (Harlan et al., 1988) found a correlation between blood lead and blood pressure. Possible mechanisms for a lead effect on blood pressure include changes in plasma renin and in urinary kallikrein; alterations in calcium-activated functions of vascular smooth muscle cells, including contractility, by decreasing Na^+/K^+-ATPase activity and stimulation of the Na/Ca exchange pump; and changes in responsiveness to catecholamines (Victery, 1988; ATSDR, 1999).

Immunotoxicity Studies of workers with occupational exposures to lead suggest that lead is an immunosuppressive. McCabe and Lawrence (1991) suggest that decreases in immunoglobulins as well as other components of the immunologic system may be affected by lead. Changes in chemotaxis have been found in polymorphonuclear lymphocytes in workers with blood lead levels < 33 µg/dL (Valentino et al., 1991). Also, numbers of peripheral B lymphocytes may be decreased (Jaremin, 1983).

Bone Effects The regulation of skeletal mass, including lead in bone, are determined by four different types of cells; osteoblasts, lining cells, osteoclasts, and osteocytes. These cells line and penetrate the mineralized matrix of bone and are responsible for matrix formation, mineralization, and bone resorption. Lead toxicity directly and indirectly alters many aspects of bone cell function. Retention and mobilization of lead in bone occur by the same mechanisms involved in regulating calcium influx and efflux, namely parathyroid hormone, calcitonin, vitamin D, and other hormones that influence calcium metabolism (Pounds et al., 1991). Lead also competes with calcium for gastrointestinal absorption (Fullmer et al., 1992). The interrelationship of vitamin D and calcium is complex and involves interactions with parathyroid hormone. Lead in bone readily exchanges with blood lead. Using stable isotope techniques, Gulson and coworkers (1995) have shown that lead in bone contributes between 45 and 70 percent of the lead in blood of women of childbearing age, and a similar percent of lead is identified in the fetus as being from mother's skeleton. Pregnancy and lactation further increase mobilization of lead from the maternal skeleton, with a proportionate increase in blood lead in the prenatal period (Gulson et al., 1998).

Reproductive Effects Overt or clinically apparent lead toxicity has long been associated with sterility and neonatal deaths in humans. Gametotoxic effects have been demonstrated in both male and female animals (Stowe and Goyer, 1971). A few clinical studies have found increased chromosomal defects in workers with blood lead levels above 60 µg/dL; reduction in sperm counts and abnormal sperm motility and morphology are found in lead battery workers with blood lead levels as low as 40 µg/dL (Assenato et al., 1986). Decreases in testicular endocrine function were found to be related to duration of lead exposure of smelter workers with mean blood lead level of 60 µg/dL (Rodamilans et al., 1988). An effect of chronic exposure to low levels of lead on female reproduction including abortion has not been demonstrated (Murphy et al., 1990).

Birth Outcomes The early literature on toxicology of lead focused on an increased incidence of spontaneous abortion and stillbirth, but these outcomes are rare today. Andrews et al. (1994) reviewed 25 epidemiologic studies to determine the relationship of prenatal lead exposure and birth outcomes. They concluded that prenatal lead exposure is unlikely to increase the risk of premature rupture of membranes but does appear to increase the risk of preterm delivery. An increase in the maternal blood lead level may also contribute to reducing gestational duration and birth weight (McMichael et al., 1988; Borschein et al., 1989).

Carcinogenicity Lead is classified as a 2B carcinogen by the IARC (1987). A study of workmen with occupational exposure to lead in England many years ago did not show an increased incidence of cancer (Dingwall-Fordyce and Lane, 1963). Causes of mortality in 7000 lead workers in the United States showed a slight excess of deaths from cancer (Cooper and Gaffey, 1975), but the statistical significance of these findings has been debated (Kang et al., 1980). The most common tumors found were of the respiratory and digestive systems, not the kidney. However, case reports of renal adenocarcinoma in workmen with prolonged occupational exposure to lead have appeared (Baker et al., 1980; Lilis, 1981).

Epidemiologic studies suggest a relationship between occupational lead exposure and cancer of the lung and brain. Anttila et al. (1995) correlated blood lead levels and mortality rates and cancer incidence for a cohort of 20,700 workers coexposed to lead and engine exhausts. Blood lead levels were monitored for over 10 years. A 1.4-fold increase in the overall cancer incidence was found, as well as a 1.8-fold increase in lung cancer among those who had ever a blood-lead level over 1.0 µmol/dL. Another epidemiologic study provides evidence for a potential link between occupational exposure to lead and brain cancer (Cocco et al., 1998). A job-exposure matrix for lead to occupation and industry codes was applied to information on death certificates of 27,060 brain cancer cases and 108,240 controls who died of nonmalignant disease in 24 U.S. states in 1984 to 1992. Brain cancer risk increased by probability of exposure to lead among Caucasian men and women with high-level exposure. Fu and Boffetta (1995) performed a meta-analysis of published data on cancer incidence among various industries. They focused the analysis on overall cancer, stomach cancer, kidney cancer, and bladder cancer. The meta-analysis indicates a significant excess of cancer deaths from stomach cancer, lung cancer, and bladder cancer among workers exposed to lead. There was also a non-statistically-significant excess of deaths from kidney cancer. The investigators concluded that most of the studies lacked data on the level of cumulative exposure. Suggested relationships between high occupational exposure are from multimedia exposure, largely from inhalation, and often in association with potential toxins and/or cocarcinogens, so that the role of lead is generally nonconclusive.

Lead induction of renal adenocarcinoma in rats and mice is dose related and has not been reported at levels below that which produces nephrotoxicity. Lead-induced tumors may be a consequence of increased cellular proliferation (Calabrese, 1992). Lead compounds have been shown to stimulate the proliferation of renal tubular epithelial cells (Choie and Richter, 1980), and similar effects have been noted in the livers of rats (Columbano et al., 1983). Lead compounds induce cell transformation in Syrian hamster embryo cells (Zelikoff et al., 1988). Lead-related renal tumors may be a nonspecific response to epithelial hyperplasia, as has been noted in other experimental nephropathies and human diseases where renal tubular cysts and hyperplasia occur (Goyer, 1992).

Other Effects Lead lines (Burton's lines) or purple-blue discoloration of gingiva is a classic feature of severe lead toxicity in children with lead encephalopathy. However, this feature of lead toxicity, as well as the presence of lead lines at the epiphyses margins of long bones, is uncommon today.

Dose Response The toxic effects of lead and the minimum blood lead level at which the effect is likely to be observed are shown in Table 23-4. A detailed compilation of lowest observed effect levels in humans and animals from individual reports is available (ATSDR, 1999). Levels provided in this table are meant to be guidelines recognizing variation in susceptibility between individuals.

EFFECT	Blood Lead Levels, µg/dL	
	ADULT	CHILDREN
Neurologic		
Encephalopathy (overt)	80–100	100–120
Hearing deficits	20	—
IQ deficits	10–15	—
In utero effects	10–15	—
Nerve conduction velocity ↓	40	40
Hematologic		
Anemia	80–100	80–100
U-ALA ↑	40	40
B-EP ↑	15	15
ALA-D inhibition	10	10
Renal		
Nephropathy	40	40–60
Vitamin D metabolism	< 30?	30?
Blood pressure	30?	
Reproduction		
Males	40	
Females	?

Table 23-4 Summary of Lowest Observed Effect Levels for Lead-Related Health Effects

Treatment Foremost in the treatment of increased blood lead levels and lead toxicity is removal of the subject from source(s) of exposure. The blood lead levels at which treatment with chelating drugs should begin are debatable. Certainly chelation usually has a role in the treatment of the symptomatic worker or child. Institution of chelation therapy is probably warranted in workers with blood lead levels over 60 µg/dL, but this determination must be made after an assessment of exposure factors, including biological estimates of clinical and biochemical parameters of toxicity. For children, criteria have been established that may serve as guidelines to assist in evaluating the individual case (CDC, 1991). For children with severe lead poisoning, including encephalopathy, chelation therapy is standard practice. Even then, the mortality rate may be 25 to 38 percent when EDTA or BAL is used singly, whereas combination therapy of EDTA and BAL has been shown to be effective in reducing mortality.

The decision to chelate children with blood lead levels above 45 µg/dL is a matter of clinical judgment. The oral chelating agent succimer [dimercaptosuccinic acid,

(DMSA)] has been licensed by the U.S. Food and Drug Administration (FDA) for reduction of blood lead levels of 45 µg/dL or greater. DMSA has an advantage over EDTA in that it can be administered orally and is effective in temporarily reducing blood lead levels. Studies in rats suggest it may be effective in the treatment of acute lead poisoning (Kostial et al., 1999). However, DMSA does not seem to improve long-term blood lead levels in children with blood lead levels between 30 and 45 µg/dL. (O'Connor and Rich, 1999). Studies in monkeys suggest that DMSA does not reduce brain lead beyond the effect of cessation of exposure of lead alone (Cremin et al., 1999).

Organic Lead Compounds Tetraethyl lead (TEL) was used for many years as a gasoline additive, but production and use have now stopped in the United States. While the importance of TEL as a potential toxin for workers and the general population has lessened, it is still produced and used in some other countries. The potential use of gasoline as a recreational drug (gasoline sniffing) for a psychedelic high is an additional reason for concern about its potential toxicity.

Toxicokinetics Organic lead compounds have a special affinity for lipoid and nerve tissue, resulting in rapid metabolism and toxicity to the brain. Within 24 h of exposure, 50 percent of TEL is metabolized by P450 metabolizing enzymes to trimethyl lead (TML). The second metabolic product of TEL is inorganic lead, which is distributed to various tissues and excreted in urine. Most TEL is excreted from the body in about 20 days. Mechanisms of toxicity include damage to membranes, impairment of energy metabolism, and direct interference with neurotransmitter synthesis. Exposure to TEL is usually by inhalation, and about 60 to 80 percent is absorbed. The liquid is readily absorbed by the gastrointestinal tract and skin (Bolanowska et al., 1968; Bondy, 1991; Audesirk et al., 1995).

Toxicity Symptoms of acute intoxication include nausea, vomiting, and diarrhea associated with nervous system symptoms of irritability, headache, and restlessness. These symptoms progress rapidly to severe signs of central nervous system toxicity, including convulsions and coma. The mortality rate for acute intoxication is about 29 percent. Chronic exposure may result in milder symptoms. An immediate effect among recreational users may be euphoria, followed by violent excitement and then coma. Chronic, heavy sniffing of leaded gasoline results in signs of dementia and encephalopathy, with cerebellar and corticospinal symptoms. Which aspects of these symptoms are due to TEL per se or other components of gasoline is unknown. Chelating agents are not thought to be a rational aspect of treatment and experience with gasoline sniffers has shown that chelation does not benefit these patients (Tenenbein, 1997). A case-control study of former workers in a TEL-producing plant found a strong association between exposure to the TEL manufacturing process and colorectal cancer (Fayerweather et al., 1997).

Mercury (Hg)

No other metal better illustrates the diversity of effects caused by different chemical species than does mercury. [1] There have been several major reviews (ATSDR, 1999; WHO, 1990; WHO, 1991; Goyer, 1996).

Mercury is unique as being the only metal that is in a liquid state at room temperature. The vapor from this liquid, usually referred to as *mercury vapor,* is much more hazardous than the liquid form. This element exists in three oxidation states. In the zero oxidation state (Hg^0) mercury exists in its metallic form or as the vapor. The mercurous and mercuric states are the two higher-oxidation states where the mercury atom has lost one (Hg^+) and two electrons (Hg^{2+}), respectively. In addition, mercuric mercury can form a number of stable organic mercury compounds by attaching to one or two carbon atoms. Methyl mercury (CH_3Hg^+) is the most important organic form from the point of view of human exposure. Each oxidation state and each organic species has characteristic toxicokinetics and health effects.

Exposure The major source of mercury (as mercury vapor) in the atmosphere is the natural degassing of the earth's crust. It is difficult to assess what quantities of mercury come from human activities, but these are believed to be approximately similar in magnitude to natural sources. Calculations based on the mercury content of the Greenland ice cap show an increase from the year 1900 to the present.

Mercury vapor in the atmosphere represents the major pathway of global transport of mercury. It resides there unchanged for periods of a year or so. Thus there is time for it to be distributed globally even from a point source of pollution. Eventually it is converted to a water-soluble form and returned to the earth's surface in rainwater.

At this stage, two important chemical changes may occur. The metal may be reduced back to mercury vapor and returned to the atmosphere, or it may be methylated by microorganisms present in sediments of bodies of fresh and ocean water. The main product of this natural biomethylation reaction is monomethyl mercury compounds, usually referred to generically as "methyl mercury." Some of the oldest organisms on an evolutionary scale, the methanogenic bacteria, carry out this methylation reaction.

Once produced, methyl mercury enters an aquatic food chain involving plankton, herbivorous fish, and finally carnivorous fish. In the tissues of fish consuming sea mammals, mercury can rise to levels a millionfold higher than those in the surrounding water. The sequence of biomethylation and bioconcentration can result in human dietary exposure to methyl mercury, whether the latter originated from natural or anthropogenic sources of inorganic mercury. Methyl mercury is found in most if not all fish tissues but most importantly in edible tissue, mainly muscle, in a water-soluble protein-bound form. Unlike the case of PCBs, which are deposited in fat, cooking the fish does not lower the methyl mercury content.

Inorganic compounds of mercury are also found in food. The source is unknown and the amount ingested is far below known toxic intakes.

Other sources of human exposure to mercury are occupational, where the main route is inhalation of mercury vapor from the working environment. Mercury has numerous uses, as in the chlor-alkali industry, where it is used as a cathode in the electrolysis of brine; in making a variety of scientific instruments and electrical control devices; in dentistry, as amalgam tooth filling; and in the extraction of gold. The last has now become a widespread activity in developing countries, where large quantities of metallic mercury are used to form an amalgam with gold. The amalgam is heated to drive off the mercury, resulting in a substantial release to the atmosphere.

Mercury vapor emitted from amalgam dental fillings is the major source of mercury vapor affecting the general public. Chewing increases the rate of release. Although the amount inhaled is low compared to known toxic levels, some individuals with a history of excessive chewing might attain levels that could pose a health risk.

Mercury levels in the general atmosphere and in drinking water are so low that they do not constitute an important source of exposure to the general population.

Disposition and Toxicokinetics Liquid metallic mercury, such as may be swallowed from a broken thermometer, is only slowly absorbed by the gastrointestinal tract (0.01 percent) at a rate related to the vaporization of the elemental mercury and is generally thought to be of no toxicologic consequence.

The vapor from metallic mercury is readily absorbed in the lungs, and, in mercury's dissolved form in the bloodstream, diffuses to all tissues in the body. Its high mobility is due to the fact that it is a monatomic gas, highly diffusible and lipid-soluble. It is rapidly oxidized to mercuric mercury, as discussed below.

Since human exposure to compounds of mercurous mercury now occurs rarely if at all, we have little information on its disposition in the body. Compounds of mercurous mercury, especially the chloride salt, have a low solubility in water and are poorly absorbed from the gastrointestinal tract. In the presence of protein, the mercurous ion disproportionates to one atom of metallic mercury (Hg^0) and one of mercuric mercury (Hg^{2+}). The latter will probably be absorbed into the bloodstream and distributed to tissues, as discussed below.

Gastrointestinal absorption of compounds of mercuric mercury from food is about 15 percent in a study of human volunteers, whereas absorption of methyl mercury is on the order of 90 to 95 percent. Distribution between red blood cells and plasma also differs. For inorganic mercury the cell-to-plasma ratio ranges from a high of 2 with high exposure to less than 1 but for methyl mercury it is about 10. The distribution ratio of the two forms of mercury between hair and blood also differs; much higher concentrations of methyl mercury are accumulated from blood.

Kidneys contain the greatest concentrations of mercury following exposure to inorganic salts of mercury and mercury vapor, whereas organic mercury has a greater affinity for the brain, particularly the posterior cortex. Mercury vapor also has a greater predilection for the central nervous system than do inorganic mercury salts.

Excretion of mercury from the body is by way of urine and feces, again differing with the form of mercury, size of the dose, and time after exposure. Exposure to mercury vapor is followed by exhalation of a small fraction, but fecal excretion is the major and predominant route of excretion initially after exposure to inorganic mercury. Renal excretion increases with time. About 90 percent of methyl mercury is excreted in feces after acute or chronic exposure, and this figure does not

change with time (Miettinen, 1973).

All forms of mercury cross the placenta to the fetus, but most of what is known has been learned from experimental animals. Fetal uptake of elemental mercury in rats has been shown to be 10 to 40 times higher than uptake after exposure to inorganic salts. Concentrations of mercury in the fetus after exposure to alkyl-mercuric compounds are twice those found in maternal tissues, and levels of methyl mercury in fetal red blood cells are 30 percent higher than those in maternal red cells. Although maternal milk may contain only 5 percent of the mercury concentration of maternal blood, neonatal exposure to mercury may be increased by nursing (Grandjean et al., 1994).

Metabolic Transformation Elemental or metallic mercury is oxidized to divalent mercury after absorption to tissues in the body and is probably mediated by catalases. Inhaled mercury vapor absorbed into red blood cells is transformed to divalent mercury, but a portion is also transported as metallic mercury to more distal tissues, particularly the brain, where biotransformation may occur.

Methyl mercury undergoes biotransformation to divalent mercury compounds in tissues by cleavage of the carbon mercury bond. There is no evidence of formation of any organic form of mercury in mammalian tissues. The aryl (phenyl) compounds are converted to inorganic mercury more rapidly than the shorter-chain alkyl (methyl) compounds.

Biological half-lives are available for a limited number of mercury compounds. Elimination of methyl mercury from the body is adequately described by a single half-life. The most recent estimate is 44 days. More complex kinetics describe the elimination of mercury after inorganic salts or exposure to mercury vapor. The half-lives vary between tissues and sometimes more than one half-life is needed to characterize the kinetics of elimination. Generally, the half-lives are in the range of 20 to 90 days.

Cellular Metabolism Within cells, mercury may bind to a variety of enzyme systems including those of microsomes and mitochondria, producing nonspecific cell injury or cell death. It has a particular affinity for ligands containing sulfhydryl groups. In liver cells, methyl mercury forms soluble complexes of glutathione, which are secreted in bile and reabsorbed from the gastrointestinal tract. Inorganic mercury is also secreted in bile as a glutathione complex. The cysteine complex of methyl mercury enters the endothelial cells of the blood-brain barrier on the large neutral amino acid transporter.

Mercuric mercury, but not methyl mercury, induces synthesis of metallothionein in kidney cells; but unlike cadmium-metallothionein, it does not have a long biological half-life. Mercury within renal cells becomes localized in lysosomes (Madsen and Christensen, 1978).

Toxicology *Mercury Vapor* Inhalation of mercury vapor at extremely high concentrations may produce an acute, corrosive bronchitis and interstitial pneumonitis and, if not fatal, may be associated with symptoms of central nervous system effects such as tremor or increased excitability. With chronic exposure to mercury vapor, the major effects are on the central nervous system. Early signs are nonspecific, and this condition has been termed the *asthenic-vegetative syndrome* or *micromercurialism*. Identification of the syndrome requires neurasthenic symptoms and three or more of the following clinical findings: tremor, enlargement of the thyroid, increased uptake of radioiodine in the thyroid, labile pulse, tachycardia, dermographism, gingivitis, hematologic changes, or increased excretion of mercury in urine. With increasing exposure, the symptoms become more characteristic, beginning with tremors of muscles that perform fine-motor functions (highly innervated)—such as fingers, eyelids, and lips—and may progress to generalized trembling of the entire body and violent chronic spasms of the extremities. This is accompanied by changes in personality and behavior, with loss of memory, increased excitability (erethism), severe depression, and even delirium and hallucination. Another characteristic feature of mercury toxicity is severe salivation and gingivitis.

The triad of increased excitability, tremors, and gingivitis has been recognized historically as the major manifestation of mercury poisoning from inhalation of mercury vapor and exposure to mercury nitrate in the fur, felt, and hat industries (Goldwater, 1972).

Sporadic instances of proteinuria and even nephrotic syndrome may occur in persons with exposure to mercury vapor, particularly with chronic occupational exposure. The pathogenesis is probably immunologically similar to that which may occur following exposure to inorganic mercury.

There is growing concern that the toxic potential of mercury vapor released from dental amalgams may cause various health effects. Estimates of absorption of mercury by an adult with the average number of amalgams (8 per adult) is 30 to 40 percent of the total mercury exposure of 5 to 6 µg per day (Richardson et al., 1995). An increase in urinary mercury and accumulation in several organs, including the central nervous system and kidneys, has been related to the release of mercury from dental amalgams (Clarkson et al., 1988; Langworth et al., 1988). Aposhian and coworkers (1992) found a highly positive correlation between mercury excreted in urine following the administration of dimercapto-succinic acid (DMPS) and numbers of dental amalgams. However, this level of mercury exposure is believed to be below that which will produce any discernible health effect except for highly sensitive people.

Mercuric Salts Bichloride of mercury (corrosive sublimate) is the best-known mercuric salt of mercury from a toxicologic standpoint. Even the trivial name suggests its most apparent toxicologic effect when the salt is ingested in concentrations greater than 10 percent. A reference from the Middle Ages in Goldwater's book on mercury describes oral ingestion of mercury as causing severe abdominal cramps, bloody diarrhea, and suppression of urine (Goldwater, 1972). This is an accurate report of the effects following accidental or suicidal ingestion of mercuric chloride or other mercuric salts. Corrosive ulceration, bleeding, and necrosis of the gastrointestinal tract are usually accompanied by shock and circulatory collapse. If the patient survives the gastrointestinal damage, renal failure occurs within 24 h owing to necrosis of the proximal tubular epithelium, followed by oliguria, anuria, and uremia. If the patient can be maintained by dialysis, regeneration of the tubular lining cells is possible. These changes may be followed by ultrastructural changes consistent with irreversible cell injury, including actual disruption of mitochondria, release of lysosomal enzymes, and rupture of cell membranes.

Injection of mercuric chloride produces necrosis of the epithelium of the pars recta kidney (Gritzka and Trump, 1968). Cellular changes include fragmentation and disruption of the plasma membrane and its appendages, vesiculation and disruption of the endoplasmic reticulum and other cytoplasmic membranes, dissociation of polysomes and loss of ribosomes, mitochondrial swelling with appearance of amorphous intramatrical deposits, and condensation of nuclear chromatin. These changes are common to renal cell necrosis due to various causes. Slight tubular cell injury, manifest by enzymuria and low-molecular-weight proteinuria may occur in workers with low-level exposure to metallic mercury vapor (Roels et al., 1985).

Although a high dose of mercuric chloride is directly toxic to renal tubular lining cells, chronic low-dose exposure to mercuric salts or even elemental mercury vapor levels may induce an immunologic glomerular disease. Exposed persons may develop a proteinuria that is reversible after workers are removed from exposure.

Experimental studies have shown that the pathogenesis has two phases: an early phase characterized by an anti–basement membrane glomerulonephritis, followed by a superimposed immune-complex glomerulonephritis with transiently raised concentrations of circulating immune complexes (Henry et al., 1988). The pathogenesis of the nephropathy in humans appears similar, although antigens have not been characterized. Also, the early glomerular nephritis may progress in humans to an interstitial immune-complex nephritis (Pelletier and Druet, 1995).

Mercurous Mercury Mercurous compounds of mercury are less corrosive and less toxic than mercuric salts, presumably because they are less soluble. Calomel, a powder containing mercurous chloride, has a long history of use in medicine. Perhaps the most notable modern usage has been in teething powder for children, and this powder is now known to be responsible for acrodynia or "pink disease." This is most likely a hypersensitivity response to the mercury salts in skin, producing vasodilation, hyperkeratosis, and hypersecretion of sweat. Children develop fever, a pink-colored rash, swelling of the spleen and lymph nodes, and hyperkeratosis and swelling of the fingers. The effects are thought to be a hypersensitivity reaction (Matheson et al., 1980).

Methyl Mercury Methyl mercury is the most important form of mercury in terms of toxicity and health effects from environmental exposures. Many of the effects produced by short-term alkyls are unique in terms of mercury toxicity but nonspecific in that they may be found in other disease states. Most of what is known about the clinical signs and symptoms and neuropathology of high-level or overt methyl mercury toxicity has been learned from studies of epidemics in Japan and Iraq (WHO, 1990; Berlin, 1986) and from published reports of occupational exposures (Hunter et al., 1940). Observations of changes in nonhuman primates studied experimentally are consistent with findings in humans and therefore provide additional information about the relationship between time, dose, and tissue burden, particularly for subclinical and subtle low-level effects (Mottet et al., 1985).

The major human health effects from exposure to methyl mercury are neurotoxic effects in adults (Bakir et al., 1973) and toxicity to the fetuses of mothers exposed to methyl mercury during pregnancy (Cox et al., 1989). The major source of exposure for people in the general population is from the consumption of fish, and in this

instance the brain is the critical organ.

Clinical manifestations of neurotoxic effects are (1) paresthesia, a numbness and tingling sensation around the mouth, lips, and extremities, particularly the fingers and toes; (2) ataxia, a clumsy, stumbling gait, difficulty in swallowing and articulating words; (3) neurasthenia, a generalized sensation of weakness, fatigue, and inability to concentrate; (4) vision and hearing loss; (5) spasticity and tremor; and finally (6) coma and death.

Neuropathologic observations have shown that the cortex of the cerebrum and cerebellum are selectively involved with focal necrosis of neurons, lysis and phagocytosis, and replacement by supporting glial cells. These changes are most prominent in the deeper fissures (sulci), as in the visual cortex and insula. The overall acute effect is cerebral edema; but with prolonged destruction of gray matter and subsequent gliosis, cerebral atrophy results (Takeuchi, 1977).

The mechanisms of damage to the mature brain are not known. Inhibition of protein synthesis is among the earliest biochemical effects seen in animals. Syversen (1982) has proposed that all neuronal cells may be affected initially, but those cells having the least repair capacity eventually succumb whereas cells with more repair capacity survive. This mechanism may account for the highly localized focal pathology seen in the adult brain.

Experimental studies on the mechanisms of methyl mercury toxicity provide some insight into the basis for the clinical observations as well as the greater sensitivity of the developing brain (Clarkson, 1983). Exposure of the fetus in utero to high levels of mercury result in abnormal neuronal migration and deranged organization of brain nuclei (clusters of neurons) and layering of neurons in the cortex. Studies in mice have demonstrated an effect of methyl mercury on the microtubules of neurons. These observations may provide the cellular basis for the observed neuropathologic changes in the migration pattern of neurons during development, which is thought to be the basis for the developmental effects in the central nervous system. Male mice are more sensitive than females, consistent with the findings in humans (Sager et al., 1984; Choi et al., 1978).

Biological Indicators *Inorganic Mercury* The recommended standard (time-weight average) for permissible exposure limits for inorganic mercury in air in the workplace is 0.05 mg/m^3 (DHEW, 1977) and is equivalent to an ambient air level of 0.015 mg/m^3 for the general population (24-h exposure) (Table 23-5). The U.S. federal standard for alkyl mercury exposure in the workplace is 0.01 mg/m^3 as an 8-h time-weighted average with an acceptable ceiling of 0.04 mg/m^3. A study of the Iraq epidemic has provided estimates of the body burden of mercury and the onset and frequency of occurrence of symptoms (Fig. 23-7).

Equivalent Concentrations[a]			
AIR, mg/m^3	BLOOD, µg/100 mL	URINE, µg/L	EARLIEST EFFECTS
0.05	3.5	150	Nonspecific symptoms
0.1–0.2	7–14	300–600	Tremor

[a]Blood and urine values may be used only on a group basis owing to gross individual variations. These average values reflect exposure for a year or more. After shorter periods of exposure, air concentrations would be associated with lower concentrations in blood and urine.
SOURCE: WHO (1976).

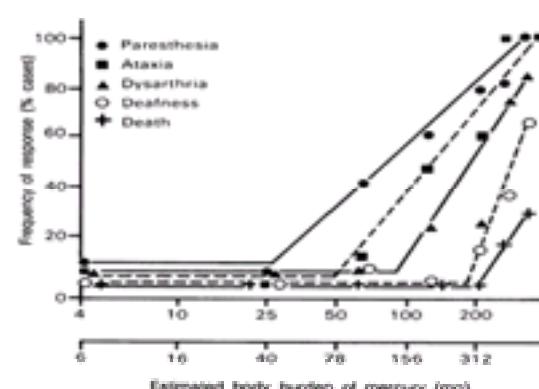
Table 23-5 The Time-Weighted Average Air Concentrations Associated with the Earliest Effects in the Most Sensitive Adults following Long-Term Exposure to Elemental Mercury Vapor


Figure 23-7. Dose–response relationships for methyl mercury.

Methyl Mercury The relationship between health risks and intake of methyl mercury has been developed from toxicologic data obtained from studies of epidemics due to accidental poisoning in Minamata and Niigata, Japan, in the 1950s and 1960s and from studies of the episode in Iraq in 1972 (Berlin, 1986).

The critical or lowest level of observed adverse health effect in adults is paresthesia. By combining two relationships, body burden versus intake and effect versus body burden, a Swedish Expert Group (1971) was able to calculate the average long-term daily intake associated with health effects in the most susceptible individual. This was estimated to be about 300 µg/day for an adult or 4.3 µg/kg/day and would correspond to a steady-state blood level of 200 µg/L or a hair level of 50 µg/g.

Treatment Therapy for mercury poisoning should be directed toward lowering the concentration of mercury at the critical organ or site of injury. For the most severe cases, particularly with acute renal failure, hemodialysis may be the first measure, along with infusion of chelating agents for mercury, such as cysteine or penicillamine. For less severe cases of inorganic mercury poisoning, chelation with BAL may be effective.

However, chelation therapy is not very helpful for alkyl mercury exposure. Biliary excretion and reabsorption by the intestine and the enterohepatic cycling of mercury may be interrupted by surgically establishing gallbladder drainage or by the oral administration of a nonabsorbable thiol resin, which binds mercury and enhances intestinal excretion (Berlin, 1986).

Nickel (Ni)

Nickel[1] is a respiratory tract carcinogen in workers in the nickel-refining industry. Other serious consequences of long-term exposure to nickel are not apparent, but severe acute and sometimes fatal toxicity may follow exposure to nickel carbonyl. Allergic contact dermatitis is common among the general population.

Metallic nickel is produced from sulfide and silcate-oxide ores. In the United States approximately 200,000 metric tons of nickel (primary plus secondary use) are utilized per year. Nickel is included in various metal alloys, stainless steels, and electroplating. Major properties are strength, corrosion resistance, and good thermal and electrical conductivity (NIDI, 1997).

Exposure Nickel is ubiquitous in nature, occurring mainly in the form of sulfide, oxide, and silicate minerals. Very low levels of nickel can be found in ambient air as a result of industrial uses, combustion of fossil fuels, and sludge and waste incineration. Human exposure may be by inhalation, ingestion, and dermal contact. The main route of occupational exposure to nickel is through inhalation and to a lesser degree skin contact. Nickel refinery dust contains a mixture of many chemical species. Occupational exposures may contain elemental nickel, nickel compounds, complexes and alloys, and fumes from alloys used in welding and brazing. While there are no refineries in operation in the United States at present, there is still concern regarding effects on former workers from past exposures. Exposure to individuals in the general environment may result from contact with everyday items such as nickel-containing jewelry, cooking utensils, and clothing fasteners. Food is

a major source of exposure for most people. The Environmental Protection Agency (EPA) estimates that an average adult consumes 100 to 300 µg of nickel per day. Drinking water contains very small amounts of nickel (ATSDR, 1997).

Toxicokinetics In the workplace, inhalation is the most serious toxicologic concern, followed by dermal exposure. Almost 35 percent of inhaled nickel is absorbed into the blood from the respiratory tract (WHO, 1991). Deposition, absorption, and elimination of nickel particles in the respiratory tract depend largely on the particle size and concentration of nickel. Only about half of particles larger than 30 µm are inhalable. Particles less than 10 µm may be deposited in the lower respiratory tract. Half-lives of 1 to 3 days for nickel sulfate, 5 days for nickel subsulfide, and more than 100 days for nickel oxide have been reported for inhaled or intratracheally instilled nickel compounds (Benson et al., 1987; Dunnick, 1989). Nickel has a half-life ranging from 30 to 53 h in the urine of workers exposed to insoluble nickel particles of small diameter (Raithel et al., 1982). Urinary nickel ranges from approximately 0.2 to 10 µg/L in unexposed individuals but from 2.6 µg/L in high nickel alloy production to 222 µg Ni/L in electrolyte refinery workers (Bernacki et al., 1978). In human volunteers exposed orally to soluble nickel sulfate hexahydrate, a half-life of 11 h was observed (Christensen and Lagesson, 1981). Nickel concentrations in the serum of unexposed individuals ranged from 0.05 to 1.1 µg/L (Sunderman et al., 1986). Urinary nickel has been shown to correlate closely with airborne levels of insoluble nickel compounds. It is not influenced by duration of exposure and may serve as a suitable measure of current nickel exposure (White and Boran, 1988).

The rate of dermal absorption depends on the rate of penetration of the epidermis, which differs for different chemical species of nickel. Nickel chloride penetrates in amounts ranging from 0.23 to 3.5 percent of the applied dose, whereas nickel sulfate may penetrate at rates 50 times lower (NIDI, 1997).

Nickel administered parenterally to animals is rapidly distributed to the kidneys, pituitary, lungs, skin, adrenals, ovaries, and testes (Sunderman, 1981). The intracellular distribution and binding of nickel is not well understood. Ultrafilterable ligands seem to be of major importance in the transport in serum and bile and urinary excretion as well as in intracellular binding. The ligands are not well characterized, but Sunderman (1981) suggests that cysteine, histidine, and aspartic acid form nickel complexes either singly or as nickel–ligand species. In vivo binding with metallothionein has been demonstrated, but nickel at best induces metallothionein synthesis in liver or kidney only slightly. A nickel-binding metalloprotein, called nickeloplasmin, has also been identified in plasma with properties suggesting that it is an a_1-glycoprotein complex and is important in the extracellular transport, intracellular binding, and urinary and biliary excretion of nickel (Niebor et al., 1988; Tabata et al., 1992).

Essentiality Evidence has accumulated over the past few years indicating that nickel is a nutritionally essential trace metal for some plant life, bacteria, and invertebrates (summarized by Nielson, 1996). Jackbean urease has been identified as a nickel metalloenzyme, and nickel is required for urea metabolism in cell cultures of soybean. However, a nickel-containing metalloenzyme has not yet been recovered from animal tissues. Nickel deficiency in rats is associated with retarded body growth and anemia, probably secondary to impaired absorption of iron from the gastrointestinal tract. In addition, there is a significant reduction in serum glucose concentration. An interaction of nickel with copper and zinc is also suspected because anemia-induced nickel deficiency is only partially corrected with nickel supplementation in rats receiving low dietary copper and zinc (Spears, 1978). A defined biochemical function in higher animals and humans has not been described, and human nutritional requirements have not been established (WHO, 1996).

Toxicity *Carcinogenicity* The IARC working group for consideration of nickel and nickel compounds concluded that nickel compounds are carcinogenic to humans (IARC, 1990). The respiratory tract is the main site of chronic effects reported in relation to nickel and its compounds. Risks were highest for lung and nasal cancers among workers heavily exposed to nickel sulfide, nickel oxide, and to metallic nickel. A cohort of 418 workers employed in a Finnish refinery reported a twofold increased incidence of lung cancer and a large increase in sinonasal cancers (Karjalainen et al., 1992). A follow-up of this study, including a total of 1155 workers, confirmed an elevated risk of lung and nasal cancers among refinery workers, with a greater risk among workers with a longer latency (greater than 20 years), (Anttila et al., 1998).

Because the refining of nickel in the plants that were studied involved the Mond process, with the formation of nickel carbonyl, it was believed for some time that nickel carbonyl was the principal carcinogen. However, additional epidemiologic studies of workers in refineries that do not use the Mond process also showed an increased risk of respiratory cancer, suggesting that the source of the increased risk is the mixture of nickel sulfides present in molten ore. Studies with experimental animals have shown that the nickel subsulfide (Ni_3S_2) produces local tumors at injection sites and by inhalation in rats, and in vitro mammalian cell tests demonstrate that Ni_3S_2 and $NiSO_4$ compounds give rise to mammalian cell transformation (IARC, 1990). Differences in the carcinogenic activities of nickel compounds may be attributable to variations in their capacities to provide nickel ion at critical sites within target cells (Sunderman, 1989; Costa, 1995). The order of lung toxicity corresponds to the water solubility of various compounds, with nickel sulfate being most toxic, followed by nickel subsulfide and nickel oxide (Dunick et al., 1989). However, nickel compounds lose their original chemical identity upon entering the blood, so that it is not possible to identify the original source of exposure (Grant and Mushak, 1989).

Mechanisms For Nickel Carcinogenesis The carcinogenicity of nickel is thought to be due to the ionic nickel species, but it has been difficult to explain the differences in carcinogenic potency between different nickel compounds. Some studies have suggested that water-insoluble crystalline nickel compounds were responsible for lung and nasal cancers seen in animal and human studies (IARC, 1990). However, not all water-insoluble crystalline nickel compounds induce tumors, so it was assumed that factors other than solubility were involved. More recently, Costa (1995) has proposed an epigenic model suggesting that tumor induction is related to the ability of the cell to incorporate the crystalline compound into the cell by phagocytosis. Costa showed that Syrian hamster cells undergoing transformation selectively phagocytosed the negatively charged crystalline nickel sulfide compounds and not the positively charged amorphous nickel sulfide particles. When a negative charge was induced on the amorphous nickel sulfide particles, they too were phagocytosed and were able to exhibit transformation potency equivalent to that of crystalline nickel sulfide particles. Inside the cell, the particles dissolved in the intracellular space, a process enchanced by the acidic pH of the cytoplasm. Therefore, transformation appeared to directly relate to the ability of the particle to enter the cell and increase intracellular nickel concentrations. The model is based upon the known ability of nickel compounds to enhance DNA chromatin condensation. DNA found in heterochromatin is hypermethylated for direct protein binding for increased condensation. Another theory is that nickel damages DNA indirectly through reactive oxygen species (McCoy and Kenny, 1992). This proposal is supported by evidence that the antioxidant vitamin E inhibits some chromosomal condensation caused by nickel (Lin et al., 1991).

Sunderman and Barber (1988) proposed that nickel interacts with DNA by replacement of Zn^{2+} with Ni^{2+} on the Zn^{2+} binding sites of DNA-binding proteins. Ni^{2+} has a similar ionic radius to Zn^{2+}. DNA-binding proteins or "finger loop domains" have been identified on some proto-oncogenes and are thought to be likely targets for metal toxicity.

Nickel Carbonyl Poisoning Metallic nickel combines with carbon monoxide to form nickel carbonyl ($Ni[CO]_4$), which decomposes to pure nickel and carbon monoxide on heating to 200°C (the Mond process). This reaction provides a convenient and efficient method for the refinement of nickel. However, nickel carbonyl is extremely toxic, and many cases of acute toxicity have been reported. The illness begins with headache, nausea, vomiting, and epigastric or chest pain, followed by cough, hyperpnea, cyanosis, gastrointestinal symptoms, and weakness. The symptoms may be accompanied by fever and leukocytosis and the more severe cases progress to pneumonia, respiratory failure, and eventually to cerebral edema and death (WHO, 1991).

Dermatitis Nickel dermatitis is one of the most common forms of allergic dermatitis: 4 to 9 percent of persons with contact dermatitis react positively to nickels patch tests. Sensitization might occur from any of the metal products in common use, such as coins and jewelry. The notion that increased ingestion of nickel-containing food increases the probability of external sensitization to nickel is supported by the finding that increased urinary nickel excretion is associated with episodes of acute nickel dermatitis (Liden et al., 1995).

Indicators of Nickel Toxicity Blood nickel levels immediately following exposure to nickel carbonyl provide a guideline as to the severity of exposure and indication for chelation therapy (Sunderman, 1979). Sodium diethyldithiocarbamate is the preferred drug, but other chelating agents, such as D-penicillamine and DMPS, provide some degree of protection from clinical effects.

ESSENTIAL METALS WITH POTENTIAL FOR TOXICITY

This group includes eight metals generally accepted as essential: cobalt, copper, iron, magnesium, manganese, molybdenum, selenium, and zinc. The traditional criteria for nutritionally essential metals is that deficiency produces either functional or structural abnormalities and that the abnormalities are related to or a consequence of specific biochemical changes that can be reversed by the presence of the essential metal (WHO, 1996). There are other metals in this chapter that may be nutritionally essential for vegetative life and may have beneficial health effects in humans but have not met the criteria for essentiality for human health. For essential trace elements, risk assessment requires consideration of both toxicity from excess exposures and health consequences as a result of deficiencies. There is increasing use of various standards that are designed to protect human health from excess exposure but provide risk for health effects from deficiency. Recognition of this problem prompted conferences in the United States and Scandinavia to address aspects of this problem (Mertz et al., 1994; Oskarsson et al., 1995). A

methodology has been proposed to determine an acceptable level of oral intake for these metals (Nordberg et al., 1999).

Cobalt (Co)

Cobalt[1] is a relatively rare metal produced primarily as a by-product of other metals, chiefly copper. It is used in high-temperature alloys and in permanent magnets. Its salts are useful in paint dryers, as catalysts, and in the production of numerous pigments. Cobalt, in the form of cobalamin, is an essential component of vitamin B[12] required for the production of red blood cells and prevention of pernicious anemia. Cobalamin is actually synthesized by intestinal flora, so that in actuality the nutritional requirement for cobalt in humans is as cobalamin produced by intestinal bacteria and not for cobalt ion per se. This consideration has led nutritionists not to regard cobalt as an essential element for humans. However, insufficient natural levels of cobalt in feed stock of sheep and cattle result in cobalt deficiency disease, characterized by anemia and loss of weight or retarded growth. If other requirements for cobalt exist, they are not well understood (WHO, 1996; Herbert, 1996).

The toxicokinetics and possible health effects of cobalt are summarized by Elinder and Friberg (1986) , and Schrauzer (1995). Cobalt salts are generally well absorbed after oral ingestion, probably in the jejunum. Despite this fact, increased levels tend not to cause significant accumulation. About 80 percent of the ingested cobalt is excreted in the urine. Of the remaining portion, about 15 percent is excreted in the feces by an enterohepatic pathway, while the milk and sweat are other secondary routes of excretion. The total body burden has been estimated as 1.1 mg. Muscle contains the largest total fraction, but fat has the highest concentration. The liver, heart, and hair have significantly higher concentrations than other organs, but the concentration in these organs is relatively low. The normal levels in human urine and blood are about 1.0 and 0.18 µg/L, respectively. The blood level is largely associated with the concentration in red cells. Significant species differences have been observed in the excretion of radiocobalt. In rats and cattle, 80 percent is eliminated in the feces.

Cobalt has an erythropoietic effect when an excessive amount of cobalt is ingested by most mammals, including humans. High levels of chronic oral administration of cobalt for treatment of anemia may result in the production of goiter, and epidemiologic studies suggest that the incidence of goiter is higher in regions containing increased levels of cobalt in the water and soil. The goitrogenic effect has been elicited by the oral administration of 3 to 4 mg/kg to children in the course of treatment of sickle cell anemia. Toxicity resulting from overzealous therapeutic administration has been reported to produce vomiting, diarrhea, and a sensation of warmth. Intravenous administration leads to flushing of the face, increased blood pressure, slowed respiration, giddiness, tinnitus, and deafness due to nerve damage. Cardiomyopathy has been caused by an excessive intake of cobalt, >10 mg day, particularly from the drinking of beer to which cobalt was added to enhance its foaming qualities. The signs and symptoms were those of congestive heart failure. Autopsy findings have found a tenfold increase in the cardiac levels of cobalt.

Occupational inhalation of cobalt-containing dust in the cemented tungsten carbide industry may cause respiratory irritation at air concentrations of 0.002 to 0.01 mg/m^3. Higher concentrations (0.1 mg Co/m^3 or higher) may be a cause of "hard metal" pneumoconiosis, a progressive form of interstitial fibrosis. Skin contact is sometimes associated with an allergic dermatitis of an erythematous papular type. Affected persons may have positive skin tests.

Injection of cobalt in animal models produces myocardial degeneration. Also, hyperglycemia due to b-cell pancreatic damage has been reported after injection of cobalt into rats. Single and repeated subcutaneous or intramuscular injection of cobalt powder and salts in rats may cause sarcomas at the site of injection. Cobalt is only weakly mutagenic and there is no evidence of carcinogenicity from any other route of exposure.

Trivalent Chromium, Cr(III)

Chromium,[1] the most common form found in nature and chromium in biological materials, is probably always trivalent. There is no evidence that trivalent chromium is converted to hexavalent forms in biological systems. However, hexavalent chromium readily crosses cell membranes and is reduced intracellularly to trivalent chromium.

Essentiality Cr (III) is considered an essential trace nutrient serving as a component of the "glucose tolerance factor." Evidence for the physiologic role of chromium is summarized by Stoecker (1996). It is thought to be a cofactor for insulin action and to have a role in the peripheral activities of this hormone by forming a ternary complex with insulin receptors, facilitating the attachment of insulin to these sites. The role for chromium in carbohydrate metabolism is based on epidemiologic studies showing that chromium supplementation improved the efficiency of insulin effects on blood lipid profiles. Of 15 controlled studies, only three found no effect on glucose, insulin, or lipids. Subjects with some degree of impaired glucose tolerance were more responsive to chromium supplementation than others. In studies of patients whose total parenteral nutrition solutions contained no chromium, chromium supplementation reduced insulin requirements and glucose intolerance. Other evidence for a physiologic role for chromium is from animal studies. Decreased weight gain has been reported for rats, mice, and guinea pigs whose diets were depleted of chromium. Also, chromium in mouse liver is concentrated in the nuclei 48 h after intraperitoneal injection. Also, Cr(III) bound to DNA in vitro, thus enhancing RNA synthesis. Chromium supplementation in diets of "travel-stressed cattle" significantly decreased serum cortisol and increased serum immunoglobulin. It is recognized, however, that further research is needed to resolve questions about the structure and function of the glucose tolerance factor and other possible physiologic functions of Cr(III). The Food and Nutrition Board of the United States Academy of Sciences has established that an estimated safe and adequate daily intake for chromium in adults ranges from 50 to 200 µg (NRC, 1989).

Copper (Cu)

Copper[1] is widely distributed in nature and is a nutritionally essential element. Ambient air levels are generally low in the United States; for the general population, food, beverages, and drinking water are potential sources of excess exposure. Daily intake of copper in adults varies between 0.9 and 2.2 mg. Intake in children has been estimated to be 0.6 to 0.8 mg/day (0.07 to 0.1 mg/kg body weight per day) (WHO, 1998). The EPA's maximum contaminant level for copper in drinking water is 1.3 mg/L, but this is under revision (EPA, 1994). The provisional WHO guideline for copper in drinking water is 2 mg/L (WHO, 1993). Copper exposures in industry are to particulates in miners or to metal fumes in smelting operations, welding, and related activities.

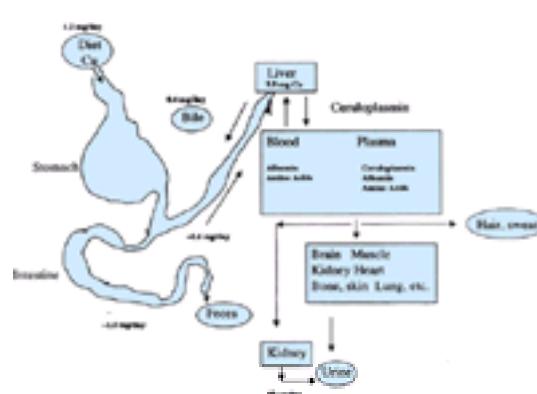
Toxicokinetics The metabolism and health effects of copper are reviewed by WHO (1996), Sheinberg and Sternlieb (1996), Chan et al. (1998), Harris (1997), and NRC (2000). An overview of copper metabolism is shown in Fig. 23-8.


Figure 23-8. Overview of copper absorption, transport, and excretion.

The liver receives copper from the intestine via the portal circulation and redistributes the copper to the tissue via ceruloplasmin, albumin, and amino acids. Approximately half the copper consumed is not absorbed and passes into the feces. Another two-thirds of the daily intake is returned to the liver and released into the bile. Consequently fecal excretion accounts quantitatively for nearly all of the copper consumed as the systems endeavor to stay in balance. A small amount, 60 µg/day, is excreted by the kidney via the urine, and still lesser amounts appear in hair and sweat. This interplay among the various systems maintains homeostasis and balance throughout the organism. The values in the figure are based on a dietary input of 1.2 mg/day. [Adapted from Harris (1997).]

Gastrointestinal absorption of copper is normally regulated by homeostatic mechanisms. It is transported in serum bound initially to albumin and later more firmly to ceruloplasmin and transcuprein. The normal serum level of copper is 120 to 145 µg/L. The bile is the normal excretory pathway and plays a primary role in copper homeostasis. Most copper is stored in liver and bone marrow, where it may be bound to metallothionein. Copper as Cu(II) entering into hepatocytes is initially reduced

and complexed by glutathione prior to binding with metallothionein. Alternatively, copper entering the cell may be exported by a copper ATPase translocase. Copper is not an effective inducer of metallothionein relative to zinc or cadmium. Nevertheless, copper bound to metallothionein is thought to be a normal storage form of copper, particularly in infancy and childhood. Isolated hepatic cells are protected from copper toxicity by prior induction of metallothionein with zinc. Copper-metallothionein accumulates in lysosomes, facilitating the biliary excretion of copper.

The newborn is dependent on stored copper, which may not be adequate in premature infants. The amount of copper in milk is not enough to maintain adequate copper levels in the liver, lungs, and spleen of the newborn. Tissue levels gradually decline up to about 10 years of age, remaining relatively constant thereafter. Brain levels, on the other hand, tend to almost double from infancy to adulthood. The ratio of newborn to adult liver copper levels shows considerable species difference: human, 15:4; rat, 6:4, and rabbit, 1:6. Since urinary copper levels may be increased by soft water, concentrations of approximately 60 µg/L under these conditions are not uncommon.

Essentiality Copper is a component of all living cells and is associated with many oxidative processes. It is an essential component of several metalloenzymes, including type A oxidases and type b monamine oxidases. Of the type B oxidases, cytochrome *c*-oxidase is probably the most important because it catalyzes a key reaction in energy metabolism. Of the type A oxidases, lysyl oxidase plays a major role in elastin and collagen synthesis. There are two forms of superoxide dismutase. The copper/zinc superoxide dismutase is present in the cytosol of most cells, particularly brain, thyroid, liver, and erythrocytes. Both dismutases scavenger superoxide radical by reducing them to hydrogen peroxide. Impairment of the function of these enzymes is responsible for the various diseases associated with copper deficiency (Chan et al., 1998).

Deficiency Copper deficiency is uncommon in humans. The most susceptibile are low-birth-weight infants and infants who were malnourished after birth. Copper deficiency is manifest clinically by hypochromic, microcytic anemia refractory to iron as well as susceptibility to infections. This deficiency is sometimes accompanied by bone abnormalities. Less frequent manifestations are hypopigmentation of the hair and hypotonia. Molybdenum also influences tissue levels of copper. Biomarkers of copper deficiency include ceruloplasmin and serum copper levels, levels of low-density lipoproteins, and cytochrome oxidase activity.

Toxicity Experimental studies in humans suggest that ingestion of drinking water with >3 mg Cu/L will produce gastrointestinal symptoms including nausea, vomiting, and diarrhea (Pizzaro et al.,1999). Ingestion of large amounts of copper salts, most frequently copper sulfate, may produce hepatic necrosis and death. Epidemiologic studies have not found any relation between copper exposure and cancer (WHO, 1998). Individuals with glucose-6-phosphate deficiency may be at increased risk for the hematologic effects of copper, but there is uncertainty as to the magnitude of the risk (Goldstein et al., 1985).

Wilson's Disease Wilson's disease is characterized by the excessive accumulation of copper in liver, brain, kidneys, and cornea. Serum ceruloplasmin is low and serum copper that is not bound to ceruloplasmin is elevated. Urinary excretion of copper is high. Clinical abnormalities of the nervous system, liver, kidneys, and cornea are related to copper accumulation. The disorder is sometimes referred to as *hepatolenticular degeneration* in reference to effects of copper accumulation in the brain. Patients with Wilson's disease have impaired biliary excretion of copper, which is believed to be the fundamental cause of copper overload. Reversal of abnormal copper metabolism is achieved by liver transplantation, confirming that the defect is in the liver. Genetic studies have identified a linkage between the Wilson's disease locus (WND) and the erythrocyte enzyme esterase D, establishing that the defect is on chromosome 13 (Frydman et al., 1985). The abnormal gene product, WND protein, converts the energy from ATP hydrolysis to cation transport and is responsible for copper secretion from the liver cell into the biliary canaliculus (Tanzi et al., 1993). However, there appears to be several polymorphisms of the defect, which may explain the clinical variability in the disorder. Diagnosis may be suspected with elevated serum copper but must be confirmed by liver biopsy and elevated liver copper (normal 15 to 55 µg/g; Wilson's disease, >250 µg/g to as high as 300 µg/g). Fibroblasts from persons with Wilson's disease have increased intracellular copper when cultured in Eagle's minimum essential medium with fetal bovine serum (Chan et al., 1983). Clinical improvement can be achieved by chelation of copper with penicillamine (Walshe, 1964). Trien [triethylene tetramine (2HCl)] is also effective and has been used in patients with Wilson's disease who have toxic reactions to penicillamine. The antagonistic effect of zinc on copper absorption may also be useful in the treatment of Wilson's disease (Brewer, 1993). An animal model of Wilson's disease, the Long-Evans cinnamon (LEC) rat, has excessive liver copper and diminished biliary excretion (Schilsky et al., 1994).

Menke's Disease Menke's disease, or Menke's "kinky-hair syndrome," is a sex-linked trait characterized by peculiar hair, failure to thrive, severe mental retardation, neurologic impairment, and death usually by 5 years of age. Bones are osteoporotic with flared metaphases of the long bones and bones of the skull. There is extensive degeneration of the cerebral cortex and of white matter. The symptoms result from copper deficiency and effects on copper-containing enzymes. The gene responsible for Menke's disease produces a cation transporting ATPase and has some homologies with the gene responsible for Wilson's disease (Mercer et al., 1993).

Indian Childhood Cirrhosis (ICC) ICC is a peculiar disorder occurring in young children; it is characterized by jaundice due to an insidious but progressive liver disease. Diagnosis is by liver biopsy. Two distinguishing features are a widespread brown orcein staining (copper) and intralobular fibrosis progressing to portal cirrhosis and inflammation (Pradham et al., 1983). Etiology is not known but suspected to be related to bottle feeding of copper contaminated from storage in brass vessels. However, epidemiologic studies suggest an autosomal recessive genetic component because of strong familial occurrence and high consanguinity among affected children (Sethi et al., 1993).

Idiopathic Copper Toxicosis or Non-Indian Childhood Cirrhosis There are scattered reports of a disorder in children similar to ICC occurring in some western countries (WHO, 1998). The largest non-Indian series of cases are reported by Muller et al. (1996) from the Tyrol region of Austria. This group also used copper vessels to store milk, and the incidence of the disorder has declined since replacement of the copper vessels. A number of other cases have been reported from other parts of the world, some with increased amounts of copper in drinking water (Fewtrell et al., 1996).

Iron (Fe)

The major scientific and medical interest in iron[1] is as an essential metal, but toxicologic considerations are important in terms of iron deficiency and accidental acute exposures and chronic iron overload due to idiopathic hemochromatosis or as a consequence of excess dietary iron or frequent blood transfusions. The complex metabolism of iron and mechanisms of toxicity are detailed by Spivey Fox and Rader (1988) and Yip and Dallman (1996).

Toxicokinetics The disposition of iron is regulated by a complex mechanism to maintain homeostasis, mainly involving intake, stores, and loss. Generally, about 2 to 15 percent is absorbed from the gastrointestinal tract, whereas elimination of absorbed iron, is only about 0.01 percent per day (percent body burden or amount absorbed). Iron absorption is influenced by quantity and bioavailability of dietary iron, amount of storage iron, and rate of erythrocyte production. The best-known enhancer is vitamin C (ascorbic acid). Dietary inhibitors of nonheme iron absorption include calcium phosphate, bran, phytic acid, and polyphenols present in some plants. During periods of increased iron need (childhood, pregnancy, or blood loss), absorption of iron is greatly increased. Absorption occurs in two steps: (1) absorption of ferrous ions from the intestinal lumen into the mucosal cells and (2) transfer from the mucosal cell to plasma, where it is bound to transferrin for transfer to storage sites. Transferrin is a b$_1$-globulin with a molecular weight of 75,000 and is produced in the liver. As ferrous ion is released into plasma, it becomes oxidized by oxygen in the presence of ferroxidase I, which is identical to ceruloplasmin. There are 3 to 5 g of iron in the body. About two-thirds is bound to hemoglobin, 10 percent in myoglobin and iron-containing enzymes, and the remainder is bound to the iron storage proteins ferritin and hemosiderin. Exposure to iron induces synthesis of apoferritin, which then binds ferrous ions. The ferrous ion becomes oxidized, probably by histidine and cysteine residues and carbonyl groups. Iron may be released from ferritin by reducing agents. Ascorbic acid, cysteine, and reduced glutathione release iron slowly. Normally, excess ingested iron is excreted, and some is contained within shed intestinal cells and in bile and urine and in even smaller amounts in sweat, nails, and hair. Total iron excretion is usually on the order of 0.5 mg/day.

Iron Deficiency Iron deficiency is the most common nutritional deficiency in the United States and worldwide, affecting older infants, young children, and women of childbearing age. The third National Health and Nutrition Examination Survey 1991–1994 identified about 5 percent of children 1 to 2 years of age as iron- deficient. Infants are born with stores of iron roughly proportional to birth weight. Low-birth-weight infants have less stores than full-term infants, so that iron stores are depleted earlier, often by 2 to 3 months of age. The critical period for iron deficiency is between the ages of 6 months and 2 years. The major manifestation of iron deficiency is anemia, diagnosed in the presence of microcytic hypochromic red blood cells and laboratory evidence of iron deficiency. Iron status is determined by measurement of parameters of iron metabolism. For example, low serum ferritin is evidence of iron deficiency. A rise in hemoglobin levels should occur promptly after iron administration. Other effects of iron deficiency include impaired intellectual development, decreased resistance to infection, and possibly increased susceptibility to lead and cadmium toxicity.

Iron Overload With excess exposure to iron or iron overload, there may be a further increase in ferritin synthesis in hepatic parenchymal cells. In fact, the ability of the liver to synthesize ferritin exceeds the rate at which lysosomes can process iron for excretion. Lysosomes convert the protein from ferritin to hemosiderin, which

then remains in situ. The formation of hemosiderin from ferritin is not well understood, but it seems to involve denaturation of the apoferritin molecule. With increasing iron loading, ferritin concentration appears to reach a maximum, and a greater portion of iron is found in hemosiderin. Both ferritin and hemosiderin are, in fact, storage sites for intracellular metal and are protective in that they maintain intracellular iron in bound form. A portion of the iron taken up by cells of the reticuloendothelial system enters a labile iron pool available for erythropoiesis and becomes stored as ferritin.

Toxicity Acute iron poisoning from accidental ingestion of iron-containing medicines is the most common cause of acute iron toxicity. It most often occurs in children. A decrease in occurrences of this type followed the use of "childproof" lids on prescription medicines. Severe toxicity occurs after the ingestion of more than 0.5 g of iron or 2.5 g of ferrous sulfate. Toxicity becomes manifest with vomiting 1 to 6 h after ingestion. This is followed by signs of shock and metabolic acidosis, liver damage, and coagulation defects within the next couple of days. Late effects may include renal failure and hepatic cirrhosis. The mechanism of the toxicity is thought to begin with acute mucosal cell damage and absorption of ferrous ions directly into the circulation, which causes capillary endothelial cell damage in the liver.

Chronic iron toxicity or iron overload in adults is a more common problem. There are three basic ways in which excessive amounts of iron can accumulate in the body. The first circumstance is hereditary hemochromatosis due to abnormal absorption of iron from the intestinal tract. The frequency of homozygosity is approximately 3 to 4 per 1000 in populations of European extraction. The heterozygote (incidence about 1 in 10) may also have a lesser degree of increased iron absorption. A second possible cause of iron overload is excess dietary iron. The African Bantu who prepares their daily food and brew fermented beverages in iron pots are classic subjects for this form of iron overload. Sporadic other cases occur owing to excessive ingestion of iron-containing tonics or medicines. The third circumstance in which iron overload may occur is from the regular requirement for blood transfusion for some form of refractory anemia and is sometimes referred to as *transfusional siderosis*. The pathologic consequences of iron overload are similar regardless of basic cause. The body iron content is increased to between 20 and 40 g. Most of the extra iron is hemosiderin. The greatest concentrations are in the parenchymal cells of liver and pancreas as well as in endocrine organs and the heart. Iron in reticuloendothelial cells (in the spleen) is greatest in transfusional siderosis. Further clinical effects may include disturbances in liver function, diabetes mellitus, and even endocrine disturbances and cardiovascular effects. At the cellular level, increased lipid peroxidation occurs, with consequent membrane damage to mitochondria, microsomes, and other cellular organelles. There is epidemiologic evidence for a relationship between iron levels and cardiovascular disease (Salomen et al., 1992). It has also been suggested that women who are heterozygous for hereditary hemochromatosis are at increased risk for cardiovascular disease (Roest et al., 1999). Experimental evidence suggests that iron may contribute to lipid peroxidation in an early step in the formation of atherosclerotic lesions. Macrophages and endothelial cells are involved, but the details of the mechanism are only speculative (de Valk et al., 1999). Iron loading in mice can alter and damage cellular organelles in heart muscle, including mitochondria, lysosomes, and endoplasmic reticulum (Bartfay et al., 1999).

Treatment of acute iron poisoning is directed toward removal of the ingested iron from the gastrointestinal tract by inducing vomiting or gastric lavage and providing corrective therapy for systemic effects such as acidosis and shock. Desferrioxamine is the chelating agent of choice for the treatment of iron overload absorbed from acute exposure as well as for removal of tissue iron in hemosiderosis. Repeated phlebotomy can remove as much as 20 g of iron per year. Inhalation of iron oxide fumes or dust by workers in metal industries may result in deposition of iron particles in lungs, producing an x-ray appearance resembling silicosis. These effects are seen in hematite miners, iron and steelworkers, and arc welders. Hematite is the most important iron ore (mainly Fe_2O_3).

Magnesium (Mg)

Magnesium[1] is a nutritionally essential metal that can be responsible for adverse health effects due to deficiency or excess (Birch, 1995; Shils, 1996). Nuts, cereals, seafoods, and meats are high dietary sources of magnesium. The drinking water content of magnesium increases with the hardness of the water. Magnesium citrate, oxide, sulfate, hydroxide, and carbonate are widely taken as antacids or cathartics. Magnesium hydroxide, or milk of magnesia, is one of the constituents of the universal antidote for poisoning. Topically, the sulfate also is used widely to relieve inflammation. Magnesium sulfate may be used as a parenterally administered central nervous system depressant. Its most frequent use for this purpose is in the treatment of seizures associated with eclampsia of pregnancy and acute nephritis.

Toxicokinetics Magnesium is a cofactor of many enzymes involved in intermediary metabolism. In the glycolytic cycle converting glucose to pyruvate, there are seven key enzymes that require Mg^{2+}. It is also involved in the citric acid cycle and in the beta oxidation of fatty acids. Magnesium salts are poorly absorbed from the intestine. In cases of overload, this may be due in part to their dehydrating action. Magnesium is absorbed mainly in the small intestine; the colon also absorbs some. Calcium and magnesium are competitive with respect to their absorptive sites, and excess calcium may partially inhibit the absorption of magnesium. Magnesium is excreted into the digestive tract by the bile and pancreatic and intestinal juices. A small amount of radiomagnesium given intravenously appears in the gastrointestinal tract. The serum levels are remarkably constant. There is an apparent obligatory urinary loss of magnesium, which amounts to about 12 mg/day, and the urine is the major route of excretion under normal conditions. Magnesium found in the stool is probably not absorbed. Magnesium is filtered by the glomeruli and reabsorbed by the renal tubules. In the blood plasma, about 65 percent is in the ionic form while the remainder is bound to protein. The former is that which appears in the glomerular filtrate. Excretion also occurs in the sweat and milk. As in the case of other essential elements, physiologic homeostatic mechanisms prevent large fluctuations in blood through changes in absorption and excretion. Approximately 70 percent of serum magnesium is ultrafilterable, and about 95 percent of filtered magnesium is reabsorbed, an important factor in maintaining magnesium homeostasis. Endocrine activity—particularly of the adrenocortical hormones, aldosterone, and parathyroid hormone—also has an effect on magnesium levels, although this may be related to the interaction of calcium and magnesium. Tissue distribution studies indicate that of the 20-g body burden, the majority is intracellular in the bone and muscle including the myocardium, but some magnesium is present in every cell of the body. Bone concentration of magnesium decreases as calcium increases.

Deficiency Deficiency may occur and, in humans, is usually a complication of various disease states that cause intake of magnesium to be impaired (malabsorption syndromes), renal dysfunction with excessive losses, and endocrine disorders. Deficiency in humans causes neuromuscular irritability, frank tetany, and even convulsions. There is a decrease in the magnesium content of ischemic hearts, but the cause and significance are not known.

Deficiency in animals may result from ingestion of grasses grown in magnesium-poor soil. The deficiency is called *grass staggers* in cattle and *magnesium tetany* in calves.

Toxicity Magnesium toxicity can occur when magnesium-containing drugs, usually antacids, are ingested chronically by individuals with serious renal insufficiency. The toxic effects may progress from nausea and vomiting to hypotension, electrocardiograph abnormalities, and secondary central nervous system effects. Magnesium toxicity can be counteracted with calcium infusion.

With industrial exposures, increases of serum magnesium up to twice the normal levels have failed to produce ill effects but were accompanied by calcium increases. Freshly generated magnesium oxide can cause metal fume fever if inhaled in sufficient amounts, analogous to the effect caused by zinc oxide. Both zinc and magnesium exposure of animals produced similar effects.

Manganese (Mn)

Manganese[1] is a transitional metal and can exist in 11 oxidation states, from –3 to +7. The most common valences are +2, +4, and +7. The most common valence in biological systems is +2; +4 is present as MnO_2. Mn^{3+} is also important in biological systems. It is the oxidative state of manganese in superoxide dismutase and is probably the form that interacts with Fe^{3+}. Cycling between Mn^{2+} and Mn^{3+} may be potentially deleterious to biological systems because it can involve the generation of free radicals. Manganese is an essential element and is a cofactor for a number of enzymatic reactions, particularly those involved in phosphorylation, cholesterol, and fatty acids synthesis. Manganese is present in all living organisms. The principal source of intake is food. Vegetables, the germinal portions of grains, fruits, nuts, tea, and some spices are rich in manganese (Keen and Zidenberg-Cherr, 1996). Daily manganese intake ranges from 2 to 9 mg. There is current interest in the toxicology of manganese because of potential exposure from the use of the manganese-containing fuel additive MMT (methylcyclopentadienyl Mn tricarbonyl) as a replacement for lead containing additives in gasoline.

The industrial use of manganese has also expanded in recent years as a ferroalloy in the iron industry and as a component of alloys used in welding (Apostoli et al., 2000).

Toxicokinetics Gastrointestinal absorption is less than 5 percent and occurs throughout the length of the small intestine. Manganese is transported in plasma bound to a b_1-globulin, thought to be transferrin, and is widely distributed in the body. Manganese concentrates in mitochondria, so that tissues rich in these organelles—including the pancreas, liver, kidneys, and intestines—have the highest concentrations of manganese. The biological half-life in the body is 37 days. Manganese readily crosses the blood-brain barrier and its half-life in the brain is longer than in the whole body. Manganese is eliminated in the bile and is reabsorbed in the intestine, but the principal route of excretion is with feces.

Deficiency Manganese deficiency has been produced in many species of animals, but so far there are questions about whether deficiency has actually been demonstrated in humans (WHO, 1996). Deficiency in animals results in impaired growth, skeletal abnormalities, and disturbed reproductive function.

Toxicity There are few reported cases of manganese toxicity from oral ingestion. Homeostatic mechanisms involving the liver and biliary excretion, gastrointestinal mechanisms for excreting excess manganese, and perhaps the adrenal cortex, plus the tendency for extremely large doses of manganese salts to cause gastrointestinal irritation, account for the lack of systemic toxicity following oral administration or dermal application. The most common form of manganese toxicity is the result of chronic inhalation of airborne manganese in mines, steel mills, and some chemical industries (ATSDR, 1997). Industrial toxicity from inhalation exposure, generally to manganese dioxide in mining or manufacturing, is of two types: The first, manganese pneumonitis, is the result of acute exposure. Men working in plants with high concentrations of manganese dust show an incidence of respiratory disease 30 times greater than normal. Pathologic changes include epithelial necrosis followed by mononuclear proliferation.

The second and more serious type of disease resulting from chronic inhalation exposure to manganese dioxide, generally over a period of more than 2 years, involves the central nervous system. Chronic manganese poisoning (manganism) produces a neuropsychiatric disorder characterized by irritability, difficulty in walking, speech disturbances, and compulsive behavior that may include running, fighting, and singing. If the condition persists, a mask-like face, retropulsion or propulsion, and a Parkinson-like syndrome develop. The outstanding feature of manganese encephalopathy has been classified as severe selective damage to the subthalamic nucleus and pallidum. These symptoms and the pathologic lesions—degenerative changes in the basal ganglia—make the analogy to Parkinson's disease feasible. In addition to the central nervous system changes, liver cirrhosis is frequently observed. Victims of chronic manganese poisoning tend to recover slowly, even when removed from the excessive exposure. Metal-sequestering agents have not produced remarkable recovery; L-dopa, which is used in the treatment of Parkinson's disease, has been more consistently effective in the treatment of chronic manganese poisoning than in Parkinson's disease (Cotzias et al., 1971).

The oral absorption of manganese is increased by iron deficiency, which may contribute to variations in individual susceptibility. The syndrome of chronic nervous system effects has been duplicated only in squirrel monkeys by inhalation or intraperitoneal injection.

Molybdenum (Mo)

Molybdenum[1] is an essential element and may exist in multiple oxidation states, +3, +4, +5, and +6, facilitating electron transfer. Molybdenum concentration of food varies considerably, depending on the environment in which the food was grown. Molybdenum is added in trace amounts to fertilizers to stimulate plant growth. The average daily human intake in food ranges from 120 to 240 µg/day. The human requirement for molybdenum is low and easily provided by a common U.S. diet; the provisional recommended range for the dietary intake of molybdenum is based on average reported intakes. The concentration of molybdenum in urban air is minimal. Most public water supplies contribute between 2 and 8 µg/day. Excess exposure can result in toxicity to animals and humans (NRC, 1989).

The most important mineral source of molybdenum is molybdenite (MoS_2). The United States is the major world producer of molybdenum. The industrial uses of this metal include the manufacture of high temperature–resistant steel alloys for use in gas turbines and jet aircraft engines and in the production of catalysts, lubricants, and dyes.

Toxicokinetics The soluble hexavalent compounds are well absorbed from the gastrointestinal tract into the liver (Nielson, 1996). It is a component of xanthine oxidase, which has a role in purine metabolism and has been shown to be a component of aldehyde oxidase and sulfite oxidase. In plants, it is necessary for the fixing of atmospheric nitrogen by bacteria at the start of protein synthesis. Increased molybdenum intake in experimental animals has been shown to increase tissue levels of xanthine oxidase. In humans, molybdenum is contained principally in the liver, kidneys, fat, and blood. Of the approximate total of 9 mg in the body, most is concentrated in the liver, kidneys, adrenal, and omentum. More than 50 percent of molybdenum in the liver is contained in a nonprotein cofactor bound to the mitochondrial outer membrane and can be transferred to an apoenzyme, transforming it into an active enzyme molecule. The molybdenum level is relatively low in the newborn and increases until age 20, declining in concentration thereafter. More than half of the molybdenum excreted is in the urine. The blood level is in association with the level in red blood cells. The excretion of molybdenum is rapid, mainly as molybdate. Excesses may be excreted also by the bile, particularly the hexavalent forms.

Deficiency Molybdenum deficiency has been described in various animal species and consists of disturbances in uric acid metabolism and sulfite metabolism, but the clinical manifestation of molybdenum deficiency in humans is still evolving. Molybdenum is a component of sulfite oxidase, which converts sulfite to sulfates. Molybdenum deficiency resulting from parenteral methionine therapy has been described and is characterized by mouth and gum disorders as well as hypouricemia, hyperoxypurinemia, mental disturbances, and coma. The symptoms are indicative of a defect in sulfur-containing amino acid metabolism; supplementation with ammonium molybdate improved the clinical condition, reversed the sulfur handling defect, and normalized uric acid production. A rare genetic disease characterized by a deficiency of sulfite oxidase has been identified in humans and is characterized by severe brain damage; mental retardation; dislocation of the ocular lenses; increased output of sulfite, S-sulfocysteine, and thiosulfate; and decreased output of sulfate (Nielson, 1996).

Toxicity Chronic exposure to excess molybdenum in humans is characterized by high uric acid levels in serum and urine, loss of appetite, diarrhea, anemia, and slow growth. A gout-like disease has been observed in inhabitants of a high-molybdenum area of a province of Russia (Chan et al., 1998). Experimental studies have revealed differences in toxicity of molybdenum salts. In nonruminants, intake of 100 to 5000 mg/kg in food and water was required to produce clinical toxicity. In rats, molybdenum trioxide at a dose of 100 mg/kg/day by inhalation was irritating to the eyes and mucous membranes and subsequently lethal. After repeated oral administration at sufficient levels, fatty degeneration of the liver and kidney was induced (Nielson, 1996).

Selenium (Se)

The availability as well as the toxic potential of selenium [1] and selenium compounds is related to their chemical form and, most importantly, to solubility. Selenium occurs in nature and biological systems as selenate (Se^{6+}), selenite (Se^{4+}), elemental selenium (Se^0), and selenide (Se^{22}); deficiency leads to a cardiomyopathy in mammals, including humans (WHO, 1987; Levander and Burk, 1996).

Foodstuffs are a daily source of selenium. Seafoods, especially shrimp, and meat, milk products, and grains provide the largest amounts in the diet. Levels of selenium in river water vary, depending on environmental and geological factors; 0.02 ppm has been reported as a representative estimate. Selenium has also been detected in urban air, presumably from sulfur-containing materials.

Toxicokinetics Absorption of selenium does not appear to be regulated and appears to be very high, above 50 percent, whereas selenites and elemental selenium are virtually insoluble. Because of their insolubility, these forms may be regarded as a form of inert selenium sink. Elemental selenium is probably not absorbed from the gastrointestinal tract. Absorption of selenite is from the duodenum. Monogastric animals have a higher intestinal absorption than ruminants, probably because selenite is reduced to an insoluble form in rumen. Over 90 percent of milligram doses of sodium selenite may be absorbed by humans and widely distributed in organs, with the highest accumulation initially in the liver and kidneys, but appreciable levels remain in the blood, brain, myocardium, skeletal muscle, and testes. Selenium is transferred through the placenta to the fetus, and it also appears in milk. Levels in milk are dependent on dietary intake. Selenium in red cells is associated with glutathione peroxidase and is about three times more concentrated than in plasma. The excretion pattern of a single exposure to selenite appears to have at least two phases, the first being rapid, with as much as 15 to 40 percent of the absorbed dose excreted in the urine the first week. During the second phase there is an exponential excretion of the remainder of the dose, with a half-life of 103 days. The half-life of Se-methionine is 234 days. In the steady state, urine contains about twice as much as feces, and increased urinary levels provide a measure of exposure. Urinary selenium is usually less than 100 µg/L. Excretory products appear in sweat and expired air. The latter may have a garlicky odor due to dimethyl selenide (WHO, 1987).

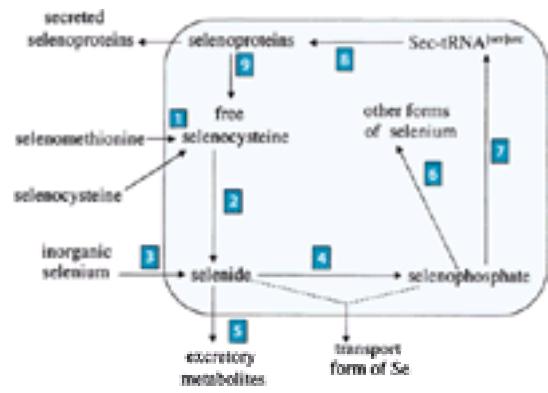
Essentiality Selenates are relatively soluble compounds, similar to sulfates, and are readily taken up by biological systems. Selenium metabolism is regulated to meet several metabolic needs and is outlined in Fig. 23-9.


Figure 23-9. Regulated selenium metabolism.

The box represents the cell. The numbers in the squares indicate (1) the transulfuration pathway, (2) selenocysteine b-lyase, (3) reduction by glutathione, (4) selenophosphate synthetase, (5) methylation, (6) replacement of sulfur in tRNA by selenium, (7) replacement of oxygen in serine with selenium to produce selenocysteine, (8) decoding of UGA in mRNA with insertion of selenocysteine into primary structure of protein, and (9) proteolytic breakdown of proteins. The origin and identity of the transport form of selenium is unknown. It might arise from selenide or selenophosphate, as indicated by the broken lines. [Adapted from Levander and Burk (1996).]

Selenophosphate is an anabolic form of selenium involved in the synthesis of selenoproteins and seleno-tRNAs. Selenoprotein synthesis is regulated transcriptionally by tissue specificity, cell development, and environmental factors. Most selenium in animal tissues is present in two forms, selenomethionein, which is incorporated in place of methionine in a variety of proteins, and selenocysteine, a cofactor for both glutathione peroxidase, an enzyme of the antioxidant defense system and type 1 iodothyronine deiodinase, and selenoprotein P. Both enzymes contain one unit of selenocysteine at each of four catalytic sites. Glutathione peroxidase uses glutathione to reduce peroxides in cells and, in this way, protects membrane lipids and possibly proteins and nucleic acids from damage by oxidants or free radicals. It is present in many tissues and in high concentrations in liver, lung, stomach mucosa, erythrocytes and skeletal muscle and has both extracellular and intracellular forms. Type 1 iodothyronine is present in liver, kidney, and skeletal muscle and catalyzes the conversion of thyroxine (T_4) to triodothyronine (T_3). Deficiency of the cofactor may lead to hypothyroidism in the elderly. Selenoprotein P is an abundant extracellular selenoprotein that contains multiple selenocysteine residues and may have an antioxidant functioning in the extracellular space. Biologically active selenium can be assessed by measuring glutathione peroxidase and selenoprotein P concentration. The requirement for selenium is related to the degree of oxidant activity and the supply of nutrients such as zinc, copper, manganese, iron, and vitamin E, so that increased amounts of these elements increase the need for selenium.

Selenium Deficiency The most extensively documented deficiency of selenium in humans is Keshan disease. This is an endemic cardiomyopathy first discovered in Keshan county in the People's Republic of China in 1935. It occurs most frequently in children under 15 years of age and in women of childbearing age. The disease is characterized clinically by various degrees of cardiomegaly and cardiac decompensation, and the histopathology of the myocardium consists of the degeneration and necrosis of myocardial fibers and their replacement by fibrosis and scar formation (Chen et al., 1980). Occurrence of the disease was invariably associated with a lower content of selenium in the diet of maize and rice than that in grain grown in unaffected areas. The average selenium concentration in the hair of residents of affected areas was 0.122 ± 0.010 ppm versus 0.270 ± 0.066 ppm in the hair of people in unaffected areas. Also, low glutathione peroxidase activities of whole blood in the affected population coincided with low blood selenium levels in affected areas. It was suggested that the low blood selenium content and low blood glutathione peroxidase activity might play a role in the myocardial lesions. Administration of sodium selenite greatly reduced the incidence of the disease—a fact that provides additional support for the role of selenium deficiency in the etiology of the disorder.

Deficiency of selenium in lambs and calves produces congenital "white muscle disease," a form of nutritionally induced muscular dystrophy. Deficiency of selenium produces liver necrosis in rats, a bleeding disorder in poultry, and cellular necrosis in the liver, kidneys, and skeletal and heart muscle in mice, resulting in cardiac failure and death. In each of these entities the health effect is prevented by adding selenium to the diet, so that now there are well-defined dietary requirements for selenium for livestock and poultry (WHO, 1987).

Toxicity Selenium toxicity occurs when the intake exceeds the excretory capacity. The potential toxicity of selenium was first suspected over 50 years ago and, through the years, well-defined syndromes of toxicity have been described in animals and humans living in seminiferous areas where the soil content is relatively rich in selenium, contributing to relatively high selenium in vegetation. Plants vary in their ability to accumulate selenium. Grasses, grains, and most weeds do not accumulate selenium even when grown in high-selenium areas, so that these plants add very little to the selenium content of livestock feed. But there are several plant species that are classified as "selenium accumulators" and they may contain selenium levels of 100 to 10,000 mg/kg. These plants, however, usually grow in nonagricultural areas and when consumed by livestock may, within a few weeks, cause a disease syndrome described as the *blind staggers.* Early symptoms are impaired vision, depressed appetite, and a tendency to wander in circles. This may progress to various degrees of paralysis and death from respiratory failure (Alexander et al., 1987). A more chronic syndrome described in livestock and horses is *alkali disease,* characterized by the loss of vitality, emaciation, deformity and shedding of hoofs, loss of long hair, and erosion of joints of long bones. Similar syndromes have been described in sheep and dogs. The areas of the world where human toxicity has been noted include several areas of China, areas of Venezuela, and parts of the state of South Dakota in the United States. A study of 70 families living in three counties of South Dakota and in one county of northern Nebraska, from farms where alkali disease in cattle had been recognized, found bad teeth, a yellowish discoloration of the skin, skin eruptions, and diseased nails of the fingers and toes in various family members. A syndrome now believed to be the result of selenium intoxication was discovered in 1961 to affect about 50 percent of 248 inhabitants of five villages in the Hubei province of China (Yang et al., 1983). There are similarities between this syndrome and the chronic effects in livestock and horses. The main symptoms were brittle hair with intact follicles, brittle nails with spots and streaks, and skin lesions on the backs of hands and feet and on the forearms, legs, and the back of the neck. These areas were red and swollen and contained blisters. In addition, 13 of 22 people in one village had neurologic symptoms, including peripheral anesthesia, pain, and hyperreflexia. In some individuals, these symptoms progressed to numbness, convulsions, paralysis, and altered motor function. Selenium has produced loss of fertility and congenital defects and is considered embryotoxic and teratogenic on the basis of animal experiments (WHO, 1987).

Biological Interactions Selenium has various biological interactions, which may affect the toxicity or deficiency of selenium as well as toxicity of another metal. If the intake of vitamin E is low, susceptibility to selenium toxicity is increased in experimental animals, whereas resistance is increased if vitamin E intake is increased. Selenium also forms insoluble complexes with silver, copper, cadmium, and mercury. Feeding silver to experimental animals results in tissue accumulations of both metals and symptoms of selenium deficiency may occur. Selenium forms complexes with copper, and toxicity to either selenium or copper is influenced by the intake of both metals. Selenium may prevent the toxic effects of cadmium on rat testicular tissue and dietary selenium can reduce the toxic effects of methyl mercury. Workers in a mercury mine and local inhabitants accumulate equimolar amounts of mercury and selenium in the pituitary and thyroid glands and in the brain. And finally, arsenite increases the biliary excretion of selenium, enhancing selenium excretion in urine. The mechanisms for these interactions are only partially understood, but their occurrence certainly influences the determination of safe and toxic levels of selenium for persons in the general population (WHO, 1987, 1996).

Anticarcinogenicity Selenium has been suspected of being a human carcinogen, but further studies have shown that it has anticarcinogenic properties (WHO, 1987).

Epidemiologic investigations have indicated a decrease in human cancer death rates (age- and sex-adjusted) correlated with an increasing selenium content of forage crops. In addition, experimental evidence supports the antineoplastic effect of selenium with regard to benzo[a]pyrene- and benzanthracene-induced skin tumors in mice, *N*-2-fluorenylacetamide- and diethylaminoazobenzene-induced hepatic tumors in rats, and spontaneous mammary tumors in mice. A possible mechanism of the protective effects of selenium has been postulated to involve inhibition of the formation of malonaldehyde, a product of peroxidative tissue damage, which is carcinogenic. In addition to the apparent protective effect against some carcinogenic agents, selenium is an antidote to the toxic effects of other metals, particularly arsenic, cadmium, mercury, copper, and thallium. The mechanism underlying these interactions is unknown.

Dose Effect in Humans Because of the potential for producing adverse health effects from both selenium excess and from deficiency, risk assessment must include both possible effects. The National Research Council's Food and Nutrition Board (NAS, 1980) recommends 200 μg/day as the maximum safe upper limit for an adult human's intake. Metabolic balance studies on North American adults showed that 70 μg/day for the standard human (70 kg body weight) appears to be required to maintain selenium balance and presumably to satisfy selenium requirements in these subjects. Chinese data indicate that daily intake of less than 20 μg can cause Keshan disease. Countries such as New Zealand have areas where daily intake is around 30 μg, but there is no evidence that this has a significant effect on the

health of the people living in these areas. The critical level for prevention of deficiency, therefore, is 20 µg/day.

Zinc (Zn)

Zinc[1] is a nutritionally essential metal, and a deficiency results in severe health consequences. At the other extreme, excessive exposure to zinc is relatively uncommon and occurs only at very high levels. Zinc is ubiquitous in the environment, so that it is present in most foodstuffs, water, and air. The zinc content of substances in contact with galvanized copper or plastic pipes may be increased. Seafoods, meats, whole grains, dairy products, nuts, and legumes are high in zinc, while vegetables are lower, although zinc applied to soil is taken up by growing vegetables. Atmospheric zinc levels are higher in industrial areas (NRC, 2000).

Essentiality and Metabolism More than 200 metalloenzymes belonging to six major categories—including oxidoreductases, transferases, hydrolases, lyases, isomerases, and ligases—require zinc as a cofactor (Cousins, 1996). Zinc induces the synthesis of metallothionein, which is a factor in regulating the metabolism of zinc, including absorption and storage (Nordberg, 1998; Miles et al., 2000). Zinc is a functional component of several proteins that contribute to gene expression and regulation of genetic activity. Zinc chelates with cysteine and/or histidine in a tetrahedral configuration forming looped structures, called "zinc fingers," which bind to specific DNA regions and are bound in various transcription factors such as steroid hormone receptors and polymerase (Berg and Shi, 1996; Wang et al., 1997). Zinc has a normal physiologic role in membrane stabilization by binding ligands in membranes for maintenance of the normal structural geometry of the protein and lipid components (Cousins, 1996). Zinc is essential for the development and normal function of the nervous system.

Zinc has a role in immune function and the cytokines, primarily interleukin-1 (IL-1) and IL-6, influence zinc metabolism (Cousins, 1996). Zinc is required for optimal vitamin A metabolism. Although the mechanisms for intestinal absorption of iron and zinc differ, they appear to be inverse. There is a reciprocal relationship between plasma levels of zinc and copper, to the degree that massive zinc ingestion may produce copper deficiency and large doses of elemental zinc result in negative copper balance in patients with Wilson's disease. The metabolisms of zinc and calcium are interrelated in that zinc is required for normal calcification of bone (Leek et al., 1988).

Toxicokinetics The average daily intake for Americans is approximately 12 to 15 mg, mostly from food. Gastrointestinal absorption of zinc is homeostatically controlled and is probably a carrier-mediated process (Cousins, 1996; WHO, 1996). It is influenced by prostaglandins E_2 and F_2 and is chelated by picolinic acid, a tryptophan derivative. A deficiency of pyridoxine or tryptophan depresses zinc absorption. Within the mucosal cell, zinc induces metallothionein synthesis and, when the cell is saturated, this may depress zinc absorption. In the blood, about two-thirds of the zinc is bound to albumin and most of the remainder is complexed with b_2-macroglobulin. Zinc enters the gastrointestinal tract as a component of metallothionein secreted by the salivary glands, intestinal mucosa, pancreas, and liver. The normal basic physiologic requirement for absorbed zinc is 1.4 mg/day. Assuming 20 percent absorption, a daily diet of 7 mg will meet the basic requirement for males, but the requirement for females is greater during pregnancy and lactation. Adaptation to low dietary zinc will increase gastrointestinal absorption to as much as 50 percent. Bile is the major route of zinc excretion. Homeostatic control of zinc is maintained primarily by fecal excretion of endogenous zinc. Urinary excretion of zinc is low and not significantly influenced by dietary zinc. Zinc concentration in tissues varies widely. The liver receives up to about 40 percent of a tracer dose, declining to about 25 dto cent within 5 days. Liver concentration is influenced by humoral factors, including adrenocorticotropic hormone, parathyroid hormone, and endotoxin. In the liver as well as in other tissues, zinc is bound to metallothionein. The greatest concentration of zinc in the body is in the prostate, probably related to the rich content of zinc-containing enzyme acid phosphatase.

Assessment of Zinc Status The concentration of zinc in the plasma is not a sensitive indicator of zinc status and does not reflect the dose-response relationship between zinc levels in the body and effects at various target sites. Other approaches include measurement of zinc levels in hair and nails and in urine and zinc in shed teeth from children. The most reliable index of zinc status is the determination of zinc balance—that is, the relationship between intake and excretion—but these measurements require the facilities of a metabolic research unit in order to control dietary zinc intake while measuring excretion. An alternative approach is to identify a biomarker sensitive to changes in zinc status, such as metallothionein, serum alkaline phosphatase, and erythrocyte superoxide dismutase. The thymic hormone thymulin, which is involved in the differentiation of T cells, is zinc-dependent (Prasad et al., 1988). Reduced activity of this hormone may provide an early indication of mild zinc deficiency.

Deficiency Zinc deficiency results in a wide spectrum of clinical effects depending on age, stage of development, and deficiencies of related metals. Zinc deficiency in humans was first characterized by Prasad (1983) in adolescent Egyptian boys with growth failure and delayed sexual maturation accompanied by protein-calorie malnutrition, pellegra, and iron and folate deficiency. Zinc deficiency in the newborn may be manifest by dermatitis, loss of hair, impaired healing, susceptibility to infections, and neuropsychological abnormalities. Dietary inadequacies coupled with liver disease from chronic alcoholism may be associated with dermatitis, night blindness, testicular atrophy, impotence, and poor wound healing. Other chronic clinical disorders—such as ulcerative colitis and the malabsorption syndromes, chronic renal disease, and hemolytic anemia—are also associated with zinc deficiency. Many drugs affect zinc homeostasis, particularly metal-chelating agents and some antibiotics, such as penicillin and isoniazid. Less common zinc deficiency may occur with myocardial infarction, arthritis, and even hypertension (Walshe et al., 1994). Latent zinc deficiency is the most common zinc deficiency syndrome, implying marginally adequate zinc status. This may be the result of zinc-deficient dietary habits, particularly among young children or the elderly, or may occur as a consequence of a disease state (USDA, 1986). Zinc deficiency in growing children may result in poor growth performance, which has been shown to be improved with zinc supplementation (Prentice, 1997).

Zinc in Neurologic Disorders Because of its requirement as a cofactor for numerous enzymes and proteins, zinc has been implicated in various degenerative diseases of the nervous system (Prasad, 1995). It has been suggested that zinc modulates the solubility of b-amyloid in the brain and contributes to the formation of degenerative plaques in brains of patients with Alzheimer's disease. Also, zinc deficiency may alter activity of the antioxidant enzyme Cu-Zn-superoxide dismutase (SOD), resulting in excess free radicals that are damaging to cell membranes (Cuajungco and Lees, 1997). A genetic abnormality of one of the forms of Cu-Zn SOD may be the basis of a familial form of amyotrophic lateral sclerosis (Lyons, 1996).

Toxicity Acute zinc toxicity from excessive ingestion is uncommon, but gastrointestinal distress and diarrhea have been reported following ingestion of beverages standing in galvanized cans or from the use of galvanized utensils. However, evidence of hematologic, hepatic, or renal toxicity has not been observed in individuals ingesting as much as 12 g of elemental zinc over a 2-day period.

With regard to industrial exposure, metal fume fever resulting from inhalation of freshly formed fumes of zinc presents the most significant effect. This disorder has been most commonly associated with inhalation of zinc oxide fumes, but it may be seen after inhalation of the fumes of other metals, particularly magnesium, iron, and copper. Attacks usually begin after 4 to 8 h of exposure—chills and fever, profuse sweating, and weakness. Attacks usually last only 24 to 48 h and are most common on Mondays or after holidays. The pathogenesis is not known, but it is thought to result from endogenous pyrogen release due to cell lysis. Extracts prepared from tracheal mucosa and from the lungs of animals with experimentally induced metal fume fever produce similar symptoms when injected into other animals. Exposure of guinea pigs for 3 h/day for 6 consecutive days to 5 mg/m^3 of freshly formed ultrafine zinc oxide (the recommended threshold limit value) produced decrements in lung volumes and carbon monoxide diffusing capacity that persisted for 72 h after exposure. These functional changes were correlated with microscopic evidence of interstitial thickening and cellular infiltrate in alveolar ducts and alveoli (Lam et al., 1985).

Carcinogenicity Epidemiologic studies of workers in lead industries have not found any evidence of a relationship between zinc and cancer (Logue et al., 1982). Testicular tumors have been produced by direct injection in rats and chickens. This effect is probably related to the concentration of zinc normally in the gonads and may be hormonally dependent (Walshe et al., 1994).

METALS RELATED TO MEDICAL THERAPY

Metals considered in this group include aluminum, bismuth, gold, lithium, and platinum. Metals at one time were used to treat a number of human ills, particularly heavy metals like mercury and arsenic. Gold salts are still useful for the treatment of forms of rheumatism, and organic bismuth compounds are used to treat gastrointestinal disturbances. Lithium has become an important aid in the treatment of depression. The toxicologic hazards from aluminum are not from its use as an antacid but rather from the accumulations that occur in bone and from neurotoxicity in patients with chronic renal failure receiving hemodialysis therapy. A more recent concern regarding the potential neurotoxicity of aluminum involves its relationship to Alzheimer's dementia and its increase in bioavailability from changes in soil and water pH from acid rain. Platinum is receiving attention as an antitumor agent. Barium and gallium are used as radiopaque and radiotracer materials, respectively, and gallium is used for treating hypercalcemia.

Aluminum (Al)

Aluminum[1] is the most abundant metal and the third most abundant element in the earth's crust. Due to its high reactivity, aluminum is not found in the free state in

nature. All the chemical compounds involve aluminum in the +3 valence state (Al^{3+}). As a hard trivalent ion, Al^{3+} binds strongly to oxygen-donor ligands such as citrate and phosphate. The chemistry of aluminum compounds is complicated by a tendency to hydrolyze and form polynuclear species, many of which are sparingly soluble (Harris et al., 1996).

Aluminum has, until recently, existed predominantly in forms that are not available to humans and most other species. Acid rain, however, has dramatically increased the amount of aluminum appearing in biological ecosystems, resulting in well-described destructive effects on fish and plant species. However, it is not bioaccumulated to any significant extent except in the tea plant.

Aluminum has many uses, mainly in the form of alloys in packaging, building, construction, transportation, and electrical applications. Over 95 percent of beer and carbonated drinks are packaged in two-piece aluminum cans. Cooking in aluminum utensils results in the transfer of aluminum to food. Human exposure to aluminum comes from food and drinking water as well as from pharmaceuticals. The normal average daily intake is 1 to 10 mg for adults (Greger, 1992).

Toxicokinetics Aluminum is poorly absorbed following either oral or inhalation exposure and is essentially not absorbed dermally. Inhalation of particulate aluminum may result in direct transfer to brain tissue via the olfactory system (Roberts 1986; Perl and Good, 1987). Approximately 0.1 percent of aluminum in the diet is absorbed, but this figure may rise to 1 percent depending on speciation. Absorption from the gut depends largely on pH and the presence of complexing ligands, particularly carboxylic acids, which are absorbable. For example, intestinal absorption is enhanced in the presence of citrate. However, the citrate complex is not itself absorbed. Apparently citrate makes aluminum available to other transport pathways across the gastrointestinal (GI) tract (Jouhanneau et al., 1997). Silicon is a potent inhibitor of GI absorption of aluminum and may also accelerate urinary excretion (Flaten et al, 1993). It probably interacts with aluminum to form poorly absorbed hydroxyalumino-silicates.

Biological speciation is also of major importance in distribution, and excretion of aluminum in mammals. In plasma, 80 to 90 percent of aluminum binds to transferrin, an iron-transport protein for which there are receptors in many body tissues. Based on potentiometric and nuclear magnetic resonance studies, it is predicted that the remainder of aluminum in plasma is in the form of small-molecule hydroxy species and small complexes with carboxylic acids, phosphate, and, to a lesser degree, amino acids (DeVoto and Yokel, 1994).

Bone and lung have the highest concentrations of aluminum, suggesting that bone may be a sink for aluminum. It does not normally accumulate in blood to any great extent (Ganrote, 1986). It is removed from blood by the kidneys and excreted in urine. Uremic animals and humans have higher-than-normal levels of aluminum in spite of increased urinary clearance.

Aluminum compounds can affect absorption of other elements in the gastrointestinal tract and alter intestinal function. Aluminum inhibits fluoride absorption and may decrease the absorption of calcium and iron compounds and salicylic acid, which, in turn, may affect the absorption of aluminum (Exley et al., 1996). The absorption of cholesterol may be inhibited by forming an aluminum pectin complex that binds fats to nondigestible vegetable fibers (Nagyvary and Bradbury, 1977). The binding of phosphorus in the intestinal tract can lead to phosphate depletion and osteomalacia. Aluminum may alter gastrointestinal tract motility by inhibition of acetylcholine-induced contractions and may be the explanation of why aluminum-containing antacids often produce constipation.

Toxicity In cases of human toxicity, the target organs are the lung, bone, or central nervous system. Aluminum affects the same target organs in animals as well as producing developmental effects. In addition, aluminum released into bodies of fresh water via the action of acid rain kills fish by damaging the gills (Flaten et al., 1993).

Lung and Bone Toxicity Occupational exposure to aluminum dusts can produce lung fibrosis in humans. The effects are probably due to lung overload caused by excessive deposits of dust (Morrow, 1992). Osteomalacia has been associated with excessive intake of aluminum-containing antacids in otherwise healthy individuals; this is assumed to be due to interference with intestinal phosphate absorption. Osteomalacia also can occur in uremic patients exposed to aluminum in the dialysis fluid. In these patients, osteomalacia may be a direct effect of aluminum on bone mineralization as bone levels are high.

Neurotoxicity Aluminum has markedly different effects on animals at different points in their life span and in different species. The normal concentration of aluminum in the mammalian brain is approximately 1 to 2 μg/g. In certain aluminum-sensitive species, such as cats and rabbits, increased aluminum by intrathecal infusion so that brain concentration is greater than 4 μg/g induces a characteristic clinical and pathologic response. Initially, animals show subtle behavioral changes, including learning and memory deficits and poor motor function. These changes progress to tremor, incoordination, weakness, and ataxia. This is followed by focal seizures and death within 3 or 4 weeks of initial exposure. With lesser doses, there is longer survival but no recovery (DeBoni et al., 1976).

The most prominent early pathologic change is an accumulation of neurofibrillary tangles (NFT) in cell body, proximal axons, and dendrites of neurons of many brain regions. This is associated with loss of synapses and atrophy of the dendritic tree. Not all species show this reaction to aluminum, however. The rat fails to develop NFTs or encephalopathy and the monkey develops these only after more than a year following aluminum infusion. NFTs are found primarily in large neurons such as Purkinje cells of the cerebellum and large neurons of the cerebral cortex. There is marked reduction in the numbers of neurotubules and the rate of cytoplasmic transport with impairment of intracellular transport. Aluminum also interacts with neuronal chromatin or DNA and is associated with a decreased rate of DNA synthesis. RNA polymerase activity is also reduced.

Aluminum competes with or alters calcium metabolism in several organ systems including the brain. Brain tissue calcium rises following aluminum exposure. Aluminum also binds to calmodulin and induces changes in its structure, leading to the suggestion that aluminum impairs the function of calmodulin as a calcium regulator. While these studies in animals have provided some insights into the mechanisms of the neurotoxicity of aluminum in experimental models, the relationship to human disease is presently uncertain (Siegel and Hagu, 1983; Bizzi and Gambetti, 1986; Birchall and Chappel, 1988).

Human Dementia Syndromes *Dialysis Dementia* A progressive, fatal neurologic syndrome has also been reported in patients on long-term intermittent hemodialysis treatment for chronic renal failure (Alfrey, 1993). The first symptom in these patients is a speech disorder followed by dementia, convulsions, and myoclonus. The disorder, which typically arises after 3 to 7 years of dialysis treatment, may be due to aluminum intoxication. The aluminum content of brain, muscle, and bone tissues increases in these patients. Sources of the excess aluminum may be from oral aluminum hydroxide commonly given to these patients or from aluminum in dialysis fluid derived from the tap water used to prepare the dialysate fluid. The high serum and aluminum concentrations may be related to increased parathyroid hormone, which is due to the low blood calcium and osteodystrophy common in patients with chronic renal disease. The syndrome may be prevented by avoidance of the use of aluminum-containing oral phosphate binders and by monitoring of aluminum in the dialysate. Chelation of aluminum may be achieved with use of desferrioxamine, and progression of the dementia may be arrested or slowed (Wills and Savory, 1983).

Amyotrophic Lateral Sclerosis and Parkinsonism-Dementia Syndromes of Guam (Guam ALS-PD Complex) The Chamorro peoples of the Marina Islands in the western Pacific Ocean, particularly Guam and Rota, have an unusually high incidence of neurodegenerative diseases associated with nerve cell loss and neurofibrillary degeneration of the Alzheimer's type. Garruto et al. (1984) noted that the volcanic soils of the regions of Guam with a high incidence of ALS-PD contained high concentrations of aluminum and manganese and were low in calcium and magnesium. They postulated that a low intake of calcium and magnesium induced high secondary hyperparathyroidism, resulting in an increase in calcium, aluminum, and other toxic metals, resulting in neuronal injury and death. How and why aluminum enters the brain of these people is unclear. A recent study of mineral content of food did not indicate high exposure to aluminum or low dietary calcium (Crapper-McLachlan et al., 1989). These authors suggest that the diet of the inhabitants of Guam may be the source of the aluminum, particularly through the respiratory tract. Perl and Good (1987) have shown that aluminum may be taken up through nasal-olfactory pathways. On the other hand, the consumption of the neurotoxic seed of the false sago palm tree may also play a role in the prevalence of ALS in these areas.

Alzheimer's Disease A possible relationship between aluminum and Alzheimer's disease has been a matter of speculation for many decades. The basis for this relationship is the finding of increased aluminum levels in Alzheimer brains, neurofibrillary lesions in experimental animals, and the fact that aluminum is associated with various components of the pathologic lesions in Alzheimer brain tissue. However, elevated aluminum levels in Alzheimer brains may be a consequence and not a cause of the disease. The reduced blood-brain barrier in Alzheimer's might allow more aluminum into the brain (Banks et al., 1988; Liss and Thornton, 1986; Shore and Wyatt, 1983). Also, recent studies have raised the possibility that the staining methods in earlier studies may have lead to aluminum contamination (Makjanic et al., 1998). Furthermore, the neurofibrillary tangles seen in aluminum encephalopathy differ structurally and chemically from those in Alzheimer's (Goyer, 1996).

Epidemiologic and case-control studies examining the role of aluminum exposure in Alzheimer's disease arrive at conflicting conclusions. Some studies have found significant associations (Martyn et al., 1989; McLachlan et al., 1996; Michel et al., 1990) whereas other studies did not find a significant relationship (Forster et al.,

1995; Martyn et al., 1997; Wettstein et al., 1991).

In conclusion, whereas a causative role for aluminum in the etiology of Alzheimer's and other neurodegenerative diseases has not been established, observations on dialyzed patients provide convincing evidence that aluminum is the causative agent of "dialysis dementia."

Bismuth (Bi)

Bismuth[1] has a long history of use in pharmaceuticals in Europe and North America. Both inorganic and organic salts have been used, depending on the specific application. Trivalent insoluble bismuth salts are used medicinally to control diarrhea and other types of GI distress. Various bismuth salts have been used externally for their astringent and slight antiseptic properties. Bismuth salts have also been used as radiocontrast agents. Further potential for exposure comes from the use of insoluble bismuth salts in cosmetics. Injections of soluble and insoluble salts, suspended in oil to maintain adequate blood levels, have been used to treat syphilis. Bismuth sodium thioglycollate, a water-soluble salt, was injected intramuscularly for malaria (*Plasmodium vivax*). Bismuth glycolyarsanilate is one of the few pentavalent salts that have been used medicinally. This material was formerly used for treatment of amebiasis (Fowler and Vouk, 1986). Exposure to various bismuth salts for medicinal use has decreased with the advent of newer therapeutic agents.

Recently there has been an increased interest in bismuth to treat peptic ulcer disease. This interest was prompted by the discovery in 1982 of a gram-negative bacterium from the gastric mucosa of patients suffering from gastritis. The bacterium, *Helicobacter pylori,* is now thought to predispose patients with chronic gastritis to peptic ulcer formation and duodenal ulceration. Antacids containing bismuth compounds have been effective in promoting healing of peptic ulcers, which is now thought to be due to the antibacterial action of bismuth.

Toxicokinetics Most bismuth compounds are insoluble and poorly absorbed from the GI tract or when applied to the skin, even if the skin is abraded or burned. The three compounds used clinically, colloidal tripotassium dicitrato bismuthate, bismuth subsalicylate (Pepto Bismol) and bismuth citrate are also poorly absorbed (less than 1 percent of an oral dose) (Tillman et al., 1996). Binding in blood is thought to be due largely to a plasma protein with a molecular weight greater than 50,000. In vitro studies have shown the Bi^{3+} binds to serum transferrin (Li et al., 1996). Tissue distribution, omitting injection depots, reveals the kidney as the site of the highest concentration (Zidenberg et al., 1989), probably due to its capacity to induce metallothionein (Tanaka-Kagawa et al., 1993). Passage of bismuth into the amniotic fluid and into the fetus has been demonstrated. The urine is the major route of excretion. It is also secreted in bile in association with glutathione (Gyurasics et al., 1992). Traces of bismuth can be found in milk and saliva. The elimination half-life is reported to be about 21 days (Froomes et al., 1989); but after injection, elimination of total bismuth may be slow, depending on its mobilization from the injection site.

Toxicity Acute renal failure can occur following oral administration of such compounds as bismuth sodium triglycocollamate or thioglycollate, particularly in children (Urizar and Vernier, 1966). The tubular epithelium is the primary site of toxicity, producing degeneration of renal tubular cells and nuclear inclusion bodies composed of a bismuth-protein complex analogous to those found in lead toxicity (Fowler and Goyer, 1975).

The symptoms of chronic toxicity in humans consist of decreased appetite, weakness, rheumatic pain, diarrhea, fever, metal lines on the gums, foul breath, gingivitis, and dermatitis. Jaundice and conjunctival hemorrhage are rare but have been reported. Bismuth nephropathy with proteinuria may occur. In the 1970s reports appeared from France and Australia of a unique encephalopathy occurring in colostomy and ileostomy patients using bismuth subgallate, subnitrate, and subcarbonate for control of fecal odor and consistency (Slikkerveer and de Wolff, 1989). The symptoms included progressive mental confusion, irregular myoclonic jerks, a distinctive pattern of disordered gait, and a variable degree of dysarthria. The disorder was fatal to patients who continued use of the bismuth compounds, but full recovery was rapid in those in whom therapy was discontinued. The severity of the disorder seemed to be independent of dose and duration of therapy (Thomas et al., 1977). Bismuth-containing paste dressings have produced encephalopathy when applied to brain tissues after neurosurgery (Sharma et al., 1994).

Chelation therapy using dimercaprol (BAL) is said to be helpful in the removal of bismuth from children with acute toxicity (Arena, 1974).

Gallium (Ga)

The main valence state of gallium[1] is +3 (gallic), but the +2 (gallous) also can form stable compounds. Gallium is of interest because of the use of radiogallium as a diagnostic tool for the localization of bone lesions and the use of nonradioactive gallium nitrate, $Ga(NO_3)_3$ as an antitumor agent. Also, it has recently been approved in the United States for the treatment of hypercalcemia. Gallium is obtained as a by-product of copper, zinc, lead, and aluminum refining and is used in high-temperature thermometers, as a substitute for mercury in arc lamps, as a component of metal alloys, and as a seal for vacuum equipment. It is the only metal other than mercury that is liquid at or near room temperature.

Toxicokinetics Gallium is sparsely absorbed from the GI tract, but concentrations of less than 1 ppm can be localized radiographically in bone lesions. Higher doses will allow one to visualize the liver, spleen, and kidney as well (Hayes, 1988). Gallium binds to plasma transferrin and enters cells on iron (Fe^{3+}) transport mechanisms. Urine is the major route of excretion. The half-life in the body is about 4 to 5 days.

Toxicity Clinical studies on $Ga(NO_3)_3$ as an antitumor agent, reveal that it accumulates in metabolically active regions of bone and increases the calcium and phosphate content. It inhibits osteoclastic bone resorption without poisoning the osteoclast cells (Bockman, 1991). Therapeutic trials with intravenous doses indicate that nephrotoxicity is dose-limiting. Other effects include nausea, vomiting, and anemia with mild leukopenia. Less frequent are neurologic, pulmonary, and dermatologic effects. It can elicit a variety of biochemical and hormonal changes. The mechanism of bone uptake and inhibition of bone resorption is not known, but the gallate anion, $Ga(OH)_4^-$, may be the active species. Uptake by and effects on other cells may be explained by Ga^{3+} competition with Fe^{3+} for transferrin and other iron-binding proteins leading the depletion of intracellular iron and apoptosis. [For a detailed review, see Bernstein (1998).]

Administration of gallium arsenide to experimental animals results in arsenic intoxication (Webb et al., 1984). There are no reported adverse effects of gallium following industrial exposure.

Gold (Au)

Gold[1] is widely distributed in small quantities, but economically usable deposits occur as the free metal in quartz veins or alluvial gravel. Gold is almost always found in association with silver. Seawater contains 3 or 4 mg/ton and small amounts, 0.03 to 1 percent, have been reported in many foods. Gold has a number of industrial uses because of its electrical and thermal conductivity. While gold and its salts have been used for a wide variety of medicinal purposes, their present uses are limited to the treatment of rheumatoid arthritis and rare skin diseases such as discoid lupus.

Toxicokinetics Gold salts are poorly absorbed from the gastrointestinal tract. The upper limit of normal levels can be considered to be 0.5 µg/L for both whole blood and urine (Perelli and Piolotto, 1992). After injection of most of the soluble salts, gold is excreted via the urine, while the feces account for the major portion of insoluble compounds. Gold seems to have a long biological half-life, and detectable blood levels can be demonstrated for 10 months after cessation of treatment. Trivalent gold binds strongly to metallothionein (Saito and Kuraski, 1996).

Toxicity Dermatitis is the most frequently reported toxic reaction to gold and is sometimes accompanied by stomatitis probably involving allergic mechanisms (Hostynek, 1997). The use of gold in the form of organic salts to treat rheumatoid arthritis may be complicated by the development of proteinuria and the nephrotic syndrome, which morphologically consists of an immune-complex glomerulonephritis, with granular deposits along the glomerular basement membrane and in the mesangium (Bigazzi, 1994). The pathogenesis of the immune-complex disease is not certain, but gold may behave as a hapten and generate the production of antibodies with subsequent disposition of gold protein-antibody complexes in the glomerular subepithelium. Another hypothesis is that antibodies are formed against damaged tubular structures, particularly mitochondria, providing immune complexes for the glomerular deposits (Voil et al., 1977).

The pathogenesis of the renal lesions induced by gold therapy also has a direct toxicity to renal tubular cell components. From experimental studies it appears that gold salts have an affinity for mitochondria of proximal tubular lining cells, which is followed by autophagocytosis and accumulation of gold in amorphous phagolysosomes (Stuve and Galle, 1970). Gold particles can be identified in degenerating mitochondria in tubular lining cells and in glomerular epithelial cell by x-ray microanalysis (Ainsworth et al., 1981).

Lithium (Li)

Lithium[1] (carbonate) is used in the treatment of depression. There must be careful monitoring of usage to provide optimal therapeutic value and to avoid toxicity. The therapeutic index is narrow (0.6 to 1.5 meq/L). Lithium is present in many plant and animal tissues. It has some industrial uses, in alloys, as a catalytic agent, and as a lubricant. Lithium hydride produces hydrogen on contact with water and is used in manufacturing electronic tubes, in ceramics, and in chemical synthesis.

Toxicokinetics The physiology, pharmacology, and toxicology of lithium compounds have been reviewed in detail by Timer and Sands (1999). Daily intake is about 2 mg. It is readily absorbed from the GI tract. Distribution is to total body water with higher levels in kidney, thyroid, and bone as compared to other tissues. Excretion is chiefly through the kidneys with 80 percent of the filtered load reabsorbed. The usual elimination half-life is 12 to 27 h, but it may rise to nearly 60 h if renal excretion is compromised. Lithium can substitute for sodium or potassium on several transport proteins. It enters cells via the amiloride-sensitive sodium channel or the Na/H^+ exchanger. The greater part of lithium is contained in the cells, perhaps at the expense of potassium. In general it may be competing with sodium at certain sites—for example, in renal tubular reabsorption.

Toxicity From the industrial point of view, except for lithium hydride, none of the other salts is hazardous, nor is the metal itself. Lithium hydride is intensely corrosive and may produce burns on the skin because of the formation of hydroxides (Cox and Singer, 1981). The therapeutic use of lithium carbonate may produce unusual toxic responses. These include neuromuscular changes (tremor, muscle hyperirritability, and ataxia), central nervous system changes (blackout spells, epileptic seizures, slurred speech, coma, psychosomatic retardation, and increased thirst), cardiovascular changes (cardiac arrhythmia, hypertension, and circulatory collapse), GI changes (anorexia, nausea, and vomiting), and renal damage (albuminuria and glycosuria). The last is believed to be due to temporary hypokalemic nephritis. Long-term sequelae from acute lithium poisoning include cognitive losses such as impaired memory, attention and executive functions, and visuospatial deficits (Brumm et al., 1998).

Chronic lithium nephrotoxicity and interstitial nephritis can occur with long-term exposure even when lithium levels remain within the therapeutic range (Singer, 1981). Animal studies have shown a similarity between lithium and sodium handling and that lithium may cause an antidiuretic hormone (ADH)–resistant polyuria and secondary polydipsia. This abnormality appears to be mediated by a central pituitary effect that reduces ADH release (Carney et al., 1996). Treatment with lithium salts has also been associated with nephrotic syndrome with minimal glomerular changes. The cardiovascular and nervous system changes may be due to the competitive relationship between lithium and potassium and may thus produce a disturbance in intracellular metabolism. The effects of lithium on neurotransmitter, neuropeptide, and signal transduction systems have been reviewed by Lenox et al. (1998).

Thyrotoxic reactions, including goiter formation, have also been suggested (Davis and Fann, 1971). While there has been some indication of adverse effects on fetuses following lithium treatment, none was observed in rats (4.05 meq/kg), rabbits (1.08 meq/kg), or primates (0.67 meq/kg). This dose to rats was sufficient to produce maternal toxicity and effects on the pups of treated, lactating dams.

Lithium overdosage and toxicity may be treated by the administration of diuretics (amiloride) and lowering of blood levels (via hemodialysis). Treatment with diuretics must be accompanied by replacement of water and electrolytes (Steele, 1977).

Platinum (Pt) and Related Metals

Platinum-group metals include a relatively light triad of ruthenium, rhodium, and palladium, and the heavy metals osmium, iridium, and platinum.[1] They are found together in sparsely distributed mineral deposits or as a by-product of refining other metals, chiefly nickel and copper. Osmium and iridium are not important toxicologically. Osmium tetroxide, however, is a powerful eye irritant. The other metals are generally nontoxic in their metallic states but have been noted to have toxic effects in particular circumstances. Toxicologic information for ruthenium is limited to references in the literature indicating that fumes may be injurious to eyes and lungs (Browning, 1969). Palladium chloride is not readily absorbed from subcutaneous injection, and no adverse effects have been reported from industrial exposure. Colloid palladium ($Pd[OH]_2$) is reported to increase body temperature, produce discoloration and necrosis at the site of injection, decrease body weight, and cause slight hemolysis.

Allergenic Effects of Platinum Salts Platinum is interesting because of its extensive industrial applications and because of the use of certain complexes as antitumor agents. Higher platinum levels are found in roadside dust where traffic density is high because of its use in catalytic converters. Mean levels of platinum in whole blood and urine in nonoccupationally exposed adults are reported as 0.13 μg/L of blood and 0.11 μg/g of creatinine, respectively (Farago et al., 1998). Platinum metal itself is generally harmless, but an allergic dermatitis can be produced in susceptible individuals (Hunter, 1969). Skin changes are most common between the fingers and in the antecubital fossae. Symptoms of respiratory distress, ranging from irritation to an asthmatic syndrome—with coughing, wheezing, and shortness of breath—have been reported following exposure to platinum dust. The skin and respiratory changes are termed *platinosis*. They are mainly confined to persons with a history of industrial exposure to soluble compounds such as sodium chloroplatinate, although cases resulting from the wearing of platinum jewelry have been reported (WHO, 1991). The complex salts of platinum may act as powerful allergens, particularly ammonium hexachloroplatinate and hexachloroplatinic acid. Platinum salt sensitization may persist for years after cessation of exposure (Brooks et al., 1990). In general, platinum allergy is confined to a small group of charged compounds that contain reactive ligands, the most effective of which are chloride ligands (Farago et al., 1998).

Antitumor Effects of Platinum Complexes Major consideration for this group of metals are the potential antitumor and carcinogenic effects of certain neutral complexes such as *cis*-dichlorodiammine platinum (II) (or cisplatin), and various analogs (Kazantzis, 1981). Other metals in the group give complexes that are inactive or less active than the platinum analog. They can inhibit cell division and have antibacterial properties as well. These compounds can react selectively with specific chemical sites in proteins such as disulfide bonds and terminal NH_2 groups, with functional groups in amino acids and, in particular, with receptor sites in nucleic acids. These compounds also exhibit neuromuscular toxicity and nephrotoxicity. Platinum complexes, particularly cisplatin, are effective antitumor agents and are used clinically for the treatment of cancers of the head and neck, certain lymphomas, and testicular and ovarian tumors. For antitumor activity, the complexes should be neutral and should have a pair of *cis*-leaving groups. At dosages that are therapeutically effective (antitumor), these complexes produce severe and persistent inhibition of DNA synthesis and little inhibition of RNA and protein synthesis. DNA polymerase activity and transport of DNA precursors through plasma membranes are not inhibited. The complexes are thought to react directly with DNA in regions that are rich in guanosine and cytosine (Abrams and Murrer, 1993).

Mutagenic and Carcinogenic Effects of Platinum Complexes Cisplatin is a strong mutagen in bacterial systems and has been shown to form both intrastrand and interstrand cross-links. There is also a correlation between antitumor activity of cisplatin and its ability to bind DNA and induce phage from bacterial cells. It also causes chromosomal aberrations in cultured hamster cells and a dose-dependent increase in sister chromosome exchanges. Although cisplatin has antitumorigenic activity, it also seems to increase the frequency of lung adenomas and give rise to skin papillomas and carcinomas in mice. These observations are consistent with the activity of other alkylating agents used in cancer chemotherapy. There are no reports of increased risk of cancer from occupational exposure to platinum compounds.

Nephrotoxicity Cisplatin is also a nephrotoxin, which compromises its usefulness as a therapeutic agent. Platinum compounds with antitumor activity produce proximal and distal tubular cell injury, mainly in the corticomedullary region, where the concentration of platinum is highest (Madias and Harrington, 1978). Although 90 percent of administered cisplatin becomes tightly bound to plasma proteins, only unbound platinum is rapidly filtered by the glomerulus and has a half-life of only 48 min. Within tissues, platinum is protein-bound, with the largest concentrations in kidney, liver, and spleen, and it has a half-life of 2 or 3 days. Tubular cell toxicity seems to be directly related to dose, and prolonged weekly injection in rats causes atrophy of the cortical portions of nephrons, cystic dilatation of inner cortical or medullary tubules, and chronic renal failure due to tubulointerstitial nephritis (Choie et al., 1981). Experimental studies suggest that the preadministration of bismuth subnitrate, a potent inducer of metallothionein in the kidney, reduces the nephrotoxicity of cisplatin without interfering with its anticancer effect (Kondo et al., 1992).

MINOR TOXIC METALS

Antimony (Sb)

Antimony[1] belongs to the same periodic group as arsenic and has the same oxidation states. Most compounds of antimony involve the tri- and pentavalent states. Antimony is included in alloys in the metals industry and is used for producing fireproofing chemicals, ceramics, glassware, and pigments. Antimony has been used medicinally in the treatment of schistosomiasis and leishmaniasis. Antimony is a common air pollutant from industrial emissions, but exposure for the general

population is largely from food. The average daily intake from food and water is about 5 µg (ATSDR, 1992).

The disposition of antimony in the body resembles that of arsenic. Most antimony compounds can be absorbed from the lung and GI tract, but no quantitative data are available on humans. Clearance from the lung is estimated to be on the order of days to weeks and GI absorption from most compounds has been estimated to be about 1 percent (ICRP, 1981). Many antimony compounds are GI irritants. Trivalent antimony is concentrated in red blood cells and liver, whereas the pentavalent form is mostly in plasma. The pentavalent form is predominantly excreted in urine, whereas the trivalent is found mainly in feces after injection into animals. [For detailed review, see ATSDR (1992).]

Most information about antimony toxicity has been obtained from industrial experiences. Occupational exposures are usually by inhalation of dust containing antimony compounds, such as the pentachloride and trichloride, trioxide, and trisulfide. Effects may be acute, particularly from the pentachloride and trichloride exposures, producing a rhinitis and even acute pulmonary edema. Chronic exposures by inhalation of other antimony compounds result in rhinitis, pharyngitis, tracheitis, and, over the longer term, bronchitis and eventually pneumoconiosis with obstructive lung disease and emphysema. Transient skin eruptions (antimony spots) may occur in workers with chronic exposure (Elinder and Friberg, 1986). Antimony-containing compounds may also produce alterations in cardiac function, and autopsy studies have shown that cardiac toxicity was the cause of death in patients treated with antimonial drugs (Winship, 1987).

A recent review by Léonard and Garber (1996) concluded that evidence that antimony compounds have mutagenic properties is insufficient. In most studies claiming to find carcinogenic properties, exposure to antimony compounds has been accompanied by other proven or likely carcinogens. Two exceptions are antimony trioxide and trisulfide, for which evidence for carcinogenicity was described as sufficient and limited respectively by the IARC (1989). In general, the mutagenic, carcinogenic, and teratogenic risks of antimony compounds, if they exist at all, are not very important in relation to such metals as arsenic, chromium, and nickel.

The metal hydride of antimony, stibine (H_3Sb), is a highly toxic gas that can be generated when antimony is exposed to reducing acids or when batteries are overcharged. High-purity stibine is also used in the production of semiconductors. Stibine, like arsine, causes hemolysis.

Barium (Ba)

Barium[1] is used in various alloys; in paints, soap, paper, and rubber; and in the manufacture of ceramics and glass. Barium fluorosilicate and carbonate have been used in pesticides. Barium sulfate, an insoluble compound, is used as a radiopaque aid to x-ray diagnosis. Barium is relatively abundant in nature and is found in plants and animal tissue. Brazil nuts have very high concentrations (3000 to 4000 ppm). Barium from natural sources may exceed federal safety standards in some bodies of freshwater. Daily intake is about 750 µg coming mainly from the diet.

The toxicity of barium compounds depends on their solubility. Aerosols of soluble barium compounds are well absorbed in the lung. Ingested soluble compounds are absorbed similarly to calcium to the extent of about 8 percent of the dose. Bone and teeth are the major sites of deposition, up to 90 percent of the body burden. The lung has an average concentration of 1 ppm (dry weight). The kidney, spleen, muscle, heart, brain, and liver concentrations are 0.10, 0.08, 0.05, and 0.03 ppm, respectively. Barium is reabsorbed by the renal tubules with only minor amounts appearing in the urine. The major route of excretion is the feces. The elimination half-life is about 3 to 4 days.

Occupational poisoning to barium is uncommon, but a benign pneumoconiosis (baritosis) may result from inhalation of barium sulfate (barite) dust and barium carbonate. It is not incapacitating and is usually reversible with cessation of exposure. Accidental poisoning from ingestion of an acute toxic dose (over 200 mg) of soluble barium salt results first in perioral paresthesia, intractable vomiting, and severe diarrhea. Hypertension and cardiac dysrhythmias may ensue. Profound hypokalemia and weakness progressing to flaccid paralysis are the hallmarks of barium poisoning (Johnson and VanTassell, 1991). Experimental studies indicate that barium directly stimulates muscle cells. Its basic mechanism of action probably involves the blocking of calcium activated potassium channels responsible for the cellular efflux of potassium. As a result, intracellular potassium rises and extra cellular levels fall leading to hypokalemia. Treatment with intravenous potassium appears beneficial. The lethal dose is between 1 to 15 g as barium carbonate. [For more detailed reviews, see Reeves (1986), ATSDR (1992).]

Germanium (Ge)

The chemical and physical properties of germanium[1] are intermediate between a metal and a nonmetal. It has two stable oxidation states, divalent and tetravalent. It forms organometallic compounds such as dimethyl germanium and a hydride (GeH_4). It was widely used in the semiconductor industry up to the mid-1970s, when it was replaced by silicon. Its current uses are in infrared lenses, optic fibers, as a catalyst, and in alloys with other metals. Some organogermanium compounds such as spirogermanium have antineoplastic properties but so far have not achieved therapeutic applications.

The diet is the dominant source of exposure to the general population. Germanium concentrations in most foods are similar to the natural abundance level of about 0.6 to 1.0 ppm in soils. But some canned foods are higher (tuna 2.2; baked beans 5.8 ppm). The daily intake from food is reported in the range of 370 to 3700 µg. Intake from drinking water and ambient air (except for occupational exposures) is negligible.

Inorganic germanium compounds are well absorbed from the diet. It is widely distributed throughout the body with the highest concentrations occurring in the spleen. Germanium is excreted mainly via the kidneys. The whole-body half-lives are between 1 and 4 days. Hair and nails may be useful media for biological monitoring.

The gas germane (GeH_4) is highly toxic to the cardiovascular system, liver and kidneys. It causes hemolysis of red cells and probably acts in the same way as stibine (SbH_3). The inorganic compounds exhibit low toxicity when taken orally. The LD_{50} values in animals are above 100 mg/kg body weight of germane. Ingestion of germanium dioxide (GeO_2) in an elixir, according to a case report on 18 people, resulted in renal damage that did not completely disappear after cessation of exposure. Approximately 16 to 328 g of germanium were ingested over a period of 4 to 36 months.

Germanium is not carcinogenic and may even inhibit carcinogenesis. The organo derivative, spirogermanium, selectively kills cancer cells. It is not mutagenic and can inhibit the action of other mutagens. High doses can cause embryonic resorption and the organo derivative, dimethyl germanium oxide, can produce fetal malformations in animal tests. [For references and details see the review by Gerber and Leonard (1997).]

Indium (In)

Indium[1] is a rare metal whose principal valence state is +3. In its metallic form, it is used in alloys, solders, and as a hardening agent for bearings. Its compounds such as indium phosphide (InP) are widely used in the electronics industry for production of semiconductors and photovoltaic. It is currently being used in medicine for the scanning of organs and the treatment of tumors. The average human intake of indium has been estimated in the range of 8 to 10 µg/day (Smith et al., 1978).

Indium compounds, specially InP, are poorly absorbed from the gastrointestinal tract or after intratracheal instillation (Zheng et al., 1994). It is excreted in the urine and feces. Its tissue distribution is relatively uniform.

There are no meaningful reports of human toxicity to indium. From animal experiments it is apparent that toxicity is related to the chemical form. Indium chloride given intravenously to mice produces renal toxicity and liver necrosis. Intratracheal instillation of the trichloride can produce severe pulmonary damage with fibrosis (Blazka et al., 1994). The phosphide appears less toxic (Oda, 1997). No evidence could be found for reproductive toxicity of $InCl_3$ in animal tests (Chapin et al., 1995) and teratogenic effects were found only when maternal toxicity occurred (Ungvary et al., 2000).

Silver (Ag)

Silver[2] forms only a +1 valence state, Ag^+, from which all its chemical compounds are formed. It occurs naturally as a silver ore often in association with gold and copper deposits. Silver mines are known to have been worked in Asia Minor before 2500 BC. Its principal industrial use is as silver halide in the manufacture of photographic plates. Other uses are for jewelry, coins, and eating utensils. Silver nitrate is used for making indelible inks and for medicinal purposes. The use of silver nitrate for prophylaxis of ophthalmia neonatorum is a legal requirement in some states. Other medicinal uses of silver salts are as an antiseptic and astringent. Silver sulfadiazine is widely used in the treatment of burn injuries. Dietary intake including fluids is in the range of 70 to 90 µg/day.

Silver compounds can be absorbed orally, by inhalation, and through damaged skin. In the unexposed general population, average blood levels of silver are about 2.4 µg/L, urinary excretion is 2 µg/day, and tissue levels are about 0.05 µg/g (Wan et al., 1991). Dental amalgam fillings lead to higher tissue levels (Drasch et al., 1995). Complexes with serum albumin accumulate in the liver, from which a fractional amount is excreted. In animals parenterally dosed with silver salts, silver is widely distributed to most tissues. It can cross the blood-brain barrier and produce long-lasting deposits in many structures of the nervous system (Rungby, 1990). It is located exclusively in lysosomes of neuronal cells (Stoltenberg et al., 1994). A specific transporter protein may be involved (Havelaar et al., 1998). Autopsy findings after treatment of burn injuries indicated highest levels in skin, gingiva, cornea, liver, and kidneys (Wan et al., 1991). Excretion is via the GI tract and kidneys. Specific transport proteins are responsible for secretion of silver from liver cells to bile (Dijkstra et al., 1996).

The major effect of excessive absorption of silver is local or generalized impregnation of the tissues, where it remains as silver sulfide, which forms an insoluble complex in elastic fibers, resulting in argyria. The complexes also contain selenium (Matsumura et al., 1992). Industrial argyria, a chronic occupational disease, has two forms, local and generalized. The local form involves the formation of gray-blue patches on the skin or may manifest itself in the conjunctiva of the eye. In generalized argyria, the skin shows widespread pigmentation, often spreading from the face to most uncovered parts of the body. In some cases the skin may become black, with a metallic luster. The eyes may be affected to such a point that the lens and vision are disturbed. The respiratory tract may also be affected in severe cases. Large oral doses of silver nitrate cause severe gastrointestinal irritation due to its caustic action. Lesions of the kidneys and lungs and the possibility of arteriosclerosis have been attributed to both industrial and medicinal exposures. Chronic bronchitis has also been reported to result from medicinal use of colloidal silver (Browning, 1969). Animal experiments indicate that silver disturbs copper metabolism (Hirasawa et al., 1994) and that metallothionein may protect against the toxic action of silver (Shinogi and Maeizumi, 1993).

Tellurium (Te)

Tellurium[1] is a semimetallic element in the sulfur and selenium family. It is found in various sulfide ores along with selenium and is produced as a by-product of metal refineries. Its industrial uses include applications in the refining of copper and in the manufacture of rubber. Tellurium vapor is used in "daylight" lamps and in various alloys as a catalyst and as a semiconductor frequently in combination with other metals.

Tellurium in food is probably in the form of tellurates. Condiments, dairy products, nuts, and fish have high concentrations of tellurium. Food packaging contains some tellurium; higher concentrations are found in aluminum cans than in tin cans. Some plants, such as garlic, accumulate tellurium from the soil. Potassium tellurate has been used to reduce sweating. The average body burden in humans is about 600 mg, mainly in bone.

The biochemistry and toxicity of the metal has been reviewed recently by Taylor (1996). Soluble tetravalent tellurates, absorbed into the body after oral administration, are reduced to tellurides, partly methylated, and then exhaled as dimethyl telluride. The latter is responsible for the garlic odor in persons exposed to tellurium compounds. The kidney has the highest content among the soft tissues. Tellurium may also accumulate in the liver (Schroeder and Mitchener, 1972). The urine and bile are the principal routes of excretion. Sweat and milk are secondary routes of excretion.

Tellurates and tellurium are of low toxicity, but tellurites are generally more toxic. Acute inhalation exposure results in sweating, nausea, a metallic taste, and sleeplessness. A typical garlic breath is an indicator of exposure to tellurium by the dermal, inhalation, or oral route. Serious cases of tellurium intoxication from industrial exposure have not been reported. One of the few serious recorded cases of tellurium toxicity resulted from accidental poisoning by injection of tellurium into the ureters during retrograde pyelography. Two of the three victims died. Garlic breath, renal pain, cyanosis, vomiting, stupor, and loss of consciousness were observed in this unlikely incident. The amount of sodium telluride used was about 2 g (Hunter, 1969).

In rats, chronic exposure to high doses of tellurium dioxide has produced decreased growth and necrosis of the liver and kidney (Cerwenka and Cooper, 1961; Browning, 1969). Rats fed 1 percent of metallic tellurium in the diet developed demyelination of peripheral nerve (Goddrum, 1998), probably due to the inhibition of squalene monooxygenase, a key enzyme in cholesterol biosynthesis (Laden et al., 2000). Cadmium telluride is a novel compound used in semiconductors. On inhalation this compound was shown to cause severe pulmonary inflammation and fibrosis in rats (Morgan et al., 1997). Tellurium compounds can produce hydrocephalus in experimental animals. Dimercaprol treatment for tellurium toxicity increases the renal damage. While ascorbic acid decreases the characteristic garlic odor, it may also adversely affect the kidneys in the presence of increased amounts of tellurium (Fishbein, 1977).

Thallium (Tl)

Thallium[1] is one of the more toxic metals. The thallium ion, Tl^+, has a similar charge and ionic radius as the potassium ion. Some of its toxic effects (see below) may result from interference with the biological functions of potassium. It is obtained as a by-product of the refining of iron, cadmium, and zinc. It is used as a catalyst in certain alloys, optical lenses, jewelry, low-temperature thermometers, semiconductors, dyes and pigments, and scintillation counters. Industrial poisoning is a special risk in the manufacture of fused halides for the production of lenses and windows. It has been used medicinally as a depilatory. Thallium compounds, chiefly thallous sulfate, have been used as rat poison and insecticides. This is one of the commonest sources of human thallium poisoning.

Thallium is absorbed through the skin and gastrointestinal tract. The highest concentrations after poisoning are in the kidney. Following the initial exposure, large amounts are excreted in urine during the first 24 h, but after that period excretion is slow and the feces may be an important route of excretion. The half-life in humans has been reported in the range of 1 to 30 days and may be dose-dependent. Thallium undergoes enterohepatic circulation. Prussian blue, the most commonly used antidote, is given orally to break the enterohepatic cycle by trapping thallium secreted in bile and carrying it into the feces. For major reviews, see Malkey and Oehme (1993), Galván-Arzate and Santamaría (1998).

There are numerous clinical reports of acute thallium poisoning in humans characterized by GI irritation, acute ascending paralysis, psychic disturbances, and alopecia. The estimated acute lethal dose in humans is 8 to 12 mg/kg. Epilation begins about 10 days after ingestion and complete hair loss in about 1 month. Thallium targets the epithelial cells of the hair papillae. The turnover of these cells allows complete restoration of the hair in about 2 to 3 months. The growth of fingernails is impaired and transverse white stripes appear in the nails.

The acute cardiovascular effects of thallium ions probably result from competition with potassium for membrane transport systems, inhibition of mitochondrial oxidative phosphorylation, and disruption of protein synthesis. It also alters heme metabolism.

In humans, fatty infiltration and necrosis of the liver, nephritis, gastroenteritis, pulmonary edema, degenerative changes in the adrenals, degeneration of the peripheral and central nervous system, alopecia, and in some cases death have been reported as a result of long-term systemic thallium intake. These cases usually are caused by the contamination of food or the use of thallium as a depilatory. Loss of vision plus the other signs of thallium poisoning have been related to industrial exposures (Browning, 1969).

Studies on animals suggest that the mitochondrion is an important intracellular target. Thallium, besides competing with potassium, may combine with the sulfhydryl groups in the mitochondria and thereby interfere with oxidative phosphorylation. Its affinity for sulfhydryl groups may also explain its ability to induce lipid peroxidation and deplete intracellular glutathione levels.

Evidence is scanty that thallium is mutagenic or carcinogenic (Leonard and Gerber, 1997). On the other hand, it may be teratogenic, especially with regard to cartilage and bone formation, but most of the evidence comes from chicks, not mammals. A teratogenic response to thallium salts characterized as achondroplasia (dwarfism) has been described in rats (Nogami and Terashima, 1973). Prenatal exposure of humans has resulted in skin and nail dystrophy, alopecia, and low body weight in newborns.

Tin (Sn)

Tin[1] has two higher valence states: stannous, Sn^{2+} and stannic, Sn^{4+}, tin. Both form stable inorganic compounds. In addition, stannic tin can form a volatile hydride, SnH_4 and a number of toxicologically important organometallic compounds in which the stannic atom form is covalently attached to one or more carbon atoms. Tin has a long history of use dating back to ancient Egypt. Currently it is used in the manufacture of tinplate, in food packaging, and in solder, bronze, and brass. Stannous and stannic chlorides are used in dyeing textiles. Organic tin compounds have been used in fungicides, bactericides, and slimicides, as well as in plastics as stabilizers. The daily intake is about 3.5 mg of tin, considerably lower than the 17 mg estimated in previous decades thanks to better food packaging methods. [The disposition and possible health effects of inorganic and organic tin compounds have been summarized in a number of reviews (WHO (1980), Alessio and Dell'Orto

(1998), and Winship (1988).]

There is only limited absorption of even soluble inorganic compounds after oral administration. Ninety percent of the tin administered in this manner is recovered in the feces. The small amounts absorbed are reflected by increases in the liver and kidneys. Injected tin is excreted by the kidneys, with smaller amounts in bile. A mean normal urine level of 16.6 μg/L or 23.4 μg/day has been reported. The majority of inhaled tin remains in the lungs, most extracellularly, with some in the macrophages, in the form of SnO_2.

The organic tins, particularly the trimethyltin and triethyltin compounds, are better absorbed than inorganic species of tin. The tissue distribution of tin from these compounds shows the highest concentrations in the blood and liver, with smaller amounts in the muscle, spleen, heart, or brain. Tetraethyltin is converted to triethyltin in vivo.

Chronic inhalation of tin in the form of dust or fumes leads to benign pneumoconiosis. Tin hydride (SnH_4) is more toxic to mice and guinea pigs than is arsine; however, its effects appear mainly in the central nervous system and no hemolysis is produced. Orally, tin or its inorganic compounds require relatively large doses (500 mg/kg for 14 months) to produce toxicity. Inorganic tin salts given by injection produce diarrhea, muscle paralysis, and twitching. Studies on animals reveal that administration of inorganic tin compounds disturbs copper, zinc, and iron metabolism [Yu and Beynen (1995), Reicks and Rader (1990)]. The stannous ion also interacts with N-type calcium channels enhancing calcium transport into neurons (Hattori and Maehashi, 1991, 1992). Stannous is a more potent inducer than stannic tin of hemeoxygenase (HO-1), the rate determining enzyme in the catabolism of the heme ring (Neil et al., 1995). Tin also inhibits aminolevulinic dehydratase, a key enzyme in the synthesis of the heme ring, but not as potently as lead (Zareba and Chmielnicka, 1992). This action may be another example of tin displacing an essential metal cofactor, in this case zinc (Chmielnicka et al., 1992). Experimental studies have failed to find any evidence of mutagenicity, carcinogenicity, or teratogenicity of inorganic tin compounds. In fact some anticarcinogenic properties have been detected (Winship, 1988).

Some organic tin compounds are highly toxic, particularly triethyltin. Trimethyltin and triethyltin cause encephalopathy and cerebral edema. Toxicity declines as the number of carbon atoms in the chain increases. An outbreak of almost epidemic nature took place in France due to the oral ingestion of a preparation (Stalinon) containing diethyltin diodide for the treatment of skin disorders. Excessive industrial exposure to triethyltin has been reported to produce headaches, visual defects, and electroencephalographic (EEG) changes that were very slowly reversed (Prull and Rompel, 1970). Experimentally, triethyltin produces depression and cerebral edema. The resulting hyperglycemia may be related to the centrally mediated depletion of catecholamines from the adrenals. Acute burns or subacute dermal irritation has been reported among workers as a result of tributyltin. Triphenyltin has been shown to be a potent immunosuppressant (Verschuuren et al., 1970). Inhibition on the hydrolysis of adenosine triphosphate and an uncoupling of the oxidative phosphorylation taking place in the mitochondria have been suggested as the cellular mechanisms of tin toxicity (WHO, 1980).

Some butyl and methyl compounds of tin were positive in the Ames mutagenicity test (Hamasaki et al., 1993). Tributyl tin can suppress natural killer cells in mice. This inhibition may predispose animals to malignancy (Ghoneum et al., 1990).

Titanium (Ti)

Most titanium compounds are in the oxidation state +4 (titanic), but oxidation state +3 (titanous) and oxidation state +2 compounds as well as several organometallic compounds do occur. Because of its resistance to corrosion and inertness, metallic titanium[1] has many metallurgic applications, particularly as a component of surgical implants and prostheses. Titanium dioxide, the most widely used compound, is a white pigment used in paints and plastics; as a food additive to whiten flour, dairy products, and confections; and as a whitener in cosmetic products. It occurs widely in the environment; in urban air, rivers, and drinking water and is detectable in many foods. Titanium in feces is sometimes used as a measure of soil ingestion.

Approximately 3 percent of an oral dose of titanium is absorbed. The majority of that absorbed is excreted in the urine. The normal urinary concentration has been estimated at 10 μg/L (Schroeder et al., 1963; Kazantzis, 1981). The estimated body burden of titanium is about 15 mg. Most of it is in the lungs, probably as a result of inhalation exposure, as it tends to remain in the lungs for long periods. Lung burdens increase with age and vary according to geographic location. Mean concentrations of 8 and 6 ppm for the liver and kidney, respectively, were reported in the United States. Titanium IV may circulate in plasma bound to transferrin (Messori et al., 1999). Newborns have little titanium.

Occupational exposure to titanium, usually in the form of titanium dioxide, (TiO_2) may be heavy, and concentrations in air up to 50 mg/m^3 have been recorded. TiO_2 has been classified as a nuisance particulate with a TLV of 10 mg/m^3. Nevertheless, slight fibrosis of lung tissue has been reported following inhalation exposure to titanium dioxide pigment, but the injury was not disabling. Ultrafine particles of TiO_2 are more likely to produce pulmonary inflammation than larger particles (Baggs et al., 1997). Excessive deposits in the lung will cause pulmonary overload, impairing the clearance mechanism (Warheit et al., 1997). Otherwise, titanium dioxide has been considered physiologically inert by all routes (ingestion, inhalation, dermal, and subcutaneous). Titanium dioxide was found not to be carcinogenic in a bioassay study in rats and mice (NCI, 1979).

The metal and other salts are also relatively nontoxic except for titanic acid, which, as might be expected, will produce irritation (Berlin and Nordberg, 1986). A titanium coordination complex, titanocene, suspended in trioctanoin and administered by intramuscular injection to rats and mice produced fibrosarcomas at the site of injection and hepatomas and malignant lymphomas (Furst and Haro, 1969). A titanocene is a sandwich arrangement of titanium between two cyclopentadiene molecules.

Uranium (U)

The chief raw material of uranium[2] is pitchblende or carnotite ore. This element is largely limited to use as a nuclear fuel and, as a spent fuel in military ordinance. It is present naturally in air, water, food, and soil. The average daily intake from food is 1 to 2 μg and about 1.5 μg from 1 L of drinking water. This metal has five oxidation states but only the +4 and +6 forms are stable enough to be of practical importance. The +6 forms the uranyl ion (UO_2^{2+}), which forms water-soluble compounds and is an important species of uranium in body fluids.

The uranyl ion is rapidly absorbed from the GI tract. About 60 percent is carried as a soluble bicarbonate complex, while the remainder is bound to plasma protein. Sixty percent is excreted in the urine within 24 h. About 25 percent may be fixed in the bone (Chen et al., 1961).

Naturally occurring depleted uranium, although radioactive, presents predominantly a toxicologic rather than radiologic health risk. Following inhalation of the insoluble salts, retention by the lungs is prolonged. Uranium tetrafluoride and uranyl fluoride can produce toxicity because of hydrolysis to hafnium. For example, they will burn skin on contact.

The soluble uranium present in plasma as the uranyl ion complexed with bicarbonate produces systemic toxicity in the form of acute renal damage and renal failure, which may be fatal. However, if exposure is not severe enough, the renal tubular epithelium is regenerated and recovery occurs. Renal toxicity with the classic signs of impairment—including albuminuria, elevated blood urea nitrogen, and loss of weight—is brought about by filtration of the bicarbonate complex through the glomerulus, bicarbonate reabsorption by the proximal tubule, liberation of uranyl ion, and subsequent damage to the proximal tubular cells. Uranyl ion is most likely concentrated intracellularly in lysosomes (Ghadially et al., 1982). A study of uranium mill workers suggested that workers' long-term low level exposure is associated with b_b-microglobulinuria and amino aciduria (Thun et al., 1985).

In those studies where a higher incidence of lung cancer has been found in uranium miners, the cancer is probably due to radon and its daughter products, not to uranium itself (ATSDR, 1999). In fact, there is no convincing evidence that uranium is carcinogenic.

The threshold limit for uranium in the workroom (TWA) is 200 μg/m^3 and the EPA-established limit in drinking water is 100 μg/L. [For a detailed review of uranium, see ATSDR (1999).]

Vanadium (V)

Vanadium[1] may be an essential trace element, but a deficiency disease has not yet been defined in humans. It has several oxidation states, the most common being

+3, +4, and +5. It is a by-product of petroleum refining, and vanadium pentoxide is used as a catalyst in the reactions of various chemicals including sulfuric acid. It is used in the hardening of steel, in the manufacture of pigments, in photography, and in the formulation of insecticides. Food is the major source of human exposure. Significant amounts are found in milk, seafood, cereals, and vegetables. The daily intake in the U.S. population ranges from 10 to 60 µg. The normal blood and urine levels are estimated to be around 1 and 10 nmol/L respectively (Sabbioni et al., 1996).

Metallic vanadium does not occur in nature, but human tissues come into long-term contact in medical implants. The lungs absorb soluble vanadium compounds well, but the absorption of vanadium salts from the gastrointestinal tract is poor. In the body, the pentavalent form (VO_3^-) is the predominant species in extracellular fluid whereas quadrivalent form (VO^{2+}) is most common inside the cell. The largest single compartment is the fat. Bone and teeth stores contribute to the body burden. The principal route of excretion of vanadium is the urine with a biological half-life of 20 to 40 h.

The pentavalent compounds are the most toxic. The toxicity of vanadium compounds usually increases as the valence increases. The toxic action of vanadium is largely confined to the respiratory tract. Bronchitis and bronchopneumonia are more frequent in workers exposed to vanadium compounds. In industrial exposures to vanadium pentoxide dust, a greenish-black discoloration of the tongue is characteristic. Irritant activity with respect to skin and eyes has also been ascribed to industrial exposure. Gastrointestinal distress, nausea, vomiting, abdominal pain, cardiac palpitation, tremor, nervous depression, and kidney damage, too, have been linked with industrial vanadium exposure (Waters, 1977; Wennig and Kirsch, 1988; Goyer, 1996; Barceloux, 1999).

---

[1]Chelating agents are a subset of the more general class of complexing agents. However, the terms *chelation* and *chelating agents* are now used to cover all types of metal complexation therapy even though some agents cannot form ring structures—for example, penicillamine, to be discussed later. Also, bidentate complexing agents such as BAL that have the capacity to form ring structures with metals; in fact, they may form complexes without ring structures, depending on the molar ratio of metal to BAL (for further discussion, see Clarkson and DiStefano, 1971). In this text we follow the common practice of using the terms *chelation* and *chelating agent* to cover all types of complexation therapy.

TOXIC EFFECTS OF SOLVENTS AND VAPORS

James V. Bruckner and D. Alan Warren

INTRODUCTION

The term *solvent* refers to a class of liquid organic chemicals of variable lipophilicity and volatility. These properties, coupled with small molecular size and lack of charge, make inhalation the major route of solvent exposure and provide for ready absorption across the lung, gastrointestinal (GI) tract, and skin. In general, the lipophilicity of solvents increases with increasing molecular weight, while volatility decreases. Solvents are frequently used to dissolve, dilute, or disperse materials that are insoluble in water. As such, they are widely employed as degreasers and as constituents of paints, varnishes, lacquers, inks, aerosol spray products, dyes, and adhesives. Other uses are as intermediates in chemical synthesis, and as fuels and fuel additives. Most solvents are refined from petroleum. Many such as naphthas and gasoline are complex mixtures, often consisting of hundreds of compounds. Early in the twentieth century, there were perhaps a dozen or so known and commonly used solvents. By 1981, this number had climbed to approximately 350 (OSHA, 2000).

Solvents are classified largely according to molecular structure or functional group. Classes of solvents include aliphatic hydrocarbons, many of which are chlorinated (i.e., halocarbons); aromatic hydrocarbons; alcohols; ethers; esters/acetates; amides/amines; aldehydes; ketones; and complex mixtures that defy classification. The main determinants of a solvent's inherent toxicity are (1) its number of carbon atoms; (2) whether it is saturated or has double or triple bonds between adjacent carbon atoms; (3) its configuration (i.e., straight-chain, branched-chain, or cyclic); and (4) the presence of functional groups. Some class-wide generalizations regarding toxicity can be made. For example, amides/amines tend to be potent sensitizers; aldehydes are particularly irritating; hydrocarbons that are extensively metabolized tend to be more cytotoxic/mutagenic; and many unsaturated, short-chain halocarbons are animal carcinogens. The toxicity of solvents within the same class may vary dramatically. For example, 1,1,1-trichloroethane (TRI) and 1,1,2-trichloroethylene (TCE) are both halocarbons, yet the unsaturated TCE is carcinogenic in the rat and mouse, but TRI is not. Similar results have been reported for 2,4- and 2,6-diaminotoluene in rodents, as only the 2,4 isomer is capable of inducing significant hepatocyte proliferation and liver tumors. Slight structural differences in solvent metabolites are also of toxicologic consequence. The peripheral neuropathy induced by *n*-hexane and 2-hexanone is dependent on the production of the g-diketone metabolite, 2,5-hexanedione. Diketones lacking the gamma structure are not neurotoxic. Thus, subtle differences in chemical structure can translate into dramatic differences in solvent toxicity.

Nearly everyone is exposed to solvents in the conduct of their normal daily activities. Consider, for example, a person who works in an aircraft factory as a metal degreaser (TCE exposure); drives to the neighborhood bar after work and has a few drinks (ethanol exposure) and a cigarette (benzene and styrene exposure); stops on the way home at a self-service filling station for gasoline (benzene, toluene, 1,3-butadiene exposure) and the dry cleaner's for laundry [tetrachloroethylene (PERC) exposure]; and after dinner enjoys his hobby of model shipbuilding that requires the use of glue (toluene exposure). While everyone may not identify with the above scenario, detailed surveys of indoor and outdoor air such as EPA's Total Exposure Assessment Methodology (TEAM) and National Human Exposure Assessment Survey (NHEXAS) studies, indicate that airborne solvent exposure is unavoidable (Wallace, 1990; Clayton et al., 1999). Drinking water is also a common source of solvent exposure due to discharge of solvents and the presence of disinfection by-products, such as the animal carcinogens, chloroform (CHCl$_3$), trichloroacetic acid (TCA), and di-chloroacetic acid (DCA). TCA and DCA are metabolites of TCE and PERC.

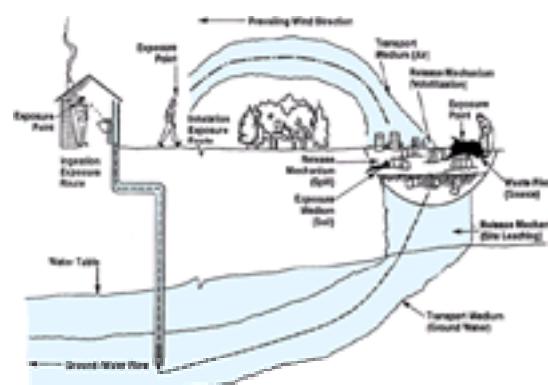
Environmental exposures to solvents in air and groundwater are frequent subjects of toxic tort litigation, despite concentrations typically in the low parts per billion (ppb) range. Multiple exposure pathways frequently exist (Fig. 24-1). Though not reflected in Fig. 24-1, household use of solvent-contaminated water may result in solvent intake from inhalation and dermal absorption as well as ingestion. In many cases, environmental risk assessment requires that risks be determined for physiologically diverse individuals who are exposed to several solvents by multiple exposure pathways. As an aid to the risk assessment process, the EPA has derived toxicity factors for many of the most toxic solvents. These toxicity factors are referred to as Reference Concentrations (RfCs), Reference Doses (RfDs), and Cancer Slope Factors (CSFs). Values for these are available from the EPA's on-line Integrated Risk Information System (IRIS). Additional sources of exposure guidelines for noncancer endpoints are found in the toxicologic profiles of the U.S. Agency for Toxic Substances and Disease Registry (ATSDR). These profiles often contain Minimal Risk Levels (MRLs) that are derived in a similar manner to EPA's RfCs and RfDs, but are frequently based on different critical studies or derived with the use of different uncertainty factors.


Figure 24-1. Solvent exposure pathways and media. [From EPA Risk Assessment Guidance for Superfund. *Human Health Evaluation Manual Part A, Interim Final. Washington, DC: Office of Emergency and Remedial Response, 1989.]*

Occupational solvent exposures involve situations ranging from a secretary using typewriter correction fluid to the loading and offloading of tanker trucks with thousands of gallons of gasoline. The greatest industrial use of solvents is as metal degreasers. The work environment is typically where the highest exposures occur, mainly via inhalation and dermal contact. An estimated 10 million people are potentially exposed to organic solvents in the workplace (OSHA, 2000). Many of the most severe exposures to solvents have occurred as a result of their use in confined spaces with inadequate ventilation. While the Occupational Safety and Health Administration (OSHA) has established legally enforceable Permissible Exposure Limits (PELs) for over 100 solvents, most PELs are outdated. The majority of existing PELs were adopted from the list of Threshold Limit Values (TLVs) published by the American Conference of Governmental Industrial Hygienists (ACGIH) in 1968, and have not been updated. Many current TLVs are more stringent than the PELs but do not carry the weight of law. (See appendix of this book for TLV and PEL.) While the ACGIH's TLVs for an 8-h work day, 40-h work week are designed to be protective for a working lifetime, its Short-Term Exposure Limits (STELs) and ceiling values are designed to protect against the acute effects of high-level, short-term solvent exposures. If warranted, the ACGIH will assign a skin notation to a solvent, indicating that a significant contribution to overall exposure is possible by the dermal route, either by contact with vapors or direct skin contact with the liquid. Biological monitoring in the workplace should find increasing use as technologic advances are made, since it often provides a better measure of exposure than classic

industrial hygiene monitoring. The ACGIH has published several Biological Exposure Indices (BEIs), on which basis the safety of internal measures of exposure can be judged (ACGIH, 1999).

Most solvent exposures involve a mixture of chemicals, rather than a single compound. Our knowledge of the toxicity of solvent mixtures is rudimentary relative to the toxicology of individual solvents. While the assumption is frequently made that the toxic effects of multiple solvents are additive, solvents may also interact synergistically or antagonistically. For example, repetitive alcohol consumption induces P450 activities, and may therefore induce the metabolic activation of other solvents to cytotoxic metabolites. Ethanol intake near the time of exposure to such solvents, on the other hand, may inhibit their metabolism and be protective. Another well-characterized example of solvent antagonism is the interaction between benzene and toluene (Medinsky et al., 1994). Coexposure to these chemicals results in diminished benzene metabolism, genotoxicity, and erythropoietic toxicity relative to that which follows benzene exposure alone. It is now recognized that significant data gaps exist in the area of mixtures toxicology, and these can preclude accurate risk assessments.

Although some solvents are less hazardous than others, all solvents can cause toxic effects. Provided that the dose is sufficient, most all have the potential to induce a state of narcosis and cause dermal and mucous membrane irritation. A number of solvents are animal carcinogens, but only a handful have been classified as known human carcinogens. Herein lies a major challenge for toxicology—determining the human relevance of tumors observed in high-dose rodent studies. As with other chemicals, whether health effects occur from solvent exposure is dependent upon several factors: (1) toxicity of the solvent, (2) exposure route, (3) amount or rate of exposure, (4) duration of exposure, (5) individual susceptibility, and (6) interactions with other chemicals. Adverse health effects may occur acutely and be readily discernible, or they may be the result of chronic exposure with insidious onset. Numerous epidemiologic studies of environmentally and occupationally exposed populations have been conducted for some solvents, but human risk assessment remains heavily reliant upon extrapolation from animal studies. One must bear in mind that the toxic effects and their underlying mechanisms discussed herein may be operative only in certain animal species or strains and under certain exposure conditions. Care must therefore be taken in generalizing beyond the experimental conditions under which data were collected. While a relatively small number of commercially available solvents is discussed in this chapter, those selected for discussion are thought to best demonstrate principles of solvent toxicology, are of particular commercial importance, and/or are currently garnering significant attention from the toxicologic and regulatory communities. A recent book chapter that examines solvents from an organ systems standpoint, in contrast to the discussion of individual solvents herein, is that of Gerr and Letz (1998).

IS THERE A SOLVENT-INDUCED CHRONIC ENCEPHALOPATHY?

The central nervous system (CNS)–depressant effects of acute, high-level exposures and the potential for permanent neurologic damage in chronic solvent abusers are not a matter of debate. It is also clear that chronic, moderate- to high-level exposure to a few solvents such as *n*-hexane and carbon disulfide can cause specific degenerative changes in the CNS or peripheral nervous system (PNS). Far less clear is whether chronic, low-level exposure to virtually any solvent or solvent mixture can produce a pattern of neurologic dysfunction referred to as *painter's syndrome, organic solvent syndrome, psychoorganic syndrome,* and *chronic solvent encephalopathy* (CSE). CSE is characterized by nonspecific symptoms (e.g., headache, fatigue, sleep disorders) with or without changes in neuropsychological function. There is a reversible form of CSE referred to as *neuroasthenic syndrome* that consists of symptoms only, and both "mild" and "severe" forms accompanied by objective signs of neuropsychological dysfunction that may or may not be fully reversible. This syndrome was first described in the Scandinavian occupational literature in the late 1970s among solvent-exposed painters (Axelson et al., 1976; Arlien-Soborg et al., 1979). Since that time, numerous studies from Scandinavia have been published suggesting that solvents as a class have chronic neurotoxic properties. These countries have actually passed legislation recognizing CSE as a compensable occupational disability. Scientists outside of Scandinavia, including those in the United States, have generally been less willing to recognize CSE as a legitimate disease state and have published studies to the contrary (Triebig et al., 1988; Bleecker et al., 1991; Spurgeon et al., 1994).

In response to the numerous reports of CSE, two conferences were convened in 1985. The first was held in Copenhagen by the Nordic Council of the World Health Organization (WHO, 1985). The second in Raleigh, NC, was attended by an international group of scientists from academia, industry, and government (Cranmer, 1986). The categorization scheme that resulted from the Raleigh meeting is presented in Table 24-1. The WHO scheme is similar. Among those who utilize the categorization scheme, it is generally believed that the most severe CSE category, type 3, results from repeated, severe intoxications like those experienced by solvent abusers. CSE types 1 and 2, on the other hand, are thought to be associated with prolonged, low-level exposure common to work environments. A major criticism of the categorization scheme is the lack of consideration of inhaled solvent concentration and exposure duration. While no consensus exists, even most CSE proponents believe that solvent exposure must occur for ³10 years before clinical symptoms are manifest.

Table 24-1 Proposed Categories of Solvent-Induced Encephalopathy

CSE researchers typically rely upon self-reported symptoms and a clinical neuropsychological evaluation (Table 24-2), and to a much lesser extent on diagnostic tests such as electroencephalography and computerized brain tomography. It has been argued that the neuropsychological tests are of questionable validity, sensitivity, specificity, and predictive value. It has also been noted that many investigations of CSE are fraught with methodologic flaws that render their results unreliable. For example, CSE investigators frequently fail to measure premorbid function or intellect; to employ a reference population; to control adequately for the potential confounders of age, alcohol use, and other CNS diseases; to corroborate functional deficits with objective evidence of brain disease; and/or examine the exposure-response relationship. Gade et al. (1988), for example, reanalyzed individuals originally reported by Arlien-Soborg et al. (1979) to have "painter's syndrome." When the influences of age, education, and intelligence were considered, the previously reported reduction in neuropsychological test scores disappeared. Another example is that of Cherry et al. (1985), who demonstrated the importance of matching solvent-exposed and control groups for preexposure intellect before making a diagnosis of CSE.

Table 24-2 Functions That May Be Assessed in a Neuropsychological Evaluation

It is evident that resolution of the controversial issue of CSE will come only through the conduct of well-designed and controlled clinical epidemiologic studies,

especially considering the absence of an appropriate animal model. Brief, but insightful reviews of CSE by Rosenberg (1995) and Schaumburg and Spencer (2000) can be found in recent texts. These reviews conclude that the current literature, including the "landmark" North American study of 187 paint manufacturing workers (Bleecker et al., 1991), does not support chronic, low-level solvent exposure as a cause of *symptomatic* CNS or PNS dysfunction. This does not preclude, however, the possibility that such exposure can be associated with *subclinical* cognitive dysfunction in the form of slight psychomotor and attentional deficits. For the viewpoint of CSE proponents, readers are directed to texts by Arlien-Soborg (1992) and Kilburn (1998).

SOLVENT ABUSE

Many solvents are intentionally inhaled in order to achieve a state of intoxication (Dinwiddie, 1994; Marelich, 1997). Solvent inhalation can rapidly produce euphoria, delusions, and sedation as well as visual and auditory hallucinations (Fig. 24-2). Solvent abuse is a unique exposure situation in that participants repeatedly subject themselves to vapor concentrations high enough to produce effects as extreme as unconsciousness. Solvents can be addicting and are often abused in combination with other drugs. The practice may be continued for years. Various solvents are present in a wide variety of household and commercial products including glue, model cement, paint thinner and stripper, aerosols, typewriter correction fluid, dry-cleaning fluid, and gasoline. These products are relatively inexpensive and readily available to children and adolescents (NIDA, 1977).

Figure 24-2. Solvent abuse: Euphoria to dysfunction. [Reproduced from NIDA (1977).]

Nearly all hydrocarbon solvents cause CNS depression, but residual organ damage is chemical-dependent. It is important to recognize the distinction between reversible CNS depression and neurotoxicity. Neurotoxicity is usually considered to be residual damage (i.e., dysfunction after elimination of the solvent). There is concern that chronic solvent abuse can lead to long-term neurologic and psychological sequelae (Ron, 1986; Marelich, 1997). Some solvents, such as *n*-hexane and methyl-*n*-butyl ketone, cause peripheral neuropathies. Chronic abuse of solvents such as toluene, which were previously thought to be relatively innocuous, may be responsible for diffuse cerebral and cerebellar atrophy (Ron, 1986; Caldemeyer et al., 1996). Blood dyscrasias, liver damage, kidney injury, and other toxicities are seen in patients who have abused solvents known to be injurious to those organs. Death, frequently due to arrhythmogenic effects of high concentrations of some solvents (e.g., 1,1,1-trichloroethane, freons, benzene), is sometimes a consequence of solvent abuse.

ENVIRONMENTAL CONTAMINATION

Widespread use of solvents has resulted in their dissemination throughout the environment (Fig. 24-1). Most everyone is exposed daily to solvents, albeit in minute amounts (Ashley et al., 1994). Since solvents as a chemical class are volatile, the preponderance of solvents entering the environment do so by evaporation. The majority of the more volatile organic compounds (VOCs) volatilize when products containing them (e.g., aerosol propellants, paint thinners, cleaners, soil fumigants) are used as intended. Solvent loss into the atmosphere also occurs during production, processing, storage and transport activities, resulting in elevated concentrations in air in the proximity of point sources. Winds dilute and disperse solvent vapors across the world. Atmospheric concentrations of most VOCs are usually extremely low (i.e., nondetectable to nanograms or a few micrograms per cubic millimeter of air). Higher concentrations of certain solvents (e.g., 10 to 520 mg/m^3, or 3 to 163 ppb of benzene) have been measured in urban areas, around petrochemical plants, and in the immediate vicinity of hazardous waste sites (Bennett, 1987; Kelly et al., 1993).

Solvent contamination of drinking water supplies has become a major health concern. Although the majority of a solvent spilled onto the ground evaporates, some may permeate the soil and migrate through it until reaching groundwater or impermeable material. In years past, the more lipophilic solvents were generally regarded as water-insoluble. It is now recognized that all solvents are soluble in water to some extent. Some (e.g., alcohols, ketones, glycols) are freely soluble. Maximum solubilities of some common hydrocarbon solvents range from 10 mg/L (ppm) for *r*-hexane to 24,000 mg/L for bromochloromethane. High concentrations of VOCs are sometimes found in the effluent of facilities of rubber producers, chemical companies, petrochemical plants, and paper mills (Comba et al., 1994). Concentrations diminish rapidly after VOCs enter bodies of water, due primarily to dilution and evaporation. VOCs in surface waters rise to the surface or sink to the bottom, according to their density. VOCs on the surface will largely evaporate. VOCs on the bottom must depend on solubilization in the water or upon mixing by current or wave action to reach the surface. VOCs in groundwater tend to remain trapped until the water reaches the surface. Concentrations in well water are rarely high enough for acute or subacute toxicity to be of concern. The very low levels of some solvents typically found in water have, however, caused a great deal of concern and debate about their potential for carcinogenicity.

Potential health effects of solvent contaminants of water have received considerable attention for over 30 years. A report by Mason and McKay (1974), of an increased incidence of cancer in persons who drank water from the Mississippi River, prompted the EPA to analyze the water supply of New Orleans. The finding of some 76 synthetic organic chemicals, many of which were solvents, prompted passage of the Safe Drinking Water Act in 1974. CHCl$_3$ is the most frequently found VOC in finished drinking water supplies in the U.S. (ATSDR, 1997b). It and certain other trihalomethanes are formed by reaction of the chlorine added as a disinfectant with natural organic compounds present in the water. Levels of solvents found in drinking water in the U.S. are typically in the ng/L (ppt) to mg/L (ppb) range, though concentrations in the low mg/L (ppm) range are found in water from wells situated in solvent plumes from hazardous waste sites and other point discharges (Barbash and Roberts, 1986; Salanitro, 1993; Mushrush et al., 1994). Of the thousands of chemicals found at hazardous waste sites, 6 of the 10 most commonly present are solvents (Fay and Mumtaz, 1996).

People are subjected to solvents in environmental media by inhalation, ingestion, and skin contact. Considerable effort was devoted by the EPA, from 1979 to 1985, to assess personal exposure to solvents in different locales of the United States. TRI, PERC, benzene, xylenes, and ethylbenzene were most frequently found in highest concentrations (~1-32 mg/m^3) in air (Wallace et al., 1987). Exhaled breath levels of some chemicals (e.g., CHCl$_3$, ethylbenzene) corresponded to indoor air levels. Personal activities (e.g., smoking, visiting dry cleaner's and service stations) and occupational exposures were believed to be largely responsible for relatively high exposures to other VOCs (e.g., benzene, toluene, xylenes, PERC) (Ashley et al., 1994). Subsequent studies, accounting for all pertinent exposure pathways, were conducted by the EPA in mid-1990s (Gordon et al., 1999). Toluene and benzene were the most commonly found VOCs in indoor air. CHCl$_3$ was most prevalent in drinking water. It should be recognized that CHCl$_3$ and other VOCs volatilize to some degree during home water usage, particularly when the water is heated. Thus, a significant proportion of one's total exposure to VOCs in tap water can occur via inhalation. Weisel and Jo (1996) estimated that inhalation and ingestion contribute equally to the internal dose of TCE a person receives when using TCE-contaminated tap water.

TOXICOKINETICS

Toxicokinetic (TK) studies are playing an increasingly important role in reducing uncertainties in risk assessments of solvents (Leung and Paustenbach, 1995; Andersen, 1995). The fundamental goal of TK studies is to delineate the uptake and disposition of chemicals in the body. It is now recognized that toxicity is a dynamic process, in which the degree and duration of injury of a target tissue are dependent upon the net effect of toxicodynamic (TD) and TK processes including systemic absorption, tissue deposition, metabolism, interaction with cellular components, elimination, and tissue repair. Estimation of risk of toxicity from TK data is based on the fundamental concept that the intensity of response from an administered dose is dependent upon the amount(s) of biologically active chemical moiety(ies) present in a target tissue (i.e., the tissue dose). A related concept is that the tissue dose in a given target organ in one species will have the same degree of effect as an equivalent target organ dose in a second species. This concept of tissue dose equivalence appears to be applicable in many cases to solvents

(Andersen, 1987). Gaining understanding of how the processes that govern solvent kinetics vary with dose, species, and even different individuals greatly reduces the number of assumptions that have to be made in assessment of health risks from toxicity data.

Volatility and lipophilicity are two of the most important properties of solvents which govern their absorption and deposition in the body. Most solvents are volatile under normal usage conditions, though volatility varies from compound to compound. Lipophilicity also can vary substantially, from quite water soluble (e.g., glycols and alcohols) to quite lipid soluble (e.g., halocarbons and aromatic hydrocarbons). Many solvents of particular concern at present are relatively lipid soluble and volatile, hence their designation as VOCs. These compounds have a relatively low molecular weight and are uncharged. Thus, they pass freely through membranes from areas of high to low concentration by passive diffusion.

Absorption

The majority of systemic absorption of inhaled VOCs occurs in the alveoli, although some absorption has been demonstrated to occur in the upper respiratory tract (Stott and McKenna, 1984). Gases in the alveoli are thought to equilibrate almost instantaneously with blood in the pulmonary capillaries (Goldstein et al., 1974). Blood: air partition coefficients (PCs) of VOCs are important determi-nants of the extent of their uptake. A PC is defined by Gargas et al. (1989) as the ratio of concentration of VOC achieved between two different media at equilibrium. As blood is largely aqueous, the more hydrophilic solvents have relatively high blood:air PCs, which favor extensive uptake. Gargas and colleagues (1989) determined PCs for 55 VOCs in F344 rats. Human blood:air values were measured for 36 of the compounds. Since VOCs diffuse from areas of high to low concentration, increases in respiration (to maintain a high alveolar concentration) and in cardiac output/pulmonary blood flow (to maintain a large concentration gradient by removing capillary blood containing the VOC) enhance pulmonary absorption.

Systemic uptake of solvents during ongoing inhalation exposures is dependent upon tissue loading and metabolism, in addition to the factors noted above. Percent uptake is initially high, but progressively declines as the chemical accumulates in tissues, and the level of chemical in blood returning to the lungs increases. A near steady-state, or equilibrium will soon be reached with inhalation of a fixed concentration of lipophilic solvents. The approach to equilibrium is asymptotic. Despite continued inhalation of lipophilic solvents, levels in the blood and tissues (other than fat) do not increase appreciably. Percent uptake remains relatively constant for the duration of exposure, with metabolism and accumulation in adipose tissue largely responsible for the continuing absorption. Hydrophilic solvents take considerably longer to reach steady-state, due to the extended time required for equilibration of chemical in the inspired air with that in the body water (Goldstein et al., 1974).

Solvents are well absorbed from the GI tract. Peak blood levels are observed within minutes of dosing, although the presence of food in the GI tract can delay absorption. It is now usually assumed that 100 percent of an oral dose of most solvents is absorbed systemically. The vehicle or diluent in which a solvent is ingested can affect the absorption and TK of the compound. Kim et al. (1990a, b) found that a corn oil vehicle served as a reservoir in the gut to delay GI absorption of carbon tetrachloride (CCl_4) in rats. Although bioavailability of CCl_4 given in corn oil and in an aqueous emulsion was the same, peak blood CCl_4 levels and acute hepatotoxicity were much lower in the corn oil group. Other factors that can influence the oral absorption of other classes of chemicals have relatively little influence on most solvents.

Absorption of solvents through the skin can result in both local and systemic effects. Skin contact with vapors and concentrated solutions of solvents is a common occurrence in the workplace. Dermal contact with solvent contaminants of water can also occur in the home and in recreational settings (Weisel and Jo, 1996). Solvents penetrate the stratum corneum, the skin's barrier to absorption, by passive diffusion. Important determinants of the rate of dermal absorption of solvents include the chemical concentration, surface area exposed, exposure duration, integrity and thickness of the stratum corneum, and lipophilicity and molecular weight of the solvent (EPA, 1998). Skin penetration can be measured in laboratory animals and humans by a variety of in vitro and in vivo techniques (Morgan et al., 1991; Nakai et al., 1999). Although absorption rates measured by these methods may vary quantitatively, there is often good agreement in their relative ranking of chemicals for ability to penetrate the skin. Dermal permeability constants are typically two to four times lower for human than for rodent skin (McDougal et al., 1990). The extent of dermal absorption in occupational and environmental exposure settings should be taken into account when conducting risk assessments of solvents.

Transport and Distribution

Chemicals and nutrients absorbed into portal venous blood from the GI tract can be removed from the bloodstream by first-pass, or presystemic elimination. Blood in the portal venous circulation passes through the liver before entering the pulmonary circulation. Thus, solvents are subject to uptake/elimination by the liver and exhalation by the lungs during their first pass along this absorption pathway. Those solvents that are well metabolized and quite volatile are most efficiently eliminated before they enter the arterial blood. The efficiency of the hepatic first-pass elimination is thus dependent upon the chemical, as well as the rate at which it arrives in the liver. Pulmonary first-pass elimination, in contrast, is believed to be a first-order process irrespective of the chemical concentration in the blood. Lee et al. (1996) demonstrated in rats that pulmonary first-pass elimination of TCE was relatively constant over a range of doses, but that hepatic elimination was inversely related to dose. Andersen (1981) has concluded that the liver is capable of removing "virtually all" of a VOC, if the amount in the blood is not great enough to saturate metabolism. This hypothesis, if proven, could have a profound effect on cancer and noncancer risk estimates of environmentally encountered levels of solvents.

Solvents are transported by the arterial blood and taken up according to tissue blood flow and mass and tissue:blood PCs (Astrand, 1983). Relatively hydrophilic solvents solubilize to different extents in plasma. Nevertheless, as much as 50 percent of such compounds is still carried by erythrocytes (Lam et al., 1990). These researchers found that 90 to 95 percent of the more lipophilic solvents is transported by erythrocytes. Lipophilic solvents do not bind to plasma proteins or hemoglobin, but partition into hydrophobic sites in the molecules. Lipophilic solvents also partition into phospholipids, lipoproteins and cholesterol present in the blood. Initial uptake into organs is largely dependent upon their rate of blood flow and the tissue:blood PC of the solvent. The brain is an example of a rapidly perfused tissue with a relatively high lipid content. Lipophilic solvents quickly accumulate in the brain after the initiation of exposures, producing CNS effects as profound as surgical anesthesia within as little as 1 to 2 min. Redistribution to poorly perfused, lipoidal tissues will subsequently occur. Adipose tissue accumulates relatively large amounts of VOCs.

Route of exposure can significantly influence target organ deposition and toxicity of solvents. Much of the toxicology database for solvents, before 1980, was comprised of results of inhalation studies. Inhalation is the major route of occupational exposure to these chemicals. Since then, much attention has been focused on potential health effects of VOC contaminants of drinking water. Due to the initial paucity of oral data, regulatory agencies sometimes extrapolated directly from inhalation data to predict risks of ingestion of VOCs. Such a practice does not appear to be scientifically valid when physiologic differences in the absorption pathways are taken into account. For example, all of the cardiac output passes through the pulmonary circulation versus ~20 percent for the GI tract. Also, the alveolar surface area for absorption is approximately 20 times that of the entire GI tract. VOCs absorbed in the lungs directly enter the arterial circulation and are transported throughout the body. In contrast, VOCs absorbed from the GI tract largely enter the portal circulation and are subject to first-pass elimination by the liver and lungs. It is not surprising then that extrahepatic organs receive a greater dose following inhalation of VOCs. The liver should take up and metabolize more of a VOC following ingestion. This has been demonstrated in rats receiving the same systemic dose of CCl_4 by inhalation and gastric infusion (Sanzgiri et al., 1997).

The pattern of ingestion of solvents can significantly influence their TK and health effects. For convenience, test chemicals are often given to animals as a single bolus by gavage in short- and long-term oral toxicity studies. Actual human exposures to solvents in drinking water are quite different, in that people typically ingest water in divided doses. High gavage doses of $CHCl_3$ and other halocarbons have produced hepatocellular carcinoma in B6C3F1 mice. No evidence of hepatic tumorigenesis was seen, however, when these mice were given the same doses of the chemicals in their drinking water (Jorgenson et al., 1985; Klaunig et al., 1986). The maximum blood level of CCl_4 was found to be 35 times higher and hepatotoxicity more severe in rats dosed with CCl_4 by gavage, than in those given the same dose over 2 h by gastric infusion (Sanzgiri et al., 1995). Oral bolus doses of solvents can cause damage by exceeding the capacity of hepatic and pulmonary first-pass elimination, as well as other protection and repair processes.

The rate of systemic elimination of different solvents varies considerably. The two major routes of systemic elimination of VOCs are metabolism and exhalation. The rate and extent of metabolic clearance are dose- and compound-dependent. Exhalation is determined largely by the rate of pulmonary blood flow, the chemical's air:blood PC, and the alveolar ventilation rate. The more volatile, lipophilic VOCs are exhaled the most readily, since they have the higher air:blood PCs (Gargas et al., 1989). A good "case in point" is comparison of toluene with acetone. The extent of CNS depression caused by each chemical is dependent upon the concentration of the parent compound present in the brain (Bruckner and Peterson, 1981). As can be seen in Fig. 24-3, recovery of rats from toluene anesthesia occurs within minutes of cessation of exposure. This can be attributed to redistribution of toluene from the brain to body fat and other tissues, as well as to relatively rapid metabolism and exhalation. In contrast, recovery from acetone narcosis does not occur for ~9 h. Acetone is water soluble and is distributed in the considerable volume of the blood and other body water. Clearance of acetone is low due to its large volume of distribution and its relatively slow metabolism and exhalation. Acetone's water solubility is responsible for its relatively low air:blood PC and retention in the pulmonary blood. Thus, acetone is available for diffusion into the brain

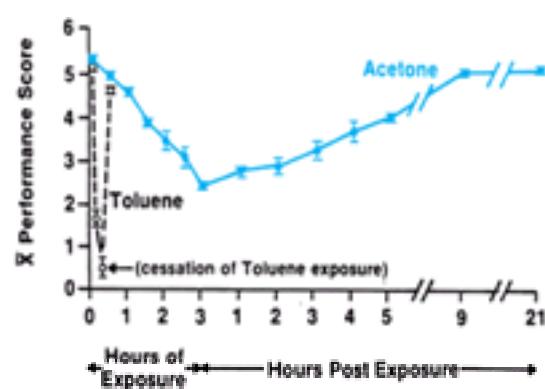
and induction of a modest degree of CNS depression for a prolonged time.


Figure 24-3. Comparison of the induction of and recovery from toluene and acetone narcosis.

Rats inhaled 45 mg/L of toluene or acetone for 20 min or 3 h, respectively. Animal performance/reflexes were monitored periodically as measures of the degree of CNS depression. [Used with permission of Bruckner and Peterson (1981).]

Body fat plays an important role in the elimination of lipophilic solvents. Blood levels of such solvents drop very rapidly during the initial elimination phase. This so-called redistribution phase is characterized by rapid diffusion of solvent from the blood into most tissues. Equilibration of adipose tissue is prolong-ed due to the small fraction of cardiac output (~3 percent) supplying fat depots (Goldstein et al., 1974). Body fat increases the volume of distribution and total body burden of lipophilic solvents. Deequilibration from adipose tissue during the terminal elimination phase is prolonged due to slow blood flow and high fat:blood PC.

Metabolism

Biotransformation plays a key role in modulating the toxicities of solvents. Many solvents are poorly soluble in water. Certain cellular enzymes can convert them to relatively water-soluble derivatives, which may be more readily eliminated in the largely aqueous urine and/or bile. Conversion of a bioactive parent compound to less bioactive or inactive metabolite(s) that (is/are) efficiently eliminated is termed *metabolic inactivation,* or *detoxification.* Toluene, for example, accumulates in neuronal membranes and inhibits their functions. Toluene is metabolized to hydroxyl and carboxyl metabolites, which are too polar to accumulate in substantial quantities in membranes. Thus, metabolism serves to detoxify and to accelerate the elimination of toluene. Metabolism of other solvents can produce reactive metabolites that are cytotoxic and/or mutagenic. This phenomenon is known as *metabolic activation,* or *bioactivation.* Benzene, for example, is oxidized to a variety of quinones and semiquinones that can produce hematopoietic toxicities and leukemias (Snyder et al., 1993). Benzene and many other VOCs are converted via multiple metabolic pathways to products of varying toxicity. Some of these competing pathways are considered bioactivation, others detoxification pathways. A variety of factors can influence the prominence of the different pathways and hence alter toxicity outcomes.

Biotransformation of relatively lipophilic solvents is catalyzed largely by cytochrome P450s. The cytochrome P450s, are a "superfamily" of hemoproteins that act as terminal oxidases of the mixed-function oxidase (MFO) system. Their mode of action is described in Chap. 6. The P450s can catalyze a number of oxidative reactions as well as certain reductive reactions (Omiecinski et al., 1999). More than 20 different human P450 isozymes have been identified to date, but 6 (2D6, 2C9, 3A4, 1A2, 2C19, and 2E1) account for the majority of xenobiotic metabolism (Smith et al., 1998). Although the P450s have generally been thought to have broad, overlapping substrate specificities, it is now believed that enzyme kinetics under physiologic conditions may favor one or two isozymes as the primary catalysts for a given chemical (Wrighton and Stevens, 1992). Different isozymes can predominate at different doses of the same chemical.

The outcome of exposure to a potentially toxic solvent can depend on the relative abundance of P450 isozymes. Expression of P450s varies considerably as a result of genetic polymorphisms and exposure to chemicals which induce or repress individual isozymes. Inheritable gene alterations, such as base changes and deletions, can result not only in functionally deficient enzymes but in the absence of certain P450s (Daly et al., 1993). As P450s have different modes of regulatory control, their expression in response to various inducers and inhibitors varies. It should also be recognized that there are interspecies differences in the presence, regulation, and catalytic activities of P450s (Lewis et al., 1998).

There has been a focus on identification of P450 isozymes which participate in the metabolism of individual solvents. Nakajima et al. (1992a) found that low concentrations of TCE in rat liver were metabolized primarily by cytochrome P450IIE1 (CYP2E1), a constitutive high-affinity, low-capacity isozyme. CYP2B1/2, a low-affinity, high-capacity form, predominated under high dose (substrate) conditions. CYP2E1 was observed to be a major contributor to the metabolism of TCE and benzene, but not toluene. CYP1A1 catalyzed the formation of *o*-cresol, but not benzyl alcohol from toluene. CYP1A1 biotransformed TCE in mice but not in rats. Thus, P450 isozymes exhibit species-, substrate-, and regioselectivity for solvents (Nakajima, 1997).

CYP2E1 has been shown to be a major catalyst of the oxidation of a variety of low-molecular-weight compounds, including many solvents. CYP2E1 is found in the liver, kidneys, and other extrahepatic tissues of rodents and humans (Lieber, 1997a). Guengerich et al. (1991) demonstrated that human CYP2E1 was primarily responsible for oxidation of some 16 halogenated and aromatic hydrocarbons, including benzene, styrene, $CHCl_3$, TCE, and vinyl chloride. These compounds are oxidized to electrophilic metabolites, capable of causing cytotoxicity and/or mutagenicity (Raucy et al., 1993). The isozyme is also responsible for reduction of CCl_4 to free radicals (see the discussion of CCl_4 in this chapter). CYP2E1 activity is associated with the pathogenesis of alcoholic cirrhosis, through formation of highly reactive oxygen radicals and acetaldehyde from ethanol (Lieber, 1997a). CYP2E1 is inducible by ethanol, acetone, and other of its substrates. Activity of the isozyme varies from species to species (Nakajima, 1997) and from human to human (Lipscomb et al., 1997). Such differences in CYP2E1 may play an important role in susceptibility to solvent toxicity and carcinogenesis (Gonzalez and Gelboin, 1994; Raunio et al., 1995).

A number of environmental factors can predispose people to harmful effects of solvents by altering P450s (Lof and Johanson, 1998). Ethanol is an effective CYP2E1 inducer when ingested repeatedly in substantial amounts. The person who drinks in such a manner may be subject to potentiation of solvent toxicity, due to increased solvent metabolic activation (Manno et al., 1996). Conversely, ethanol consumed at about the same time as a solvent exposure can be protective by competitively inhibiting metabolic activation of the solvent (Lieber, 1997a). Thus, the timing of exposures is important. Folland et al. (1976) report severe CCl_4-induced hepatorenal injury in workers at an isopropyl alcohol bottling plant. These subjects' preexposure to the alcohol, which is metabolized to acetone, caused marked CYP2E1 induction. Their induced condition resulted in a substantial increase in the metabolic activation and cytotoxicity of CCl_4, upon inhalation of a normally nontoxic concentration of the halocarbon.

The metabolic basis of solvent interactions receives considerable attention. The consequence of CYP2E1 induction by one solvent depends upon the nature of the second solvent. Kaneko et al. (1994) report that ethanol pretreatment of rats has a more profound effect on the TK of 1,1,1-trichloroethane (poorly metabolized) than TCE (well metabolized). Similarly, ethanol pretreatment of rats results in a greater increase in metabolism and hepatotoxicity of CCl_4 (poorly metabolized) than $CHCl_3$ (well metabolized) (Wang et al., 1997). These investigators reason that alterations in the metabolism of low doses of well-metabolized compounds are of little consequence, since their metabolism is perfusion- (i.e., hepatic blood flow–) limited. Capacity- (i.e., metabolic capacity of the liver) limited metabolism prevails for poorly metabolized compounds, irrespective of dose. Although chemical/solvent interactions can be toxicologically significant in occupational settings, it is not clear whether exposures to trace levels of solvents in the environment result in metabolic interactions of consequence.

Physiologic Modeling

Physiologically based toxicokinetic (PBTK) models have been developed to provide predictions of chemical concentrations in blood and tissues as a function of time. PBTK models are thus used to relate the administered dose to the tissue dose of bioactive moiety or moieties. If there is sufficient knowledge of the physiology of the test animal/tissue, interactions of the bioactive moiety with cellular components and ensuing responses, physiologically based toxicodynamic (PBTD) models can be developed (Conolly and Andersen, 1991). PBTD models describe the relationship between the tissue dose, early chemical-tissue interactions, and resulting toxic effect(s). Development of PBTK models for anesthetic gases and other pharmaceutical agents was initially undertaken in the 1920s and 1930s. Modeling enjoyed

widespread use in the design of experiments and dosage regimens for drugs, but the practice was not extended to industrial chemicals until the 1970s and 1980s. A "benchmark" paper by Ramsey and Andersen (1984) described the development of a PBTK model for styrene. By 1995, PBTK models had been developed for ~50 chemical environmental contaminants (Leung and Paustenbach, 1995). Some 28 of these 50 chemicals were solvents.

PBTK/TD models are being used with increasing frequency to incorporate dosimetry and mechanistic data into noncancer and cancer risk assessments. Physiologic modeling accounts for species- and dose-dependent shifts from linear to nonlinear kinetics, which impact tissue doses of bioactive moiety or moieties. The models are well suited for species-to-species extrapolations, since human physiologic and metabolic parameter values can be input and simulations of target tissue doses and effects in humans generated. Thus, solvent exposures necessary to produce the same target organ dose in humans, as that found experimentally to cause an unacceptable cancer or noncancer incidence in test animals, can be determined in some cases with reasonable certainty (Andersen, 1995). Modeling is now even being used for individual-specific dosimetry (Pierce et al., 1996). In a limited number of cases where there may be species differences in tissue sensitivity, PBTD models may be used to forecast toxicologically effective target organ doses.

POTENTIALLY SENSITIVE SUBPOPULATIONS

There is considerable variability in responses of humans to solvents and other xenobiotics (Hattis et al., 1987). Although information on interindividual differences in the kinetics and toxicity of solvents is limited, some significant differences are reported and should be taken into account in risk assessments (Grassman et al., 1998). Current EPA cancer and noncancer risk assessment practices are generally considered to be protective of potentially vulnerable subgroups, because of the conservative default assumptions upon which the practices are based.

Endogenous Factors

Children Currently there is considerable interest in regulatory and scientific issues related to protection of children's health. The potential sensitivity of infants and children to pesticides and other chemicals was brought to the public's attention by a National Academy of Sciences report (NAS, 1993; Bruckner, 2000). The ensuing Executive Order 13045, in 1997, directed all federal agencies to make protection of children a high priority and to consider risks to children when making policies and setting standards.

Very limited information is available on the toxic potential of solvents and other chemicals in children. The most comprehensive data sets available are compilations of LD_{50} values from studies of immature and mature laboratory animals (Done, 1964; Goldenthal, 1971). Results of these experiments and other investigations of systemic toxicity reveal that immature animals are more sensitive to some but not all chemicals. Most reported age-dependent differences are less than an order of magnitude, usually varying no more than two- to threefold. The younger and more immature the subject, the more different its response from that of an adult. Substantial anatomical, physiologic, and biochemical changes occur during infancy, childhood, and puberty. There may be developmental periods, or "windows of vulnerability" when the endocrine, reproductive, immune, audiovisual, nervous, and other organ systems are particularly sensitive to certain chemicals. Maturational changes may also substantially affect the kinetics and ensuing toxicity of solvents and other agents (Hein, 1987; ILSI, 1992; Bruckner and Weil, 1999).

Despite a virtual "data vacuum," logical assumptions can be made about age-dependent changes in the kinetics and toxicity of solvents. GI absorption of solvents would not be expected to vary with age, since most solvents are rapidly and completely absorbed by passive diffusion. Systemic absorption of inhaled VOCs may be greater in infants and children than in adults. Infants' and children's cardiac output and respiratory rates are relatively high, although their alveolar surface area is lower than that of adults (Snodgrass, 1992). Reduced plasma protein binding capacity in neonates and infants may be of consequence for solvent metabolites. Extracellular water, expressed as percentage of body weight, is highest in newborns and gradually diminishes through childhood. Body fat content is high from ~1/2 to 3 years of age, then steadily decreases until adolescence, when it increases again in females. Lipophilic solvents accumulate in adipose tissue, so more body fat would result in greater body burdens and slower clearance of the chemicals.

Changes in xenobiotic metabolism during maturation may have the greatest impact on susceptibility to solvent toxicity and carcinogenicity. Poisonings of premature and term newborns exposed to benzyl alcohol, hexachlorobenzene, chloramphenicol, and other compounds are primarily attributable to initial deficits in metabolic conjugation capacity. Studies of human liver reveal that P450 isoforms are age-dependent and develop asynchronously, possibly by different mechanisms (Treluyer et al., 1996; Cresteil, 1998). Levels of CYP2E1, the principal catalyst of oxidation of a variety of solvents, are very low at birth but "surge" within hours and then steadily increase during the first year of life (Vieira et al., 1996; Treluyer et al., 1996). Systemic clearance of many drugs is higher in children than in adults. Although Blanco et al. (2000) recently failed to find an age-related difference in the maximal activity of CYP2E1 or other hepatic P450 isozymes in vitro, it is generally believed that P450 activities are higher in infants and children than in adults. It should be recognized that increased metabolic activation does not necessarily mean increased toxicity in children. Cyclophosphamide, for example, is metabolically activated to acrolein and phosphoramide mustard. Children are less susceptible to cyclophosphamide toxicity than adults (Crom et al., 1987), due to more rapid detoxification and elimination of these reactive intermediates. Increased rates of metabolism, urinary excretion of metabolites, and exhalation by children should hasten elimination and reduce body burdens of solvents.

The net effect of immaturity on solvent disposition and toxicity is difficult to predict. An age-related change in one parameter may be offset or augmented by concurrent changes in other parameters. Susceptibility of immature subjects may be age-, organ-, chemical- and species-dependent. Newborn mice and rats are less mature at birth than are humans, though maturation of rodents is much more rapid. A few days of age can result in a marked disparity in toxicity test results in rodents (Done, 1964). Organs and their functions mature at different rates in different species. Thus interspecies extrapolations in immature animals are difficult, and selection of an appropriate animal model for a particular phase of human development can be difficult. PBTK models may be useful here. Physiologic and metabolic parameter values will need to be measured in healthy children of different ages by noninvasive methods for input into the models.

Elderly A number of factors would appear to be involved in differential sensitivities of the elderly to solvents (Dawling and Chrome, 1989; Birnbaum, 1991). With aging, body fat usually increases substantially at the expense of lean mass and body water. Thus, relatively polar solvents tend to reach higher blood levels during exposures. Relatively lipid-soluble solvents accumulate in adipose tissue and are released slowly to sites of action, metabolism, and elimination. Cardiac output diminishes 30 to 40 percent between the ages of 25 and 65, as do renal and hepatic blood flows (Cody, 1993; Woodhouse and Wynne, 1992). The latter two researchers concluded that reduced clearance of flow- and capacity-limited drugs in the elderly was due primarily to reductions in liver blood flow and liver size. Schmucker et al. (1990) did not find a relationship between aging and P450 activities and content in human liver. McMahon et al. (1994) used a PBTK model to demonstrate that reduced urinary elimination of benzene metabolites in geriatric mice was due to decreased renal blood flow rather than altered formation of metabolites.

The elderly, like infants and children, may be more or less sensitive to the toxicity of solvents than young adults. Data are lacking on age-dependent susceptibility of humans to solvents and other industrial chemicals. Older people do appear to be more sensitive to CNS-depressant effects of ethanol, due in part to lower gastric alcohol dehydrogenase activity (Seitz et al., 1993). Experiments have shown that aged rodents are more vulnerable to hepatocellular injury by some solvents including allyl alcohol, ethanol, and CCl_4. Rikans et al. (1999) have suggested that the greater liver damage could be due to increased inflammatory damage, due to age-related dysregulation of cytokines. Other major sources of variability and complexity in responses of geriatric populations to solvents include toxicodynamic (TD) changes, inadequate nutrition, the prevalence of disease states, and the concurrent use of multiple medications.

Gender Women may differ from men in some respects in their responses to solvents, but the differences do not appear to be too great. Most men have more muscle mass and larger body size. Women typically have more body fat and smaller volumes of distribution for polar solvents. Nomiyama and Nomiyama (1974) found that women retained less inhaled acetone and ethyl acetate than men. Levels of toluene and TCE in expired air were lower in females, reflecting greater fat deposition. The major sex differences in P450-mediated metabolism in rats are not seen in humans or most other mammals (Nakajima, 1997). No marked gender differences in P450-dependent enzyme activities have been identified in humans (Mugford and Kedderis, 1998). Gender differences in responses to ethanol are well recognized and described in this chapter under "Ethanol." Relatively little is known about potential influences of contraceptives, hormone replacement therapy, or pregnancy on the metabolism and kinetics of xenobiotics (Gleiter and Gundert-Remy, 1996).

Genetics A variety of genetic polymorphisms for biotransformation have been found to occur at different frequencies in different ethnic groups (Daly et al., 1993). Polymorphisms for xenobiotic metabolizing enzymes may affect the quantity and quality of enzymes and the outcomes of exposures to solvents (Ingelman-Sundberg et al., 1994). It is important to note that culturally linked environmental factors also contribute to ethnic differences in metabolism and disposition of solvents and other chemicals. It is difficult to disentangle the influences of genetic traits from those of different lifestyles, socioeconomic status, and geographic setting.

Ethnic differences in regulation of the expression of P450 isozymes and other enzymes appear to be associated with variations in drug and solvent metabolism (Ingelman-Sundberg et al., 1994; Weber, 1999). Shimada et al. (1994) found that Caucasians had higher total hepatic P450 levels than Japanese. Caucasians

exhibited higher CYP2E1 activities, as reflected by aniline p-hydroxylation and 7-ethoxycoumarin O-deethylation. Individuals with two linked polymorphisms in the transcription regulatory region of the CYP2E1 gene exhibited greater expression of the isoform. Reported frequencies of these rare alleles were 2 percent in Caucasians, 2 to 5 percent in African Americans, and 24 to 27 percent in Japanese. Kawamoto et al. (1995) found that a CYP2E1 polymorphism in Japanese workers did not affect metabolism of toluene to benzoic acid, but that CYP1A1 and aldehyde dehydrogenase (ALDH2) polymorphisms did. About half of the Japanese population lacks ALDH2 due to a structural point mutation in the ALDH2 gene. Pronounced interethnic differences in rates of ethanol metabolism have been associated with a number of ADH and ALDH polymorphisms. Ethnic differences have also been demonstrated for some phase II biotransformation reactions. Glutathione S-transferases (GSTs) are a family of enzymes which promote the detoxification of electrophilic metabolites by catalyzing their conjugation with reduced glutathione (GSH). Some individuals with a null/null genotype for GST theta lack the ability to conjugate and detoxify metabolites of methyl chloride and methylene chloride. The prevalence of this genotype ranges from 10 percent in Mexican Americans to 60 to 65 percent in Chinese and Koreans (Nelson et al., 1995).

Increased susceptibility to different cancers has been reported to be associated with certain genetic polymorphisms, which occur with different frequencies in different ethnic groups (Daly et al., 1993). Significant variations in allelic distributions for isozymes including CYP2E1, 2D6, 1A1, and GSTM1 have been observed in different racial groups. Results of investigations of a relationship between occurrence of defective alleles for CYP2E1 and cancer incidence have been contradictory. Studies with more statistical power of selected ethnic groups need to be conducted to clarify the roles of P450 polymorphisms in cancers. Although molecular markers clearly indicate variances in P450 genes, biologically plausible mechanisms linking specific genotypes with specific outcomes are lacking at present.

Exogenous Factors

P450 Inducers Considerable effort has been devoted to the study of effects of inducers of solvent metabolism. Preexposure to chemicals that induce CYP2E1 and/or CYP2B1/2 can potentiate the toxicity of high doses of solvents that undergo metabolic activation (Fig. 24-4). Induction of these P450s may be of little consequence, however, for low doses of well metabolized solvents (Kaneko et al., 1994; Wang et al., 1997). Notable inducers include ethanol and other alcohols, acetone and other ketones, polycyclic aromatic hydrocarbons, and certain drugs (e.g., phenobarbital, phenytoin, diazepam, rifampicin). Nitcotine and some of the polycyclic hydrocarbons in cigarette smoke are P450 inducers. Smoking, however, has not been clearly shown to influence the TK of VOCs (Sato, 1991). It is important to recognize that many compounds that induce P450s are also inducers of detoxifying enzymes (e.g., epoxide hydratase, glucuronyl- and sulfotransferases). A comprehensive compilation and account of solvent-solvent interactions is presented by Lof and Johanson (1998).

Figure 24-4. Potentiation of CCl$_4$ hepatotoxicity by 2-butanol.

Rats were (A) untreated; (B) given 0.1 mL CCl$_4$/kg IP; or (C) pretreated with 2-butanol (2.2 mL/kg PO) 16 h before 0.1 mL CCl$_4$ IP. Central veins and portal triads are designated V and P, respectively. Occasional hepatocytes adjacent to the central vein are vacuolated in (B). Note the demarcation between vacuolated/necrotic centrilobular and midzonal cells, and normally appearing periportal cells in (C). Hematoxylin and eosin stain. (A) and (C) ×315; (B) ×480. [Used with permission of Traiger and Bruckner (1976).]

P450 Inhibitors A number of drugs and other compounds inhibit P450s. Such agents would generally be anticipated to enhance the toxicity of solvents that are metabolically inactivated. Conversely, P450 inhibitors should protect from solvents that undergo metabolic activation. Compounds including disulfiram (Antabuse®), 3-amino-1,2,4-triazole, and several constituents of foods (e.g., diallyl sulfide, dihydrocapsaicin, phenylethyl isothiocyanate) inhibit CYP2E1 and protect animals from some carcinogens (Lieber, 1997a). Although quite high doses of the natural products were used in these studies, consumption of such foods may be shown to aid in prevention of some tumors in humans. Certain drugs and solvents are categorized as noncompetitive inhibitors, in that they bind so strongly to P450s that the amount of functional P450 is diminished. Solvents, which in the course of their own metabolism destroy P450s, are known as suicide inhibitors. *Trans*- and *cis*-1,2-dichloroethylene, for example, are potent suicide inhibitors of CYP2E1 in rat liver, but TCE is not (Lilly et al., 1998).

Physical Activity Exercise can significantly affect the kinetics of xenobiotics (van Baak, 1990) but is often not considered in occupational risk assessments of solvents. Exercise increases two of the major determinants of VOC uptake, alveolar ventilation and cardiac output/pulmonary blood flow. Polar solvents with relatively high blood:air PCs (e.g., acetone, ethanol, ethylene glycol) are very rapidly absorbed into the pulmonary circulation. Alveolar ventilation is rate-limiting for these chemicals. In contrast, pulmonary blood flow and metabolism are rate-limiting for uptake of the more lipophilic solvents (Johanson and Filser, 1992). Heavy exercise can increase pulmonary uptake of relatively polar solvents as much as fivefold in human subjects (Astrand, 1983). Light exercise doubles uptake of relatively lipid-soluble solvents, but no further increase occurs at higher workloads. Blood flow to the liver and kidneys diminishes with exercise, so biotransformation of well-metabolized solvents and urinary elimination of polar metabolites may be diminished (Lof and Johanson, 1998). Dankovic and Bailer (1994) modified the human PBTK model of Reitz et al. (1988) for methylene chloride to reflect light work conditions. The modified model predicted that light exercise would result in a twofold increase in hepatic methylene chloride deposition and in metabolite formation via P450- and GSH-dependent pathways.

Diet Dietary habits can influence the TK and toxicity of solvents in several ways. The mere bulk of food in the stomach and intestines can inhibit systemic absorption of ingested chemicals. VOCs in the GI tract partition into dietary lipids, largely remaining there until the lipids are emulsified and digested. This serves to substantially delay absorption of VOCs such as CCl$_4$, resulting in lower blood levels and diminished acute hepatotoxicity in rats (Kim et al., 1990a). Food intake results in increased splanchnic blood flow, which favors GI absorption. The accompanying increase in hepatic blood flow would be expected to enhance the biotransformation of low doses of well-metabolized solvents, but to have little effect on first-pass metabolism of relatively high (i.e., saturating) doses (Tam, 1993). Consumption of a high-fat diet can result in an increase in CYP2E1 in the liver of obese rats, possibly due to induction of the isozyme by acetone and other ketone bodies (Raucy et al., 1991). Increased incidences of several types of cancer have been observed in obese humans (Moller et al., 1994). Caloric restriction has clearly been shown to reduce the incidence of several chemically induced tumors in rodents (Kritchevsky, 1999).

Fasting results in decreased liver GSH levels due to interrupted intake of amino acids required for its synthesis. GSH plays a key role in the detoxification of electrophilic metabolites of a number of solvents. Short-term fasting (~18 to 24 h) results in induction of liver CYP2E1 and increase in metabolism of a number of aromatic hydrocarbons and halocarbons (Nakajima et al., 1982). The hepatotoxicity of CCl$_4$, which requires CYP2E1-catalyzed metabolic activation, is more severe in fasted animals (Nakajima et al., 1982). In contrast, long-term food deprivation (i.e, starvation) results in decreased synthesis and activity of P450s. Foods may contain certain natural constituents, pesticides, and other chemicals which may enhance or reduce solvent metabolism.

Clock Time Many physiologic and biochemical processes that impact solvent TK exhibit circadian or diurnal rhythms. Investigations have revealed circadian rhythms in susceptibility of rats to liver damage by several VOCs, including CCl$_4$, CHCl$_3$, 1,1-dichloroethylene, ethanol, and styrene (Labrecque and Belanger, 1991). In each instance, the chemicals were most toxic when given during the initial part of the rodents' dark/active cycle. Low hepatic GSH levels at this time were an important contributing factor to the increased liver injury by 1,1-dichloroethylene and CHCl$_3$. Restricted food intake during sleep resulted in lipolysis and formation of acetone, which contributed to the diurnal induction of CYP2E1 and the ensuing increases in hepatic metabolic activation and cytotoxicity of CCl$_4$ in rats (Bruckner et al., 2001). Furukawa et al. (1999) attributed high hepatic microsomal 7-alkoxycoumarin O-dealkylase activity during male rats' active cycle to diurnal secretion of growth hormone. Hepatic blood flow and acetone levels in expired air of humans peak before breakfast. Clearance rates for a number of well metabolized compounds, including ethanol (Sturtevant et al., 1978) and nicotine (Gries et al., 1996), are maximal in human subjects during the first part of their active/wake cycle. Thus, humans may also be more susceptible at this time to the toxicity of solvents that undergo metabolic activation.

Diseases Illness can be a major source of variability in response to solvents. Impaired drug metabolism and clearance are commonly seen in patients with cirrhosis and hepatitis (Welling and Pool, 1996). Reduced metabolism of solvents may result from decrease in hepatic mass, diminished enzymatic activity, and/or decreased portal blood flow (McLean and Morgan, 1991). Lower levels of CYP2E1, CYP1A2, and GSH are seen in livers of patients with cirrhosis (Murray, 1992). Reduced P450-catalyzed metabolic activation of certain solvents could be protective, but diminished capacity to conjugate electrophilic metabolites with GSH would have the opposite effect. Plasma levels of albumin and a_1-acid glycoprotein fall in cirrhotic patients. Thus, plasma protein binding of many drug metabolites decreases and their elimination increases (McLean and Morgan, 1991). Definitive information is lacking, however, on the net effect of liver diseases on solvents.

Little is known about the influence of kidney disease on the TK of solvents and their metabolites. The protein binding of many drugs is reduced in patients with compromised renal function. The binding and urinary elimination of relatively polar metabolites of solvents may also be diminished, resulting in accumulation of high concentrations of metabolites. Findings in studies of the influence of impaired renal function on hepatic drug metabolism are conflicting. Hepatic clearance of therapeutic agents may be increased, decreased, or unaffected (Elston et al., 1993). The mechanisms of these changes are unclear, as is their applicability to solvents.

Diabetics may be at increased risk of injury by solvents which undergo metabolic activation. Metabolic ketosis in diabetics results in elevated concentrations of acetone, an inducer of hepatic CYP2E1. Hormonal perturbations, including decreases in circulating thyroid hormone, plasma growth hormone, and testosterone, are associated with uncontrolled diabetes. These and other hormones are involved in regulation of P450 isoforms. CYP2E1 and CYP2B1, for example, are induced in diabetic rats, while other isoforms are diminished (Waxman and Chang, 1995). Thus, diabetes may predispose individuals to increased risk of cell injury and/or mutation by solvents which are metabolically activated by CYP2E1 and/or CYP2B1/2.

Persons with bacterial infections may be more sensitive to cytotoxic actions of solvents. Endotoxin, which includes a lipopolysaccharide, is released from the cell wall of gram-negative organisms. The lipopolysaccharide causes the release of inflammatory mediators, which alter cell membranes, intercellular signaling, and gene expression (Roth et al., 1997). These effects may render cells more susceptible to damage by solvents and other chemicals. Exposure of animals to small amounts of endotoxin potentiates liver injury by CCl_4, halothane, allyl alcohol, ethanol, and other solvents (Roth et al., 1997). Endotoxin apparently activates Kupffer cells to release inflammatory mediators and cytotoxic moieties to hepatocytes (Thurman, 1998).

CHLORINATED HYDROCARBONS

Trichloroethylene

1,1,2-Trichloroethylene (TCE) is a widely used solvent for metal degreasing that has been identified at more than one-half of the 1416 hazardous waste sites proposed for inclusion on the EPA's National Priority List (Fay and Muntaz, 1996). TCE has received a great deal of attention from the scientific and regulatory communities recently, due to the EPA's effort to update its more than decade-old risk assessment for TCE. Moderate to high doses of TCE, like other halocarbons, are associated with a number of noncancer toxicities (Barton and Das, 1996). Cancer is the dominant issue for TCE, however. Testament to this includes Germany's recent classification of TCE as a known human carcinogen (Bruning and Bolt, 2000) and the National Toxicology Program's reconsideration of its classification status (NTP, 2000). Attempts to understand the mechanistic underpinnings of TCE's carcinogenicity have resulted in a body of work of massive proportion, that—while providing significant insights—has not eliminated many of the uncertainties that plague the risk-assessment process. Nonetheless, TCE provides a stellar example of how research methods can be applied to generate experimental and epidemiologic data for use in a regulatory context. A 16-article series of state-of-the-science papers, upon which the EPA will heavily rely in its new risk assessment, has been recently published (Scott and Cogliano, 2000).

Cancer Epidemiology As pointed out by Wartenberg et al. (2000), there is no shortage of published studies examining cancer incidence and mortality among TCE-exposed human populations. Examples include those of Morgan et al. (1998), Blair et al. (1998), Boice et al. (1999), and Ritz (1999), of whom all but the last examined cancer mortality or incidence among aircraft manufacturing or maintenance workers. In addition to these U.S. studies, the mortality experience of smaller Swedish, Finnish, and German worker cohorts has been examined (Axelson et al., 1978; Tola et al., 1980; Axelson et al., 1994; Anttila et al., 1995; Henschler et al., 1995). All of the studies mentioned above constitute what Wartenberg and colleagues refer to as tier I studies, meaning that exposure was better characterized than in cohort studies in lower tiers. Thus, tier I studies received a greater weighting from these authors when making causal inferences than lower-tier cohort studies, case-control studies, and community-based studies. An average relative cancer risk was calculated by Wartenberg et al. (2000) for studies within each tier using a meta-analysis-like approach for both mortality and incidence data. Among the tier I studies, evidence for an excess incidence of cancer was strongest for the kidney (relative risk (RR)=1.7, 95 percent confidence interval (CI)=1.1 to 2.7), liver (RR=1.9, 95 percent CI=1.0 to 3.4), and non-Hodgkin's lymphoma (RR=1.5, 95 percent CI=0.9 to 2.3). These investigators also contend that the data support weak associations between TCE exposure and multiple myeloma, Hodgkin's disease, and cancers of the prostate, skin, and cervix.

While not as comprehensive as that of Wartenberg et al. (2000), other reviews of occupational epidemiologic studies have been conducted. Weiss (1996) concluded that the evidence for the carcinogenicity of TCE was "quite limited." He acknowledged that there was some suggestive evidence that TCE could possibly be associated with non-Hodgkin's lymphoma and cancers of the liver, biliary tract, and kidney, with evidence for the kidney coming solely from the study of German cardboard workers by Henschler et al. (1995). Another review of cohort and case-control studies (McLaughlin and Blot, 1997) concluded that the totality of the evidence did not support a role for TCE in renal cell cancer (RCC). Morgan et al. (1998) combined their data with that of others in a meta-analysis-like approach that resulted in slight, statistically insignificant elevations in meta-standardized mortality ratios for cancers of the liver, prostate, kidney, bladder, and non-Hodgkin's lymphoma. The IARC (1995) concluded that TCE is "probably carcinogenic to humans," based on its assessment of sufficient evidence in animals and limited evidence in humans.

The report of Henschler et al. (1995) was the first in a series of German studies that has provided the strongest evidence to date for an association between TCE and RCC. These authors reported on a cohort of male cardboard factory workers who were exposed to moderate to extremely high concentrations of TCE. By the closing date of the study, five of 169 exposed workers had been diagnosed with kidney cancer versus none of the 190 controls. This resulted in standardized incidence ratios (SIRs) of 7.97 (95 percent CI=2.59 to 18.59) and 9.66 (95 percent CI=3.14 to 22.55) using Danish and German Cancer Registry data for comparison, respectively. Two additional kidney cancers were diagnosed after the end of the observation period that further increased the SIRs. A single U.S. study had reported a weaker, but significantly elevated SIR for RCC (SIR=3.7, 95 percent CI=1.4 to 8.1) among paperboard workers exposed to TCE (Sinks et al., 1992). German researchers also conducted a hospital-based case-control study with 58 RCC patients and 84 patients from accident wards who served as controls. Of the 59 RCC patients, 19 had histories of occupational TCE exposure for at least 2 years, compared to only 5 of the controls. After adjustment for potential confounders, an association between RCC and long-term exposure to TCE was reported (odds ratio=10.80, 95 percent CI=3.36 to 34.75) (Vamvakas et al., 1998).

The two German studies detailed above provide some evidence of a link between kidney cancer and TCE, although the link may be operative only under extreme exposure conditions. As will be discussed later, the application of molecular biology techniques to the issue of TCE and kidney cancer has strengthened the argument for a causal association. Controversy surrounds the German studies, as indicated in a critical review (Green and Lash, 1999), to which the researchers responded (Vamvakas et al., 2000).

Metabolism With rare exception, the toxicities associated with TCE are thought to be mediated by metabolites rather than by the parent compound. Even the CNS-depressant effects of TCE are due in part to the sedative properties of the metabolite trichloroethanol (TCOH). As is often the case in risk assessment, a detailed knowledge of metabolism is a prerequisite to an accurate assessment of human risk from TCE exposure. To this end, the enormous amount of information on the subject is summarized in a state-of-the-science paper by Lash et al. (2000).

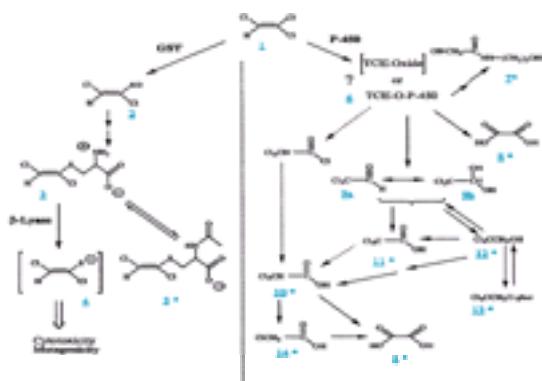
TCE is rapidly absorbed into the systemic circulation via the oral and inhalation routes. The majority of TCE undergoes oxidation via cytochrome P450s, with a small proportion being conjugated with glutathione (GSH) via glutathione *S*-transferases (GSTs). Thus, two distinct metabolic pathways exist for TCE, the GSH pathway as shown to the left in Fig. 24-5, and the oxidative pathway as shown to the right.


Figure 24-5. Scheme of metabolism of TCE.

Metabolites marked with an asterisk are known urinary metabolites. 1=TCE; 2=DCVG; 3=DCVC; 4=1,2-dichlorovinylthiol; 5=NacDCVC; 6=TCE-P450 or TCE-oxide intermediate; 7=*N*-(hydroxyacetyl)-aminoethanol; 8=oxalic acid; 9a=chloral; 9b=chloral hydrate; 10=dichloroacetic acid; 11=trichloroacetic acid; 12=trichloroethanol; 13=trichloroethanol glucuronide; 14=monochloroacetic acid. [Used with permission of Lash et al. (2000).]

TCE is first oxidized to chloral in a step that may or may not involve an epoxide intermediate. Chloral is then oxidized to trichloroacetic acid (TCA) or reduced to TCOH. TCOH, in turn, is either oxidized to TCA or glucuronidated. TCOH glucuronide may undergo enterohepatic recirculation by hydrolysis to TCOH in the gut, with reabsorption and the possibility of further conversion to TCA. TCA accumulates in the body due to strong protein binding and slow excretion. In contrast, blood levels of dichloroacetic acid (DCA), formed by TCA dechlorination or from TCOH, are very low or nondetectable in humans.

Relatively small amounts of TCE can be conjugated in the liver with GSH to form *S*-(1,2-dichlorovinyl)glutathione (DCVG). DCVG is then effluxed from the hepatocyte into plasma and bile for translocation to the kidney and small intestine, respectively. The plasma DCVG is intrarenally converted by g-glutamyltransferase and dipeptidases to the cysteine conjugate *S*-(1,2-dichlorovinyl)- L-cysteine (DCVC). The DCVG effluxed into bile can undergo extrarenal processing to DCVC, that is subsequently delivered to the kidney by enterohepatic recirculation. DCVC represents a branch point in the pathway. It may be detoxified through *N*-acetylation or bioactivated to reactive thiols via renal b-lyase located in renal proximal tubular cells.

Modes of Action in Target Tissues The goal of much of the TCE research conducted to date has been to understand the relevance of positive rodent cancer bioassays to humans. Both metabolic pathways are implicated in the carcinogenicity of TCE: reactive metabolite(s) of the GSH pathway in kidney tumors in rats, and oxidative metabolites in liver and lung tumors in mice. That tumor formation in many cases is species-, strain-, sex-, and route of exposure–dependent has provided understanding of TCE's modes of carcinogenic action. While substantial progress has been made toward this end, the reader should not infer from the following discussions that the modes of action are known with absolute certainty. Rather, they should be considered working hypotheses that await further experimental confirmation.

Liver Cancer TCE induces liver cancer in B6C3F1 mice but not in rats. This differential susceptibility can be explained by the greater capacity of the mouse to metabolize TCE via the oxidative pathway. B6C3F1 mice also develop liver tumors when chloral hydrate (CH), TCA, and DCA are administered in very high doses, suggesting that one or more of these metabolites is ultimately responsible for TCE-induced liver cancer. Of the three, TCA and/or DCA are/is most likely responsible, since TCE metabolism results in extremely low blood levels of CH due to its rapid oxidation to TCA or reduction to TCOH. The proposed mechanisms by which TCE induces liver cancer have been reviewed in a recent state-of-the-science paper (Bull, 2000), upon which the following discussion is based.

The sensitivity of B6C3F1 mice to TCE suggests that liver tumor formation might be related to the abnormally high frequency of spontaneously initiated cells in this mouse strain, which manifests itself as an unusually high background liver tumor incidence. While TCA and/or DCA might induce liver tumors in B6C3F1 mice by simply promoting preexisting initiated cells, the finding that DCA (but not TCA) also induces liver tumors in F344 rats suggests that another mechanism might also be operable.

As for a promotional mechanism for TCE, overt cytotoxicity and reparative cell proliferation are unlikely, especially at tumorigenic doses. Peroxisome proliferation represents a more viable promotional mechanism. As peroxisomes contain a variety of peroxidative enzymes, their proliferation results in an increased potential for oxidative DNA damage and decreased gap junctional intercellular communication, both of which have been implicated in neoplastic transformation. At tumorigenic doses, TCA induces sustained peroxisome proliferation in B6C3F1 mice. The peroxisome proliferative response to DCA is transient however, and requires a dose higher than that capable of inducing tumors. Therefore, a primary role for TCA is likely if liver tumor promotion occurs via peroxisome proliferation.

An alternative promotional mechanism is suggested by evidence that TCA and DCA depress replication rates of normal hepatocytes, conferring a selective growth advantage to initiated tumorigenic cells. This is referred to as *negative selection.* At high tumorigenic doses, DCA (but not TCA) is thought to stimulate cell replication within tumors. Interestingly, DCA tumors overexpress the insulin receptor relative to surrounding normal tissue. As overexpression of the insulin receptor is associated with the suppression of transforming growth factor b1–induced apoptosis in human liver cells, it is conceivable that DCA could promote cancer by a dual mechanism: enhanced mitotic activity and decreased apoptotic activity of preneoplastic cells.

DCA-promoted liver tumors differ phenotypically from those of TCA in that they express c-*jun* and c-*fos,* TGF-a, *GST*pi, and two P450s, CYP2E1 and CYP4A1. The expression of CYP2E1 raises the possibility that oxidative metabolites could be produced within targeted hepatocytes, which could be important in tumor induction. DCA- and TCA-induced tumors also differ with respect to the reversibility of the depression of cytosine methylation upon cessation of treatment. The simplest explanation for these differences is that DCA and TCA selectively modify growth and death rates of different clones of liver cells.

Kidney Cancer TCE exposure by inhalation or the oral route results in kidney tumors in male but not female rats. The susceptibility of the male rat can be explained by its greater capacity for TCE metabolism via the GSH pathway. TCE-induced kidney tumors are believed to result from reactive metabolite(s) of this pathway, particularly DCVC. DCVC is bioactivated in proximal tubular cells to a reactive thiol, *S*-(1,2-dichlorovinyl)thiol, which is chemically unstable and rearranges to reactive species capable of alkylating cellular nucleophiles, including DNA. The resulting DNA mutations lead to alterations in gene expression, which in turn lead to neoplastic transformation and tumorigenesis via a genotoxic pathway.

Alternatively, there are many processes that can lead to proximal tubular cell cytotoxicity and subsequent tumor formation via a nongenotoxic mode of action. Reactive metabolites formed within proximal tubular cells exposed to high doses of DCVC result in oxidative stress, alkylation of cytosolic and mitochondrial proteins, marked ATP depletion, and perturbations in Ca^{2+} homeostasis. Tubular necrosis ensues, with subsequent reparative proliferation that can alter gene expression and, in turn, alter the regulation of cell growth and differentiation. Modes of action for TCE-induced kidney tumor formation are discussed in greater detail by Lash et al. (2000) in their state-of-the-science paper.

Animal studies typically provide insight on mode of action, but in the case of TCE-induced RCC, human studies have been of significant value. Bruning et al. (1997a) analyzed tumor tissues from 23 RCC patients with occupational histories of long-term, high-level TCE exposure. Tumor cell DNA was isolated and analyzed for somatic mutations in the von-Hippel Lindau (VHL) tumor suppressor gene. Compared to VHL gene mutation rates of 33 to 55 percent in TCE-unexposed RCC patients, all 23 TCE-exposed RCC patients exhibited aberrations of the VHL gene. In a follow-up study, Brauch et al. (1999) sought to determine whether TCE produced a specific mutational effect in the VHL gene. These investigators analyzed VHL gene sequences in DNA isolated from renal cell tumors of patients exposed to high levels of TCE in metal-processing factories. Renal cell tumors of TCE-exposed patients showed somatic VHL mutations in 33 of 44 cases (75 percent). Of the 33 cases with VHL mutations, a specific mutational hot spot at VHL nucleotide 454 was observed in 13. The nucleotide 454 mutation was not found in any of the 107 RCC patients without TCE exposure or among 97 healthy subjects, 47 of whom had a history of TCE exposure. These data suggest that the VHL gene might be a specific and susceptible target of TCE.

Considering the implications of a genotoxic mode of action for the cancer risk assessment of TCE, the question of whether chronic tubular damage occurs in renal tumor formation is an important one. Answers have come from the use of electrophoresis to examine protein excretion patterns in the urine of RCC patients with and without a history of chronic high-level TCE exposure (Bruning et al., 1996). Protein excretion patterns indicative of tubular damage were identified in all 17 of the

TCE-exposed cases but in only about half of the 35 controls. This observation suggests that chronic tubular damage may be a prerequisite to TCE-induced RCC. Bruning and colleagues (1999) recently published a larger but similar study that also supported this concept.

Bruning and Bolt (2000) suggest that reactive metabolite(s) of the GSH pathway may have a genotoxic effect on the proximal tubule of the human kidney, but that full development of a malignant tumor requires a promotional effect such as cell proliferation in response to tubular damage. If this is true, then RCC secondary to TCE exposure would be a threshold response, something supported by the occurrence of human RCC only among cases with unusually high and prolonged TCE exposure. Factors other than the intensity and duration of exposure may determine one's susceptibility to TCE-induced RCC, however. Bruning et al. (1997b) have investigated the influence of GST isoenzyme polymorphisms on RCC risk using long-term, highly exposed workers with or without RCC. These investigators reported an unequal distribution of GSTq1 and GSTm1 polymorphisms among RCC cases and controls, which suggested a higher risk for RCC in TCE-exposed persons carrying either the GSTm1 or GSTq1 polymorphic gene. GSTq is thought to function to detoxify reactive electrophiles, while GSTm is primarily involved in conjugation reactions.

Lung Cancer As discussed in the state-of-the science paper by Green (2000), inhaled TCE is carcinogenic to the mouse lung but not to that of the rat. Oral TCE is not carcinogenic to the lung, probably due to hepatic metabolism that limits the amount of TCE reaching the organ. The primary target of TCE within the mouse lung is the nonciliated Clara cell. Toxicity to these cells is characterized by vacuolization and increases in cell replication in the bronchiolar epithelium. A dose-dependent reduction in the CYP450 activity of Clara cells is observed as well. This loss of metabolic capacity is thought to be an adaptive response, since Clara cells recover morphologically during repeated daily inhalation exposures to TCE.

Chloral is the putative toxicant responsible for pulmonary tumor formation. Clara cells of the mouse efficiently metabolize TCE to TCA and chloral. Chloral accumulates, due to its efficient production and the low activity of alcohol dehydrogenase, the enzyme responsible for the metabolism of chloral to TCOH. The lack of glucuronosyltransferase, the enzyme that normally catalyzes the formation of TCOH glucuronide, has also been implicated in chloral accumulation. This mechanism explains the species difference in susceptibility of the lung to TCE. Mouse lung Clara cells have a much higher concentration of CYP2E1 than those of the rat and thus a much higher capacity to metabolize TCE to chloral. Also, Clara cells in mice are much more numerous than in rats. The critical role for chloral is supported by the finding that its administration to mice, but not that of TCA or TCOH, causes Clara cell toxicity identical to that of TCE. Chloral does appear to have some genotoxic potential, especially in regard to inducing aneuploidy. However, the fact that tumors are not seen in species where cytotoxicity does not occur strongly implicates cytotoxicity and reparative proliferation in tumor formation.

Risk Assessment The human relevance of TCE-induced rodent tumors is an unresolved issue. For liver tumors, humans appear to be more similar to rats than mice in their capacity for oxidative TCE metabolism. For kidney tumors, evidence exists that TCE bioactivation via the GSH pathway is greater in rats than in humans. As for promotional mechanisms, rodent liver is much more responsive to the action of peroxisome proliferators than human liver, and a $_{2u}$-globulin nephropathy is thought to be specific to the male rat. With regard to lung cancer, the CYP450 content and the number of Clara cells in the human lung are but a fraction of those in the mouse. This suggests that the risk of chloral accumulation in humans is minimal. Based on the above, it appears that direct extrapolation from rodent data would overstate human TCE cancer risk.

Most mechanistic cancer research over the last decade on TCE has been focused on the liver and metabolites of TCE in mice. The most compelling mechanistic studies to date, however, are associated with kidney cancer in TCE-exposed workers. In two recent state-of-the-science papers, rodent and human PBPK models for TCE (and its metabolites) were used for cancer dose–response analyses in rodents and for extrapolation of rodent dose metrics to humans (Clewell et al., 2000; Fisher, 2000). The EPA is expected to use PBPK models in its risk assessment update, because compelling hypotheses are available concerning the mode of action (and appropriate dose metrics) for cancer in the liver, lung, and kidney of rodents.

Tetrachloroethylene

Tetrachloroethylene (perchloroethylene, PERC) is commonly used as a dry cleaner, fabric finisher, degreaser, rug and upholstery cleaner, paint and stain remover, solvent, and chemical intermediate. The highest exposures usually occur in occupational settings via inhalation. Much attention is now focused on adverse health effects experienced by dry cleaners and other persons living in the proximity of such facilities (Garetano and Gochfeld, 2000). PERC is frequently detected in the low ppt range in the breath and blood of the general populace (Wallace et al., 1987; Ashley et al., 1994; Clayton et al., 1999). Although releases are primarily to the atmosphere, PERC enters surface and groundwaters by accidental and intentional discharges (ATSDR, 1997d). Levels of 18 ppb are reported in municipal water in areas of New England, where PERC was used in a process to treat plastic water pipe (Paulu et al., 1999). Fay and Mumtaz (1996) report that PERC is the third most frequently found chemical in water at hazardous waste sites.

The systemic disposition and metabolism of *PERC* and trichloroethylene (TCE) are quite similar. Both chemicals are well absorbed from the lungs and GI tract, distributed to tissues according to their lipid content, partially exhaled unchanged, and metabolized by P450s. PERC is oxidized by hepatic P450s to a much lesser degree than TCE, though the two have a common major metabolite, trichloroacetic acid. GSH conjugation is a minor metabolic pathway, quantitatively, for TCE and PERC. The resulting conjugates of TCE and PERC are *S*-(dichlorovinyl)glutathione (DCVG) and *S*-(trichlorovinyl)glutathione (TCVG), respectively. These are cleaved to *S*-(dichlorovinyl)-ʟ-cysteine (DCVC) and *S*-(trichlorovinyl)-ʟ-cysteine (TCVC) (Birner et al., 1994). TCVC can be detoxified by acetylation and excretion in the urine, or metabolically activated by cleavage by a b-lyase in the kidney to dichlorothioketene. The latter compound can covalently bind to proteins and other macromolecules, or react with water to form dichloroacetic acid (DCA), a mutagen and high-dose animal carcinogen. DCA is also believed to be formed from TCE (see discussion of trichloroethylene, above). Dichlorothioketene is purported to be the ultimate PERC metabolite responsible for nephrotoxicity and mutagenicity (Volkel et al., 1998).

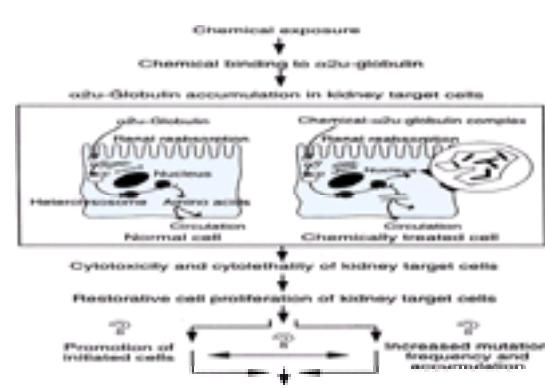
PERC has very limited capacity to produce acute or chronic hepatorenal toxicity in laboratory animals. Near-lethal IP doses of PERC were required to cause acute liver or kidney injury in mice (Klaassen and Plaa, 1966). Liver injury was not seen in B6C3F1 mice or Osborne-Mendel rats gavaged with up to ~1000 mg/kg daily for 78 weeks (NCI, 1977). Dose-dependent karyomegaly was observed in the renal proximal tubular epithelium of mice and rats exposed to PERC for 103 weeks (NTP, 1986). This change was most prominent in the male rats. Green et al. (1990) found increases in protein droplets and cell proliferation in the proximal tubular epithelium of male F344 rats gavaged with 1500 mg PERC/kg daily for up to 42 days. These changes are accompanied by an increase in a $_{2u}$-globulin, a male rat–specific protein (Fig. 24-6).


Figure 24-6. Proposed mechanism of solvent-induced kidney cancer in male rats involving a $_{2u}$-globulin.

[Used with permission of Borghoff et al: *CIIT Activities* 16(10):1–8, 1996.]

PERC's potential for causing cancer in humans continues to be a subject of controversy. Male and female B6C3F1 mice, gavaged with very high doses of PERC for up to 78 weeks, exhibited an increase in hepatocellular carcinoma (NCI, 1977). No increase in tumor incidence was seen in Osborne-Mendel rats. Hepatocellular carcinoma was seen again in B6C3F1 mice inhaling 100 or 200 ppm PERC over a 2-year period (NTP, 1986). There was a low incidence of renal adenomas and carcinomas in male F344 rats exposed to 200 or 400 ppm PERC. Such tumors are *rare* in this species. There was also a significant increase over controls in mononuclear cell leukemia in the male and female rats, but ~50 percent of the controls had this disease. There have been many epidemiologic studies of cancer

incidence and mortality in groups of dry cleaners and other persons occupationally exposed to PERC (ATSDR, 1997d). Some researchers have reported findings of excess risks of different cancers, while others have not. Frequently, there was not a determination of the degree or duration of PERC exposure, or consideration of major confounding factors (e.g., exposure to other solvents/chemicals, smoking, alcohol, socioeconomic status). Nevertheless, there was sufficient information for Weiss (1995) to conclude that cigarette smoking and alcohol consumption could only partially account for an increased rate of esophageal cancer in dry cleaners. Kidney cancer incidences did not appear to be elevated. McLaughlin and Blot (1997) concluded that epidemiologic evidence gathered to date clearly does not support a cause-and-effect relationship between either PERC or TCE and kidney cancer.

The relevance of the male rat kidney tumor findings to humans has received considerable attention. Several mechanisms have been proposed for the development of renal cell carcinoma in PERC-exposed male rats. Chronic exposure to high doses of PERC can cause ongoing cell death, regenerative hyperplasia, and the opportunity for spontaneous errors in replication during repair. Increased cell replication, protein droplet accumulation, and enhanced a_{2u}-gobulin levels in the P2 segment of renal proximal tubules appear to be unique to male rats (Green et al., 1990). Melnick et al. (1999), however, have pointed out that the association between a_{2u}-globulin accumulation and kidney cancer is unknown, and that quantitative relationships between key biological processes have yet to be demonstrated. They offered an alternative hypothesis, namely the a_{2u}-globulin may bind to and thereby increase the renal concentration and action of approximate carcinogen. As described above, a limited amount of PERC can be metabolized to TCVC, which in turn is cleaved in the kidneys to the cytotoxin and mutagen dichlorothioketene. Upon equivalent inhalation exposures of Wistar rats and humans to PERC, the rats excreted substantially larger amounts of DCA and acetylated TCVC (Volkel et al., 1998). These observations were consistent with in vitro findings of greater conversion of PERC to TCVC by rat liver cytosol and of a 10-fold higher cysteine conjugate b-lyase activity in rat kidney (Cooper, 1994). Thus, Volkel et al. (1998) concluded that humans are much less susceptible than rats to PERC-induced renal tumors. Such metabolic and physiologic differences between species can be input into PBTK models and used to predict risks of cancer in PERC-exposed humans (Reitz et al., 1996; Lash et al., 1998).

Methylene Chloride

Methylene chloride (dichloromethane, MC) enjoys widespread use as a solvent in industrial processes, food preparation, degreasing agents, aerosol propellants, and agriculture. Thus, large numbers of people are exposed occupationally and in the home. The primary route of exposure to this very volatile solvent is inhalation. The preponderance of MC escaping into the environment does so by volatilization (ATSDR, 1998b). The VOC is also frequently found in wastewater discharges and in air and water at hazardous-waste sites (Fay and Mumtaz, 1996).

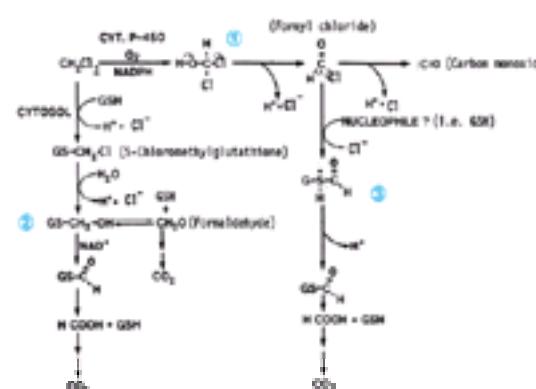
The TK of MC has been well characterized in humans and rodents. Inhaled MC was extensively absorbed and reached near steady state in the blood of human subjects within 1 to 2 h of continuous exposure (DiVincenzo and Kaplan, 1981). Less than 5 percent of the absorbed dose was exhaled unchanged. Some 25 to 34 percent was exhaled as carbon monoxide, the major end-metabolite of MC. Exposure of the volunteers to 50, 100, 150, and 200 ppm for 7.5 h produced peak blood carboxyhemoglobin saturations of 1.9, 3.4, 5.3, and 6.8 percent, respectively. MC was very rapidly eliminated from the body and did not accumulate over 5 days of exposure. Metabolism of MC in humans and rodents is believed to occur via three pathways (Andersen et al., 1987). One entails CYP2E1-catalyzed oxidation to carbon monoxide via formyl chloride, a reactive intermediate. The second, a glutathione (GSH)-mediated pathway, involves a theta-class glutathione S-transferase, GSTT1-1. The P450 pathway is a high-affinity, low-capacity pathway that predominates at MC concentrations present in occupational and environmental settings. The GST pathway is a low-affinity, high-capacity pathway operative at the high exposure levels used in cancer bioassays (Green, 1997). With the third, it is postulated that CO_2 is also formed via the oxidative pathway by reaction of formyl chloride with a nucleophile such as GSH (Fig. 24-7).


Figure 24-7. Proposed pathways for methylene chloride (CH$_2$Cl$_2$) metabolism.

(1) Mixed function oxidase pathway; (2) glutathione transferase pathway; and (3) nucleophile pathway. [Modified and used with permission from Andersen et al. (1987).]

MC has only a limited systemic toxicity potential. High, repeated inhalation exposures are required to produce slight, reversible changes in the livers of rodents. Centrilobular vacuolization and focal necrosis occur in the livers of rats exposed 6 h/day, 5 days/week for 2 years to 500 to 4000 ppm MC (Burek et al., 1984; Mennear et al., 1988). Manifestations of kidney injury are infrequent in laboratory animals but are occasionally reported in persons subjected to high vapor levels. As described above, the carbon monoxide that is formed from MC binds to hemoglobin to produce dose-dependent increases in carboxyhemoglobin. It is generally accepted that tissue hypoxia can contribute to acute CNS effects of MC. There are few reports of residual neurologic dysfunction in MC-exposed employees (Lash et al., 1991; ATSDR, 1998b).

Occupational and environmental MC exposures are of concern primarily because of MC's carcinogenicity in rodents and its potential as a human carcinogen. Burek et al. (1984) saw increased numbers of salivary gland sarcomas in male rats and benign mammary tumors in female rats exposed to very high MC vapor levels five times weekly over 2 years. Hamsters were not affected. Benign mammary tumors in female rats were also seen in subsequent inhalation bioassays (Nitschke et al., 1988; Mennear et al., 1988). Dose-dependent increases in lung and liver tumors in male and female B6C3F1 mice were also found in the latter investigation. Epidemiology studies of workers exposed to MC have not revealed increases in mortality from lung or liver tumors (ATSDR, 1998b). There have been occasional reports of cancer excess in other organs, including the pancreas (Hearne et al., 1990) and the prostate and cervix (Gibbs et al., 1996). Upon a comprehensive review of the epidemiology literature, Dell et al. (1999) recently concluded that cancer risks from occupational exposure to MC, if any, are quite small.

There has been a great deal of research to define mechanisms of MC carcinogenicity, in order to more clearly understand the relevance of the murine tumors to humans (Green, 1997). Liver and lung tumors in mice do not seem to be associated with overt cytotoxicity or increased replicative DNA synthesis (Maronpot et al., 1995). Induction of the tumors in mice is generally believed to be due to a reactive intermediate generated via the GST pathway (Andersen et al., 1987). GSTT1-1 in liver and lung catalyzes conversion of MC to S-chloromethylglutathione (GSCH$_2$Cl), which apparently breaks down rapidly to GSH and formaldehyde. GSCH$_2$Cl has yet to be isolated and quantified. Metabolism of MC via the GST pathway is an order of magnitude greater in mouse than in rat liver. Metabolic rates in hamster and human liver are even lower (Reitz et al., 1989; Thier et al., 1998). High GSTT1-1 activity was measured in the nuclei of mouse centrilobular hepatocytes. Mice may be unique in that extensive metabolic activation of MC to an unstable intermediate occurs in the proximity of the DNA. GSTT1-1 was also detected in relatively high levels in mouse lung Clara cells and ciliated cells at alveolar/bronchiolar junctions. GSCH$_2$Cl apparently causes single-strand breaks in vivo and in vitro in DNA of mouse liver and lung (Graves et al., 1995). No DNA breaks were detected in hamster or human hepatocytes in vitro. Casanova and coworkers have proposed an alternate mechanism of MC carcinogenicity, namely formation of DNA-protein cross-links (DPX) by formaldehyde. Upon incubation of MC with hepatocytes from mice, rats, hamsters, and humans, DPX were found only in the mouse samples (Casanova et al., 1996). Formaldehyde-RNA adducts, a more sensitive marker than DPX, were subsequently found in human hepatocytes incubated with MC, though the adducts were seven times more prevalent in mouse hepatocytes (Casanova et al., 1997).

We now have a substantial amount of information on the TK and mechanism(s) of carcinogenicity of MC. Considerable time and money have been spent on MC research by federal agencies and academia as well as by industry. MC was one of the first chemicals for which PBTK modeling was employed by the EPA in cancer risk estimation. Although uncertainties remain, species differences appear to be largely quantitative rather than qualitative. Persons with a GSTT1-1 null genotype (Nelson et al., 1995) may not be at risk from certain MC-induced tumors. This concept was recently incorporated into a cancer risk assessment based upon PBTK

estimation of DPX formation in humans (El-Masri et al., 1999).

Carbon Tetrachloride

Carbon tetrachloride (CCl_4) previously enjoyed widespread use as a solvent, cleaning agent, fire extinguisher, synthetic intermediate, grain fumigant, and anthelmintic for humans. Its use has steadily declined since the 1970s, due to its hepatorenal toxicity, carcinogenicity, and contribution to ozone depletion in the atmosphere (ATSDR, 1994). Nevertheless, CCl_4 appears to be ubiquitous in ambient air in the United States, and it is still found in groundwater from some wells and waste sites. CCl_4 is a classic hepatotoxin, but kidney injury is often more severe in humans. There does not appear to be a good animal model for kidney toxicity.

The time course of CCl_4-induced acute liver injury has been well characterized (ATSDR, 1994). Early signs of hepatocellular injury in rats include dissociation of polysomes and ribosomes from rough endoplasmic reticulum, disarray of smooth endoplasmic reticulum, inhibition of protein synthesis, and triglyceride accumulation. Ingested CCl_4 reaches the liver, undergoes metabolic activation, produces lipoperoxidation, covalently binds, and inhibits microsomal ATPase activity within minutes in rats. Single cell necrosis, evident 5 to 6 h postdosing, progresses to maximal centrilobular necrosis within 24 to 48 h. Most microsomal enzyme activities are significantly depressed (Recknagel et al., 1989). A variety of cytoplasmic enzymes are released from dead and dying hepatocytes into the bloodstream. The activity of these enzymes in serum generally parallels the extent of necrosis in the liver. Cellular regeneration, manifest by increased DNA synthesis and cell cycle progression, is maximal 36 to 48 h postdosing (Rao et al., 1997). The rate and extent of tissue repair are important determinants of the ultimate outcome of toxic liver injury.

It is likely that the mechanism of liver injury by CCl_4 has received more attention than that of any other chemical. Nevertheless, there is still considerable debate about the relative importance of different actions of CCl_4, notably covalent binding and lipid peroxidation. CCl_4 is known to be metabolized by P450-dependent reductive dehalogenation to a trichloromethyl radical (CCl_3). This radical can bind covalently to lipids and proteins, causing structural damage of membranes and inhibition of a variety of enzymes. CCl_3· may also react with O_2 to produce Cl_3COO·, the tri-chloromethylperoxy radical. CCl_3· can also attack enoic fatty acids, leading to organic free radicals, which may in turn react with O_2 to form peroxides and other cytotoxic metabolites (Recknagel et al., 1989). This process is known as lipid peroxidation. Numerous studies have shown various antioxidants to ameliorate CCl_4 cytotoxicity in vitro and in vivo. Agents that inhibit CCl_4 covalent binding are also protective. In vivo experiments in rats by Padron et al. (1996) demonstrated that both of these degenerative processes (i.e., covalent binding and lipid peroxidation) were necessary for CCl_4 cytotoxicity. Liu et al. (1995) have proposed that CCl_4 oxidative stress in the liver enhances nuclear factor kappa B activity, which, in turn, promotes expression of proinflammatory cytotoxic cytokines. Shi et al. (1998) have even proposed apoptosis as an additional/alternate mechanism of CCl_4-induced cell death.

Perturbation of intracellular calcium (Ca^{2+}) homeostasis appears to be an integral part of CCl_4 cytotoxicity (Stoyanovsky and Cederbaum, 1996). Increased cytosolic Ca^{2+} levels may result from influx of extracellular Ca^{2+} due to plasma membrane damage and from decreased intracellular Ca^{2+} sequestration. Elevation of intracellular Ca^{2+} in hepatocytes can cause activation of phospholipase A_2 and exacerbation of membrane damage (Glende and Recknagel, 1992). Elevated Ca^{2+} may also be involved in alterations in calmodulin and phosphorylase activity as well as changes in nuclear protein kinase C activity (Omura et al., 1999). Increased Ca^{2+} may stimulate the release of cytokines and eicosanoids from Kupffer cells. Edwards et al. (1993) demonstrated that destruction of Kupffer cells prior to CCl_4 dosing of rats resulted in significant reductions in neutrophil infiltration and in hepatocellular injury. CCl_4 hepatotoxicity is obviously a complex, multifactorial process, which is likely to continue to receive considerable attention.

CCl_4 has frequently been used as a model hepatotoxic compound with which to examine the influence of various factors that alter P450s. CYP2E1 is primarily responsible for catalyzing the bioactivation of low doses of CCl_4 in humans. CYP3A contributes to the metabolism of higher doses (Zangar et al., 2000). The preeminent role of CYP2E1 in animals is clearly demonstrated by the protection afforded CCl_4-treated rodents by 2E1 antibody (Castillo et al., 1992), the 2E1 inhibitor 3-amino-1,2,4-triazole (Padron et al., 1996), and the absence of 2E1 expression (Wong et al., 1998). As discussed previously, a variety of conditions which induce 2E1 potentiate CCl_4 hepatotoxicity in test animals and humans. Sufficient doses of 2E1 inhibitors, including several natural constituents of foods, can prevent CCl_4 toxicity (Lieber, 1997a).

Chloroform

The primary use of chloroform ($CHCl_3$, trichloromethane) at present is in the production of the refrigerant chlorodifluoromethane. $CHCl_3$ was among the first inhalation anesthetics, but its use was eventually discontinued. Under certain conditions $CHCl_3$ is hepatotoxic and nephrotoxic. These toxicities are potentiated by aliphatic alcohols, ketones, and di- and trichloroacetic acid (Davis, 1992). The latter two chemicals are produced along with $CHCl_3$ as by-products of drinking water chlorination. Concentrations of $CHCl_3$ in municipal drinking water supplies as high as several hundred parts per billion (ppb) have been measured, although levels are usually less than 50 ppb. $CHCl_3$ has also been found in ppb concentrations in swimming pool water and surrounding air (Aggazzotti et al., 1995). $CHCl_3$ can invoke CNS symptoms at subanesthetic concentrations similar to those of alcohol intoxication. Like many other halocarbons, extremely high $CHCl_3$ exposures can sensitize the myocardium to catecholamines.

The reproductive and developmental toxicities of $CHCl_3$ are rather unremarkable. The EPA's IRIS profile characterizes $CHCl_3$ as fetotoxic but not teratogenic. Schwetz et al. (1974) found that inhalation of 100 to 300 ppm $CHCl_3$ by pregnant rats caused a high incidence of fetal resorption and retardation of fetal development as well as a low incidence of fetal anomalies. Murray et al. (1979) reported that gestational exposure to just 100 ppm $CHCl_3$ resulted in the decreased ability of females to maintain pregnancy—as well as cleft palate, decreased fetal weight and length, and decreased ossification in pups. Very high $CHCl_3$ concentrations retarded development and induced diffuse cell death in cultured rat embryos (Brown-Woodman et al., 1998). These studies support $CHCl_3$ as a weak teratogen, but negative studies employing maternally toxic doses argue against this characterization (Thompson et al., 1974; NTP, 1997a).

Potentiation by cytochrome P450 inducers and protection by GSH and by P450 inhibitors suggest that a metabolite, presumably phosgene, is responsible for $CHCl_3$'s hepatorenal toxicity. Both target organs metabolize $CHCl_3$ to phosgene. By using an irreversible cytochrome CYP2E1 inhibitor and CYP2E1-knockout mice, Constan et al. (1999) have demonstrated that metabolism of $CHCl_3$ by CYP2E1 is required for liver and kidney necrosis and cell proliferation. Nakajima et al. (1995) published results indicating that CYP2E1 is responsible for metabolic activation at low doses, whereas CYP2B1/2 is more important at high doses, such as those used in cancer bioassays. Preexposure to low doses of $CHCl_3$ induces resistance to a higher dose, presumably by suicidal inhibition of P450s responsible for $CHCl_3$ activation (Pereira and Grothaus, 1997).

There is ample experimental evidence for the generation of an electrophilic intermediate (i.e., phosgene) that is initially detoxified by covalently binding cytosolic GSH. Once GSH is depleted, phosgene is free to covalently bind hepatic and renal proteins and lipids. Such binding damages membranes and other intracellular structures, leading to necrosis and subsequent reparative cellular proliferation that promotes tumor formation in rodents by irreversibly "fixing" spontaneously altered DNA and clonally expanding initiated cells. The expression of certain genes, including *myc* and *fos,* is altered during regenerative cell proliferation in response to $CHCl_3$-induced cytotoxicity (Sprankle et al., 1996; Kegelmeyer et al., 1997).

The identity of the intracellular targets of phosgene is largely unknown, but Guastadisegni et al. (1999) reported that phosgene reacts with phosphatidylethanolamine (PE). The adduct formed appears to consist of two PE moieties cross-linked at the amino head groups by the carbonyl moiety of phosgene. $CHCl_3$-modified PE preferentially accumulates on inner mitochondria membranes, inducing ultrastructural modifications and inhibiting functions of the organelle. These researchers observed the induction of hepatic apoptosis and necrosis in rats and pointed out that apoptosis may be initiated by the release of regulatory components normally sequestered in mitochondria. Evidence that Ca^{2+} perturbation plays a role in $CHCl_3$ toxicity comes from a recent report of Ca^{2+} mobilization in Madin-Darby canine kidney cells using Fura-2 as a Ca^{2+} probe. $CHCl_3$, albeit at millimolar concentrations, increased the cytosolic Ca^{2+} levels by releasing Ca^{2+} from multiple stores within the cell (Jan et al., 2000).

The status of $CHCl_3$ as a rodent carcinogen is indisputable. It causes liver and kidney tumors that are species-, strain-, sex-, and route of exposure–dependent. $CHCl_3$-induced liver tumors in mice and their dependence on ongoing liver necrosis were reported near the end of World War II (Eschenbrenner and Miller, 1945). These same authors observed that male but not female mice suffered kidney necrosis. This observation was supported by the report of Roe et al. (1979) that $CHCl_3$ ingested in a toothpaste base resulted in renal tumors in male but not female mice. This sex difference is thought to be attributable to testosterone-mediated differences in renal MFO activity (Smith et al., 1984; Wolf, 1991). The NCI (1976) cancer bioassay, on which the EPA has based its inhalation cancer potency factor,

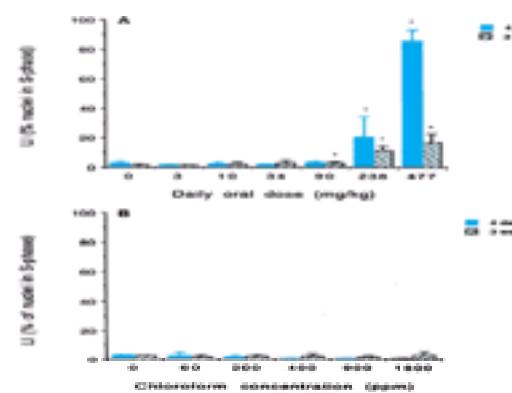
demonstrated renal tumors in male rats and an extremely high incidence of liver tumors in both sexes of B6C3F1 mice gavaged with $CHCl_3$ in corn oil. In 1985, Jorgenson and colleagues reported that daily doses of $CHCl_3$ in drinking water comparable to those in the NCI gavage assay also produced renal tumors, but failed to cause liver tumors in B6C3F1 mice. This finding provided evidence that the dose rate of $CHCl_3$ was a determinant of liver tumor formation, supporting the existence of a threshold mechanism. Hard et al. (2000) have reevaluated the kidneys from the Jorgenson et al. (1985) study and have confirmed the presence of chronic renal tubule injury, indicative of renal tumor formation via an epigenetic mechanism. In what may be a "landmark" study, Larson et al. (1994) compared cytotoxicity and cell proliferation in female B6C3F1 mice given $CHCl_3$ by gavage in corn oil versus ad libitum ingestion in drinking water. As seen in Fig. 24-8, the hepatocyte labeling index, a measure of the proliferative response, differed between the two dosage regimens at comparable doses. This suggests that ingestion of $CHCl_3$ in small increments, similar to drinking water patterns of humans, fails to produce a sufficient amount of cytotoxic metabolite(s) per unit time to overwhelm detoxification mechanisms.


Figure 24-8. Hepatocyte liver LI in female B6C3F1 mice given CHCl$_3$ in corn oil (A) or drinking water (B) for 4 days or 3 weeks.

The LI is defined as the percent of hepatocyte nuclei positive for 5-bromo-2'-deoxyuridine immunohistochemical staining (i.e., percent of cells in the S phase, the period of DNA synthesis during the cell cycle). Values represent the mean ±SD for 5 mice. Asterisks (*) denote a significant difference from similarly treated control mice ($p < 0.05$). Note that 1800 ppm $CHCl_3$ in water corresponds to a cumulative uptake of 329 mg/kg/day. [Reproduced with permission of Larson et al. (1994).]

Currently, the EPA classifies $CHCl_3$ as a probable human carcinogen (group B2), meaning that there is sufficient evidence for carcinogenicity in animals and inadequate or no evidence in humans. Experimental evidence, such as that of Larson et al. (1994), and the prevailing opinion that $CHCl_3$ is nongenotoxic, indicates that the relationship between $CHCl_3$ dose and tumor formation is nonlinear or threshold, meaning that there is a dose of $CHCl_3$ below which cytotoxicity is insufficient to produce a significant cancer risk. The EPA has, however, derived oral and inhalation cancer toxicity factors by applying the linearized multistage model to animal bioassay data. This model assumes there is no threshold. This has created controversy over EPA's approach to carcinogen regulation, a debate in which proponents of an epigenetic mechanism for $CHCl_3$ point toward EPA's recently *Proposed Guidelines for Carcinogen Risk Assessment* (EPA, 1999), that emphasize consideration of mode of action in the determination of cancer risk. The issues surrounding this debate have been summarily articulated in an article by Golden et al. (1997).

AROMATIC HYDROCARBONS

Benzene

Benzene produced commercially in the United States is derived primarily from petroleum. Benzene has been utilized as a general purpose solvent, but it is now used principally in the synthesis of other chemicals (ATSDR, 1997a). The percentage by volume of benzene in gasoline is 1 to 2 percent. Benzene plays an important role in unleaded gasoline due to its antiknock properties. Inhalation is the primary route of exposure in industrial and in everyday settings. Cigarette smoke is the major source of benzene in the home (Wallace, 1996). Smokers have benzene body burdens which are 6 to 10 times greater than those of nonsmokers. Passive smoke can be a significant source of benzene exposure to nonsmokers. Gasoline vapor emissions and auto exhaust are the other key contributors to exposures of the general populace.

The most important toxic effect of benzene is hematopoietic toxicity. Chronic exposure to benzene can lead to bone marrow damage, which may be manifest initially as anemia, leukopenia, thrombocytopenia, or a combination of these. Bone marrow depression appears to be dose-dependent in both laboratory animals and humans. Continued exposure may result in marrow aplasia and pancytopenia, an often fatal outcome. Survivors of aplastic anemia frequently exhibit a preneoplastic state, termed *myelodysplasia,* which may progress to myelogenous leukemia (Snyder et al., 1993; Rangan and Snyder, 1997).

There is strong evidence from epidemiologic studies that high-level benzene exposures result in an increased risk of acute myelogenous leukemia (AML) in humans (ATSDR, 1997a; Bergsagel et al., 1999). Evidence of increased risks of other cancers in such populations is less compelling. Only AML incidence was significantly elevated in the largest cohort study to date, in which ~75,000 benzene-exposed workers in 12 cities in China were evaluated (Yin et al., 1996). Marginal, nonsignificant increases were seen for lung cancer and chronic myelogenous leukemia. Some investigations of persons exposed to engine exhausts have reported a significant association with multiple myeloma. Bezabeth et al. (1996) and Bergsagel et al. (1999) have concluded, however, that there is no scientific evidence to support a causal relationship between benzene exposure and multiple myeloma. Increased incidences of malignant lymphomas and a variety of solid tumors were found in male and female B6C3F1 mice dosed orally with high doses of benzene for up to 103 weeks (Huff et al., 1989). Male and female F344 rats in this bioassay exhibited excesses of Zymbal gland, skin, and oral cavity carcinomas. Thus, benzene is clearly an animal and human carcinogen, but major species differences exist.

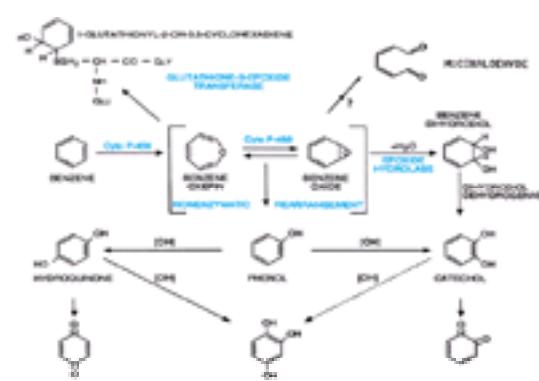
It is essential to understand the metabolism of benzene in order to address its mechanisms of toxicity. The initial metabolic step (Fig. 24-9), oxidation of benzene to an epoxide (i.e., benzene oxide), is catalyzed primarily by hepatic CYP2E1. Valentine et al. (1996) demonstrated that benzene-treated transgenic CYP2E1 knockout mice had relatively low levels of all benzene metabolites in their urine. A 5-day, 200 ppm benzene inhalation regimen produced severe genotoxicity and cytotoxicity in wild-type and B6C3F1 mice, but no adverse effects in the knockout mice. Benzene oxide, which is in equilibrium with its oxepin form, is further metabolized by three pathways: (1) conjugation with GSH to form a premercapturic acid, which is converted to phenyl-mercapturic acid; (2) rearrangement nonenzymatically to form phenol; and (3) hydration by epoxide hydratase to benzene dihydrodiol, which in turn can be oxidized by dihydrodiol dehydrogenase to catechol. If phenol is hydroxylated in the *ortho* position, more catechol will be formed. Catechol can be converted to *o*-benzoquinone. If benzene is hydroxylated in the *para* position, *p*-hydroquinone is formed. It can be oxidized to *p*-benzoquinone. The *o*- and *p*-benzoquinones are believed to be among the ultimate toxic metabolites of benzene. Another potentially toxic metabolite, muconaldehyde, may arise from ring opening of benzene oxide. Muconaldehyde undergoes a series of reactions that ultimately lead to *t,t*-muconic acid, an end-metabolite found in the urine (Snyder and Hedli, 1996; Golding and Watson, 1999).


Figure 24-9. Biotransformation of benzene.

A question mark leads from the oxepin-oxide compartment to muconaldehyde because the substrate for the ring opening has yet to be identified. The dotted line

leading to 1,2,4-trihydroxybenzene (1,2,4-T) indicates that it is not clear what the relative contributions of hydroquinone and catechol are to 1,2,4-T. [Modified and used with permission of Rangan and Snyder (1997).]

Metabolism of benzene occurs primarily in the liver, though metabolism in bone marrow is *also* believed to play an important role in myelotoxicity. It has been generally accepted that phenolic conjugates are formed in the liver and transported via the blood to the bone marrow, where they are hydrolyzed and oxidized to quinones. Researchers have been unable to reproduce benzene toxicity, however, by giving individual phenolic metabolites to animals. The quinones are believed to be too reactive to be transported in the bloodstream. Lindstrom et al. (1997) have recently reported that benzene oxide has an estimated half-life of 7.9 min in rat blood, and thus may be able to travel from the liver to the bone marrow. Ring-opened metabolites of muconaldehyde, which are less reactive, could be transported to bone marrow and reoxidized. Bernauer et al. (1999) measured activity and levels of CYP2E1 in the liver and bone marrow of five strains of mice of varying sensitivity to benzene. CYP2E1 amounts and activity were considerably greater in the liver than the marrow, but no interstrain differences were seen in either tissue. It is likely that noncytochrome P450 enzymes (e.g., peroxidase, myeloperoxidase, cyclooxygenase) play an important role in generation of semiquinones and quinones in bone marrow (Ross et al., 1996). It has been proposed that both benzene and an array of its metabolites are necessary to elicit myelotoxicity (Snyder and Hedli, 1996; Witz et al., 1996).

Benzene's metabolic pathways appear to be qualitatively similar in all species studied to date (Henderson, 1996). Mice have a greater overall capacity to metabolize benzene than do rats or primates. Mani et al. (1999) report good correlation between protein/DNA adduct levels in bone marrow and susceptibility to benzene genotoxicity and carcinogenesis in F344 rats and three strains of mice. The B6C3F1 mouse shows the highest adduct levels and is the most sensitive of the animals tested. Powley and Carlson (1999) report similar findings upon measurement of benzene metabolism in mouse, rat, rabbit, and human lung and liver microsomes.

Factors that alter the metabolism of benzene have the potential to influence the hematopoietic toxicity and carcinogenicity of the VOC. Nakajima et al. (1985) demonstrated that pretreatment of rats with ethanol, a CYP2E1 inducer, enhanced metabolism of benzene, and potentiated its acute myelotoxicity. Phenobarbital had a negligible effect. Pretreatment of male B6C3F1 mice with acetone, another CYP2E1 inducer, increased benzene oxidation about five times (Kenyon et al., 1996). Pretreatment with diethyldithiocarbamate, a CYP2E1 inhibitor, completely abolished benzene oxidation. Metabolism of benzene by hepatic microsomes from 10 human donors was directly proportional to CYP2E1 activity in the samples (Seaton et al., 1994). Thus, it would be anticipated that CYP2E1 polymorphisms may significantly influence susceptibility to benzene toxicity. Male mice have consistently been found to be more sensitive than females to genotoxic effects of benzene. PBTK analysis of data from gas uptake experiments with B6C3F1 mice of both sexes revealed that the optimized maximum rate of benzene metabolism was twice as high in males (Kenyon et al., 1996). It is not clear whether there is a sex-dependent difference in benzene metabolism in humans. Sato et al. (1975) saw a more rapid rate of pulmonary elimination of benzene in men than in women following inhalation of 25 ppm for 2 h. Benzene was retained longer in the females due to their higher body-fat content. Unfortunately, most epidemiology studies of benzene-exposed workers have not provided a gender comparison. Li et al. (1994) did not see a statistically significant difference in cancer mortality between male and female workers exposed to benzene, though risks tended to be somewhat higher for males.

There are a number of cell populations in the bone marrow that may serve as targets for benzene metabolites. Benzene exposure in vivo results in inhibited growth and development of pluripotential bone marrow stem cells. More mature precursors, such as stromal cells and erythroid and myeloid colony-forming units, are also affected. Trush et al. (1996) point out that hydroquinone-induced inhibition of interleukin-1 synthesis by stromal macro-phages results in altered differentiation of myeloid and lymphoid cells, which are normally active in immune responses. These investigators also note that killing of stromal macrophages and fibroblasts could result in such a pronounced reduction of cytokines and growth factors that immature and committed hematopoietic progenitors would die from apoptosis. The erythroid series is more susceptible than the myeloid series to benzene-induced cytotoxicity. Immature myeloid cells can proliferate when the development of erythroid cells is restricted and acquire neoplastic characteristics upon dedifferentiation. The end result is acute myelogenous leukemia (Golding and Watson, 1999).

Investigations of benzene toxicity/leukemogenesis have uncovered a variety of potential mechanisms (Golding and Watson, 1999). As mentioned before, experimental evidence indicates that the complementary actions of benzene and several of its metabolites are required for toxicity. It has been recognized for 20 years that a number of benzene metabolites can bind covalently to GSH, proteins, DNA and RNA. This can result in disruption of the functional hematopoietic microenvironment by inhibition of enzymes, destruction of certain cell populations, and alteration of the growth of other cell types. Covalent binding of hydroquinones to spindle-fiber proteins will inhibit cell replication (Smith, 1996). In vitro studies have established that reactive benzene metabolites bind covalently to DNA of several tissues of different species. Results of studies of formation of DNA adducts in vivo have been more difficult to interpret, due to benzene's low covalent binding index and the complexity of bone marrow (Snyder and Hedli, 1996). Through the use of accelerator mass spectrophotometry, Creek et al. (1997) could demonstrate DNA binding in mice exposed to extremely low ^{14}C-benzene levels. The binding was dose-dependent over a wide range of doses. DNA adduct levels were so low, however, that this mechanism alone seems insufficient to fully account for leukemogenic effects.

It appears likely that oxidative stress contributes to benzene toxicity. As the bone marrow is rich in peroxidase activity, phenolic metabolites of benzene can be activated there to reactive quinone derivatives. Ross et al. (1996) discovered that myeloperoxidase present in murine and human progenitor cells could bioactivate hydroquinone to *p*-benzoquinone. Electron spin resonance experiments by Hiraku and Kawanishi (1996) revealed the formation of a semiquinone radical in *p*-benzoquinone-treated HL-60 cells (a human myeloid cell line). This suggested that reactive oxygen moieties (e.g., $O_2^{\bullet}$ and H_2O_2) are produced via the formation of the semiquinone radicals. These active oxygen species can cause DNA strand breakage or fragmentation, leading to cell mutation or apoptosis, respectively. Ross et al. (1996), however, pointed out that quinones can also inhibit proteases involved in induction of apoptosis. These authors noted that modulation of apoptosis may lead to aberrant hematopoiesis and neoplastic progression.

A number of biomarkers of exposure to benzene have been developed and carefully evaluated. Concentrations of the parent compound in exhaled breath parallel blood concentrations. Clayton et al. (1999) recently reported a high correlation between extent of smoking-related activities and levels of benzene in exhaled breath of humans. Urinary excretion of a variety of benzene metabolites (i.e., phenol, catechol, hydroquinone, 1,2,4-trihydroxybenzene, *S*-phenylmercapturic acid and *t,t*-muconic acid) have been shown to be correlated with benzene exposure in occupational settings. Phenol, catechol, and hydroquinone, however, are neither sensitive nor specific, since relatively high levels are found in nonexposed individuals (Medeiros et al., 1997). Similarly, *t,t*-muconic acid is not specific, since it is a metabolite of sorbic acid, a common food additive. Boogaard and van Sittert (1996) conclude that *S*-phenylmercapturic acid, an end-product of the conjugation of benzene oxide and GSH, is a suitable urinary biomarker of low-level benzene exposure because of its specificity and relatively long half-life. Adducts to hemoglobin and cysteine groups of proteins have been demonstrated in rodents, but not in humans. DNA damage has been detected in benzene-exposed workers (Liu et al., 1996; Andreoli et al., 1997), though such measures have not yet found widespread acceptance as biomarkers of effect.

PBTK models have been developed to aid in predicting risks of myelotoxicity and leukemia posed to humans by benzene. Medinsky et al. (1989) published one of the first models for benzene. They assumed that benzene metabolism followed Michaelis-Menten kinetics and occurred via benzene oxide. B6C3F1 mice, which are more sensitive than F344 rats to benzene myelotoxicity, were predicted to metabolize two to three times more inhaled benzene. This and other PBTK models do not accurately simulate some laboratory data sets. Modeling benzene metabolism and disposition is difficult because of its inherent complexity and variability. In light of intricate dose–response relationships, Medinsky et al. (1996) emphasized the importance of considering competitive metabolic interactions between benzene and its metabolites as well as the balance between enzymatic activation and inactivation processes.

Toluene

Toluene is present in paints, lacquers, thinners, cleaning agents, glues, and many other products. Toluene is also used in the production of other chemicals. Gasoline, which contains 5 to 7 percent toluene by weight, is the largest source of atmospheric emissions and exposure of the general populace (ATSDR, 1998c). Inhalation is the primary route of exposure, though skin contact occurs frequently. Toluene is a favorite of solvent abusers, who intentionally inhale high concentrations of the VOC. Large amounts of toluene enter the environment each year by volatilization. Relatively small amounts are released in industrial wastewater. Toluene is frequently found in water, soil, and air at hazardous waste sites (Fay and Mumtaz, 1996).

Toluene TK has been thoroughly characterized in humans and laboratory animals. Toluene is well absorbed from the lungs and GI tract. It rapidly accumulates in and affects the brain, due to that organ's high rate of blood perfusion and high lipid content. Toluene subsequently is deposited in other tissues according to their lipid content, with adipose tissue attaining the highest levels. Toluene is well metabolized, but a portion is exhaled unchanged. Hepatic P450s catalyze metabolism of toluene to benzyl alcohol and lesser amounts of cresols. The benzyl alcohol is converted by alcohol dehydrogenase (ADH) to benzoic acid, which is conjugated and eliminated in the urine. Nakajima et al. (1992a) report that CYP2E1 and CYP2C11 are primarily responsible for catalyzing the initial hydroxylation step in rat liver at

low and high toluene levels, respectively. CYP2E1 is most active in humans (Nakajima et al., 1997).

The CNS is the primary target organ of toluene and other alkylbenzenes. Manifestations of exposure range from slight dizziness and headache to unconsciousness, respiratory depression, and death. Occupational inhalation exposure guidelines are established to prevent significant decrements in psychomotor functions. Acute CNS effects are rapidly reversible upon cessation of exposure (Fig. 24-3). Subtle neurologic effects have been reported in some groups of occupationally exposed individuals. Exposure to ~100 ppm toluene for years may result in subclinical effects, as evidenced by altered brainstem auditory evoked potentials (Abbate et al., 1993) and changes in visual evoked potentials (Vrca et al., 1995). Foo et al. (1990) reported good correlation between toluene exposure and poor scores on neurobehavioral tests of 30 female rotogravure workers. Severe neurotoxicity is sometimes diagnosed in persons who have abused toluene for a prolonged period. Clinical signs include abnormal electroencephalographic (EEG) activity, tremors, nystagmus, and cerebral atrophy as well as impaired hearing, vision, and speech (Ron, 1986; Dinwiddie, 1994). Magnetic resonance imaging has revealed permanent changes in brain structure, which correspond to the degree of brain dysfunction (Filley et al., 1990; Caldemeyer et al., 1996).

Little is known about mechanisms by which toluene and similar solvents produce acute or residual CNS effects (Balster, 1998). The Meyer-Overton theory of partitioning of the parent compounds into membrane lipids has been widely accepted for a century. Recently it has been proposed that the presence of solvent molecules in cholesterol-filled interstices between phospholipids and sphingolipids changes membrane fluidity, thereby altering intercellular communication and normal ion movements (Engelke et al., 1996). Such a process is reversible. An alternate hypothesis is that toluene partitions into hydrophobic regions of proteins and interacts with them, thereby altering membrane-bound enzyme activity and/or receptor specificity (Balster, 1998). Other evidence suggests that toluene and other VOCs may act by enhancing $GABA_A$ receptor function (Mihic et al., 1994), attenuating NMDA receptor-stimulated calcium flux (Cruz et al., 1998), and/or activating dopaminergic systems (von Euler, 1994).

As toluene is metabolized by P450s and ADH, the chemical can interact with other xenobiotics metabolized by these enzymes. Concurrent exposure to solvents metabolized by the same P450 isozymes can result in competitive metabolic inhibition. Inoue et al. (1988) observed that benzene and toluene suppressed one another's metabolism in humans. Thus, the risk of leukopenia in workers exposed to benzene and toluene should be less than that in workers exposed to benzene alone. Pryor and Rebert (1992) found that toluene greatly reduced manifestations of peripheral neuropathy caused by n-hexane in rats. Although no interaction between toluene and xylenes was seen in humans inhaling low levels of each, simultaneous exposure to higher levels resulted in mutual metabolic suppression (Tardif et al., 1991). Prior exposure to P450 inducers can result in increased rates of toluene metabolism/elimination and more rapid recovery from toluene-induced CNS depression. Nakajima and Wang (1994) observed that toluene induced four of the six P450 isozymes that metabolize it, but inhibited the other two in rat liver. The influence of toluene on the metabolism of other P450 substrates is usually modest.

Xylenes and Ethylbenzene

Large numbers of people are exposed to xylenes and ethylbenzene occupationally and environmentally (Wallace et al., 1987). Xylenes and ethylbenzene, like benzene and toluene, are major components of gasoline and fuel oil. The primary uses of xylenes industrially are as solvents and synthetic intermediates. Most of the aromatics released into the environment evaporate into the atmosphere. They may also enter groundwater from oil and gasoline spills and discharge, leakage of storage tanks, and migration from waste sites (ATSDR, 1995, 1999).

The TK and acute toxicity of toluene, xylenes, and other aromatic solvents are quite similar. Xylenes and the others are well absorbed from the lungs and GI tract, distributed to tissues according to tissue blood flow and lipid content, exhaled to some extent, well metabolized by hepatic P450s, and largely excreted as urinary metabolites (Lof and Johanson, 1998). Nielsen and Alarie (1982) state that the potency of benzene and a series of alkylbenzenes, as sensory irritants of the upper respiratory tract of mice, increases with increasing lipophilicity. Acute lethality of hydrocarbons (i.e., CNS depressant potency) also varies directly with lipophilicity (Swann et al., 1974). There is limited evidence that chronic occupational exposure to xylenes is associated with residual neurological effects (ATSDR, 1995). Exposure conditions, including the presence of other solvents, have usually not been characterized in such reports. Uchida et al. (1993), for example, reported increased subjective CNS symptoms in workers exposed for ~7 years to a mean of 21 ppm xylenes. The prevalence of symptoms was not dose-dependent. This vapor concentration is significantly lower than current occupational exposure standards in the United States, which are established on the basis of acute irritancy or CNS effects.

Xylenes and ethylbenzene appear to have very limited capacity to adversely affect organs other than the CNS. Mild, transient liver and/or kidney toxicity have/has occasionally been reported in humans exposed to high vapor concentrations of xylenes. Little evidence of hepatorenal injury is typically manifest in laboratory animals (ATSDR, 1995). Generally, hepatic P450s are moderately induced by alkylbenzenes (Gut et al., 1993). Many investigators have reported xylenes to increase liver weight and to induce liver P450s in rats and other rodents. The c, p and m isomers of xylene vary somewhat in their capacity to induce different P450 isozymes in different organs of rats (Backes et al., 1993). Concurrent exposure to an alkylbenzene and another compound metabolized by P450s generally results in their competitive metabolic inhibition. Preexposure to an alkylbenzene or another P450-inducing compound, conversely, can result in increased metabolism of the other chemical.

The majority of alkylbenzenes do not appear to be genotoxic or carcinogenic. Ethylbenzene and styrene are two exceptions. Kidney injury and an increased incidence of renal adenoma and carcinoma (combined) were found in male F344 rats exposed to 750 ppm ethylbenzene for up to 2 years (NTP, 1997b). Styrene's carcinogenic potential is discussed below.

Styrene

Styrene is primarily used in the production of polystyrene, rubbers, resins, and insulators (Gibbs and Mulligan, 1997). Worker exposures in the rubber industry are of greatest concern toxicologically. Styrene is sometimes found in indoor air of buildings and homes (Wallace et al., 1987). Sources include tobacco smoke and emissions from building materials. Discharges from industry are the major source of environmental pollution (ATSDR, 1993).

There is considerable debate as to whether styrene is a human carcinogen. Styrene is metabolized principally by P450-catalyzed side-chain oxidation to styrene oxide (Linhart et al., 2000). This epoxide is detoxified by the actions of epoxide hydratase and glutathione S-transferase. Styrene oxide can bind covalently to proteins and nucleic acids. Results of in vitro and in vivo mutagenicity and genotoxicity studies of styrene have been mixed (ATSDR, 1993). Chromosomal aberrations have been found in employees in some occupational exposure studies, but not in others. Increased rates of different cancers have been reported in workers exposed to 1,3-butadiene and styrene in the synthetic rubber industry. The excesses of cancers have largely been attributed to 1,3-butadiene, though styrene may modify the actions of 1,3-butadiene and/or be implicated itself (Matonoski et al., 1997). Styrene oxide is carcinogenic to the forestomach of orally dosed mice and rats (Roe, 1994). The activity of epoxide hydratase relative to P450 oxidation is much greater in human than in mouse liver (Mendrala et al., 1993). Carcinogenicity bioassays of inhaled styrene in rats, conducted some 20 years ago, yielded equivocal findings (McConnell and Swenberg, 1994). Recently, Cruzan et al. (1998) reported the negative results of a 104-week styrene inhalation cancer study in CD rats. Nevertheless, the question of whether styrene should be considered a human carcinogen remains highly controversial.

ALCOHOLS

Ethanol

Many humans experience greater exposure to ethanol (ethyl alcohol, alcohol) than to any other solvent. Not only is ethyl alcohol used as a solvent in industry and in many household products and pharmaceuticals, but it is heavily consumed in intoxicating beverages. Frank toxic effects are less important occupationally than injuries resulting from psychomotor impairment. Driving under the influence of alcohol is, of course, the major cause of fatal auto accidents. In many states a blood alcohol level of 100 mg/100 mL blood (100 mg %) is prima facie evidence of "driving while intoxicated." One's blood alcohol level and the time necessary to achieve it are controlled largely by the rapidity and extent of consumption of the chemical. Ethanol is distributed in body water and to some degree in adipose tissue. The alcohol is eliminated by urinary excretion, exhalation, and metabolism. The blood level in an average adult decreases by ~15 to 20 mg % per h. Thus, a person with a blood alcohol level of 120 mg % would require 6 to 8 h to reach negligible levels.

Ethanol is metabolized to acetaldehyde by three enzymes: (1) The major pathway involves alcohol dehydrogenase (ADH)–catalyzed oxidation to acetaldehyde. ADHs are present in high concentrations in the cytoplasm of hepatocytes (Yin et al., 1999). The oxidation they catalyze is reversible, but the acetaldehyde that is formed is rapidly oxidized by acetaldehyde dehydrogenase (ALDH) to acetate. (2) A second enzyme, catalase, utilizes H_2O_2 supplied by the actions of NADPH oxidase and xanthine oxidase. There is usually little H_2O_2 available in hepatocytes to support the reaction, so it is unlikely that catalase will normally account for more than 10% of

ethyl alcohol metabolism. (3) The third enzyme, CYP2E1, is the principle component of the hepatic microsomal ethanol oxidizing system (MEOS).

Ethanol interacts with other solvents which are also metabolized by ADH and CYP2E1. Ethanol can be an effective antidote for poisoning by methanol, ethylene glycol, and diethylene glycol. As ethyl alcohol has a relatively high affinity for ADH, it competitively inhibits the metabolic activation of the other alcohols. Preexposure to a single high dose or multiple doses of ethanol can induce CYP2E1, thereby enhancing the metabolic activation and potentiating the toxicity of a considerable number of other solvents and drugs (Lieber, 1997a; Klotz and Ammon, 1998). Manno et al. (1996), for example, describe heavy drinkers who developed severe hepatorenal toxicity from CCl$_4$ exposures, which caused no ill effects in nondrinkers. Other alcohols, such as 2-butanol (Fig. 24-4), can have analogous effects (Traiger and Bruckner, 1976). Such interactions are also described under "Metabolism" and "Exogenous Factors" in this chapter.

Modulation of ALDH activity can influence adverse effects experienced by drinkers. Acetaldehyde is acutely toxic. It is reactive and binds covalently to proteins and other macromolecules (Niemela, 1999). Fortunately, ALDH activity is usually sufficiently high to metabolize large amounts of acetaldehyde to acetate. Caucasians, blacks, and Asians have varying percentages of different ALDH isozymes, which impact the efficiency of acetaldehyde metabolism. Some 50 percent of Asians have inactive ALDH, due to a single base change in the gene that encodes for the enzyme (Schuckit, 1986). These persons may experience flushing, headache, tachycardia, nausea, vomiting, and hyperventilation upon ingestion of ethanol. Disulfiram, an ALDH inhibitor, is used to treat alcoholism, since it acts similarly if alcohol is consumed.

Gender differences in responses to ethanol are well recognized. Females exhibit slightly higher blood ethanol levels than men following ingestion of equivalent doses of ethanol (Pikaar et al., 1988). This phenomenon appears to be due in part to more extensive ADH-catalyzed metabolism of ethanol by the gastric mucosa of males (Seitz et al., 1993). Sex differences in ethanol metabolism in the remainder of the body appear to be small or nonexistent (Frezza et al., 1990). A second factor contributing to the higher blood ethanol levels and greater CNS effects in women is their smaller volume of distribution for relatively polar solvents such as alcohols. It is well known that women are more susceptible to alcohol-induced hepatotoxicity (Thurman, 1998). A postulated mechanism for this sex difference is described below.

Fetal alcohol syndrome (FAS) is the most common preventable cause of mental retardation. Diagnostic criteria for FAS include (1) heavy maternal alcohol consumption during gestation; (2) pre- and postnatal growth retardation; (3) craniofacial malformations including microcephaly; and (4) mental retardation. Less complete manifestations of gestational ethanol exposure also occur and are referred to as fetal alcohol effects or alcohol-related neurodevelopmental disorder. FAS is estimated to affect 4000 infants per year in the United States, with an additional 7000 cases of fetal alcohol effects (Shibley and Pennington, 1997). Although the total amount of alcohol consumed and the pattern of drinking are both important factors, peak maternal blood alcohol level is the most important determinant of the likelihood and severity of effects. Overconsumption during all three trimesters of pregnancy can result in certain manifestations, with the particular manifestations dependent upon the period of gestation during which insult occurs.

Despite an intensive research effort, the mechanisms underlying FAS remain unclear. Exposure of embryonic tissue to ethanol adversely affects many cellular functions critical to development, including protein and DNA synthesis, uptake of critical nutrients such as glucose and amino acids, and changes in several kinase-mediated signal transduction pathways (Shibley and Pennington, 1997). Some studies have suggested that oxidative stress in fetal tissues is responsible (Henderson et al., 1999), while others have implicated ethanol's effects on neurotransmitter-gated ion channels, particularly the *N*-methyl-D-aspartate receptor (Costa et al., 2000). Others have reported that ethanol produces a long-lasting reduction in synaptic efficacy (Bellinger et al., 1999) and alters the fetal expression of developmentally important genes such as Msx2 and insulin-like growth factors (Singh et al., 1996; Rifas et al., 1997). Ethanol triggers widespread apoptotic neurodegeneration in the developing brain (Ikonomidou et al., 2000). A role for CYP2E1 in the induction of FAS has been hypothesized, given its expression in human cephalic tissues during embryogenesis (Boutelet-Bochan et al., 1997).

CYP2E1 plays a key role in alcoholic liver disease and associated oxidative stress (Baker and Cramer, 1999). Results of in vitro experiments indicate that human CYP2E1 is effective in production of reactive oxygen intermediates (e.g., hydroxy radicals, superoxide anion, H$_2$O$_2$) and in causation of lipid peroxidation (Dai et al., 1993). Membrane lipids and a variety of enzymes, including CYP2E1, are targets for free radical attack. Albano and coworkers (1999) have demonstrated a marked increase in covalent binding of hydroxyethyl radicals to hepatic microsomal proteins from rats following chronic ethanol administration. There is not yet direct evidence that hydroxyethyl radicals contribute to lipid peroxidation, but they do readily react with a-tocopherol, GSH, and ascorbic acid, thereby potentially lowering liver antioxidant levels in vivo. Albano et al. (1999) also describe evidence that hydroxyethyl radical-protein adducts in hepatocytes induce immune responses, which may contribute to chronic ethanol hepatotoxicity.

Alcohol-induced hepatotoxicity is postulated to be caused by elevation of endotoxin in the bloodstream. Endotoxin, released by the action of ethanol on gram-negative bacteria in the gut, is believed to be taken up by Kupffer cells, causing the release of mediators which are cytotoxic to hepatocytes and chemoattractants for neutrophils (Bautista and Spitzer, 1999). These mediators include interleukins, prostaglandins, free radicals, and tumor necrosis factor a. Kupffer cells of female rats are more sensitive to endotoxin than cells of males. Estrogen increases the sensitivity of Kupffer cells of rats to endotoxin. This phenomenon is believed to account in part for the more severe hepatitis and cirrhosis commonly seen in female alcoholics (Thurman, 1998).

Alcohol-induced tissue damage is believed to result from nutritional disturbances as well as direct toxic effects (Lieber, 1997b). Lack of money, poor judgment, prolonged inebriation, and appetite loss contribute to poor nutrition and weight loss in alcoholics. A high percentage of calories in the alcoholic's diet are furnished by alcohol. Malabsorption of thiamine, diminished enterohepatic circulation of folate, degradation of pyridoxal phosphate, and disturbances in the metabolism of vitamins A and D can occur (Mezey, 1985). Prostaglandins released from endotoxin-activated Kupffer cells may be responsible for a hypermetabolic state in the liver. With the increase in oxygen demand, the viability of centrilobular hepatocytes would be most compromised due to their relatively poor oxygen supply (Thurman, 1998). Metabolism of ethanol via ADH and ALDH results in a shift in the redox state of the cell. The metabolites and the more reduced state can result in hyperlactacidemia, hyperuricemia, and hyperglycemia (Lieber, 1997b).

Alcoholism can result in damage of extrahepatic tissues. Cardiomyopathy is one of the more serious consequences. Alcoholic cardiomyopathy is a complex process that is believed to result from decreased synthesis of cardiac contractile proteins, attack of oxygen radicals, and antibody response to acetaldehyde-protein adducts (Richardson et al., 1998). Interestingly, light to moderate drinking is reported to protect against atherosclerosis in the carotid artery, a major cause of ischemic stroke (Hillbom, 1999). It is hypothesized that ethanol metabolism in the vascular wall may inhibit oxidation of low density lipoproteins (LDL), a requisite for atherogenesis. Phenolic antioxidants in wines may also inhibit LDL oxidation as well as reduce platelet aggregation. Conversely, heavy drinking appears to deplete antioxidants and have the opposite effects (Camargo, 1996; Hillbom, 1999). Recent heavy drinking increases the risk of both hemorrhagic and ischemic strokes. Other organ systems can be adversely affected in alcoholics including the brain and pancreas (Preedy et al., 1997; Kril et al., 1997).

There is concern about the role of ethyl alcohol in carcinogenesis, due to the frequent consumption of alcoholic beverages by millions of people. IARC (1988) concluded that there was "sufficient evidence" for causation of tumors of the oral cavity, pharynx and larynx, esophagus, and liver of humans. The associations between alcohol and cancers came primarily from epidemiologic case-control and cohort studies. One such cohort study of 276,000 American men showed increase in total cancer risk with increasing ethanol consumption (Boffeta and Garfinkel, 1990). Ethanol and smoking act synergistically to cause oral, pharyngeal, and laryngeal cancers. It is generally believed that alcohol induces liver cancer by causing cirrhosis or other liver damage and/or by enhancing the bioactivation of carcinogens. Hypotheses of Ahmed (1995) for possible mechanisms of causation of cancers are included in Table 24-3.

Congeners, additives and contaminants in alcoholic beverages influence carcinogenicity.

CYP2E1 induction by ethanol increases metabolic activation of procarcinogens.

Ethanol acts as a solvent for carcinogens, enhancing their absorption into tissues of the upper GI tract.

Ethanol affects the actions of certain hormones on hormone-sensitive tissues.

Immune function is suppressed by alcohol.

Absorption and bioavailability of nutrients are reduced by alcohol.

Table 24-3 Possible Mechanisms of Ethanol Carcinogenicity

Methanol

Methanol (methyl alcohol, wood alcohol) is found in a host of consumer products including windshield washer fluid, and is used in the manufacture of formaldehyde and methyl *tert*-butyl ether (MTBE). Methanol is being promoted as a gasoline additive and alternative automotive fuel. Risks of low-level, chronic exposures will be at issue if the latter uses become commonplace.

Like most hydrocarbon solvents, methanol can produce reversible sensory irritation and narcosis at airborne concentrations below those producing organ system pathology. Serious methanol toxicity is most commonly associated with ingestion. Left untreated, acute methanol poisoning in humans is characterized by an asymptomatic latent period of 12 to 24 h followed by formic acidemia, ocular toxicity, coma, and in extreme cases death. Visual disturbances generally develop between 18 and 48 h after ingestion and range from mild photophobia and misty or blurred vision to markedly reduced visual acuity and complete blindness (Eells et al., 1996). Although there is considerable variability among individuals in susceptibility to methanol toxicity, a frequently cited lethal oral dosage is 1 mL/kg. Blindness and death have been reported with dosages as low as 0.1 mL/kg (ATSDR, 1993).

The target of methanol within the eye is the retina, specifically the optic disk and optic nerve. Optic disk edema and hyperemia are seen, along with morphological alterations in the optic nerve head and the intraorbital portion of the optic nerve. Both axons and glial cells exhibit altered morphologies (Kavet and Nauss, 1990). Evidence is accumulating that Müller cells, neuroglia that function in the maintenance of retinal structure and in intra- and intercellular transport, are early targets of methanol (Garner et al., 1995a). Rods and cones, the photoreceptors of the retina, are also altered functionally and structurally (Seme et al., 1999). There are indications of mitochondrial disruption in Müller and photoreceptor cells. This is consistent with the long-held view that cytochrome oxidase activity in mitochondria is inhibited, resulting in a reduction in ATP. This mechanism would explain, at least in part, the selective toxicity to photoreceptors and other highly metabolically active cells (Eells et al. 1996).

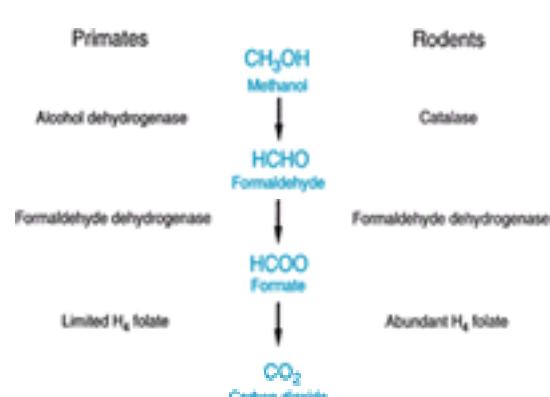
Elucidation of the mechanism of acute toxicity of methanol was hampered for years by species differences in susceptibility and the lack of appropriate animal models. Largely based on the work of Gilger and Potts (1955), it became apparent that only nonhuman primates respond to methanol similarly to humans. The severe metabolic acidosis frequently seen in humans does not occur in rodents. In all mammalian species studied, methanol is metabolized in the liver to formaldehyde (HCOH), which in turn is very rapidly converted to formate. The conversion of formate to CO_2 then occurs via a two-step, tetrahydrofolate (THF)-dependent pathway. First, formate is converted to 10-formyl-THF by formyl-THF synthetase, after which 10-formyl-THF is oxidized to CO_2 by formyl-THF dehydrogenase (F-THF-DH). The species differences in susceptibility to methanol are thought to result primarily from differences in the rate of THF-dependent oxidation of formate to CO_2. Since rodents have higher hepatic THF levels than primates, formate does not accumulate as it does in humans and monkeys (Medinsky and Dorman, 1995; Martinasevic et al., 1996). Another possible explanation is the lower F-THF-DH activity in primate liver (Johlin et al., 1989). Thus, susceptibility to methanol toxicity is dependent upon the relative rate of formate clearance. Dietary and chemical depletion of endogenous folate cofactors in rats have been shown to increase formate accumulation following methanol, resulting in the development of metabolic acidosis and ocular toxicity similar to that observed in humans (Eells et al., 1996). A simplified scheme of methanol metabolism is presented in Fig. 24-10.


Figure 24-10. Scheme for the metabolism of methanol.

Major enzymes are listed for primates (*left*) and rodents (*right*). Conversion of formate to CO_2 is rapid in rodents, but relatively slow in primates. (Used with permission of Dorman DC, Welsch F: *CIIT Activities* 16:1–7, 1996.)

For years there was considerable debate about whether HCOH or formate was responsible for methanol's ocular toxicity. The finding that HCOH does not accumulate following methanol treatment, even in folate-deficient monkeys profoundly sensitive to methanol, argues against a role for HCOH. Also, species of differing susceptibility exhibit comparable blood HCOH half-lives (~1 to 2 min). In contrast, formate has been shown to accumulate in the human and monkey following methanol treatment, and to induce ocular toxicity in monkeys after an infusion where normal blood pH was maintained (Martin-Amat et al., 1978). Eells et al. (1996), using a rat model in which formate oxidation had been selectively inhibited with nitrous oxide, have also shown that methanolinduced retinal dysfunction can be produced in the absence of metabolic acidosis. In this same publication, methanol-derived formate was quantified in the vitreous humor, retina, and to a lesser extent in the optic nerve. Moreover, these authors demonstrated that methanol-induced retinal dysfunction, as indicated by diminution of the amplitude of electroretinogram (ERG) *a* and *b* waves, was negatively correlated in a linear fashion with blood formate concentrations. Others have reported similar relationships between blood formate and ERG responses indicative of photoreceptor dysfunction (Seme et al., 1999). Thus, formate appears to act as a direct ocular toxin and not indirectly through the induction of an acidotic state, though acidosis may potentiate formate toxicity since the inhibition of cytochrome oxidase increases as pH decreases.

The question has been raised as to whether ocular toxicity is simply a function of circulating formate reaching the visual tract, or whether metabolism in retinal or optic nerve tissues generates toxic metabolites locally. This is a legitimate question considering that metabolism of methanol to formaldehyde via peroxisomal enzymes (catalase) has been demonstrated in rat retina in vitro (Garner et al., 1995a), and the presence of cytoplasmic aldehyde dehydrogenase activity has been demonstrated in several regions of the rat and mouse eye, including the retina (Messiha and Price, 1983; McCaffery et al., 1991). By use of a folate-deficient rat model that mimics human methanol toxicity, Garner et al. (1995b) showed that a level of blood formate generated by IV infusion of pH-buffered formate did not diminish the ERG *b*-wave amplitude generated by Müller cells of the retina, as did a comparable level of blood formate derived from methanol. This suggests that the intraretinal metabolism of methanol is necessary for the initiation of retinal toxicity by formate. Not only are the enzymes necessary to produce formate present in the retina, but so too are folate and formyl-THF dehydrogenase, both necessary for formate oxidation. Formyl-THF dehydrogenase was found to be localized in the mitochondria of Müller cells, prompting the suggestion that formyl-THF dehydrogenase may serve a dual role, one protective of the Müller cell and the other toxic. Protection would come in the form of formate oxidation; toxicity from the overconsumption of ATP required for formate metabolism via the folate pathway (Martinasevic et al., 1996). These findings raise new questions about the safety of methanol exposure. For example, chamber studies of human volunteers exposed to 200 ppm methanol for 4 or 6 h showed no blood formate accumulation above background (Lee et al., 1992; d'Alessandro et al., 1994). While this might be considered as evidence that exposure at the current ACGIH TLV and OSHA PEL of 200 ppm poses no risk for ocular toxicity, such an interpretation may not be valid given that ocular toxicity may be a function of intraretinal methanol metabolism rather than circulating formate levels.

While there is still much to be learned about mechanisms of methanol toxicity, what is known allows for effective therapies, if they are applied in a timely manner. Sodium bicarbonate is usually given iv to correct severe acidosis. Metabolic blockade is usually achieved with ethanol or 4-methylpyrazole, both acting as effective competitive inhibitors of ADH by virtue of their greater affinities than methanol for ADH. Folate therapy is also indicated to increase the efficiency of formate oxidation. Methanol exemplifies the benefits of knowing a chemical's mode of action when treating the poisoned patient. This knowledge also aids in identifying potentially sensitive subpopulations, such as those suffering from dietary folate deficiency.

GLYCOLS

Ethylene Glycol

Ethylene glycol (EG) is a major constituent of antifreeze, deicers, hydraulic fluids, drying agents, and inks, and is used to make plastics and polyester fibers. The most important routes of exposure are dermal and accidental or intentional ingestion. Workers may also be exposed by inhalation in situations where solutions containing EG are heated or sprayed. EG enters the environment as a result of disposal of industrial and consumer products containing the chemical (ATSDR, 1997c). It partitions into and is transported by surface waters and groundwater. EG is rapidly degraded in environmental media.

EG is acutely toxic to humans and is believed to cause over 100 deaths annually in the United States (LaKind et al., 1999). It appears to be two to five times more acutely toxic to humans and cats than to other species. LaKind et al. (1999) estimate the minimum lethal oral dose in humans to be ~1.4 mL/kg. Acute poisoning (Egbert and Abraham, 1999) entails three clinical stages after an asymptomatic period, during which EG is metabolized: (1) a period of inebriation, the duration and degree depending upon dose; (2) the cardiopulmonary stage 12 to 24 h after exposure, characterized by tachycardia and tachypnea, which may progress to cardiac failure and pulmonary edema; and (3) the renal toxicity stage 24 to 72 h postexposure. Metabolic acidosis can become progressively more severe during stages 2 and 3.

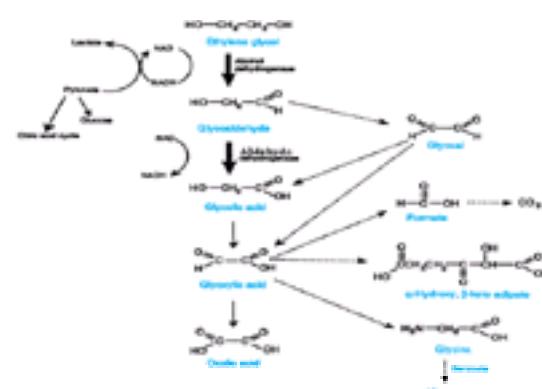
The TK of EG in humans and in laboratory animals is well understood. Absorption from the GI tract of rodents is very rapid and virtually complete (Frantz et al., 1996). Dermal absorption in humans appears to be less extensive. EG is distributed throughout the body extracellular fluid. As illustrated in Fig. 24-11, EG is metabolized by NAD^+-dependent alcohol dehydrogenase (ADH) to glycolaldehyde and on to glycolic acid (Wierner and Richardson, 1988). Ethanol is frequently given as an antidote in EG poisoning, because the alcohol effectively competes for ADH, thereby blocking the metabolic activation of EG. 4-Methylpyrazole, an ADH inhibitor, may be even more efficacious (Egbert and Abraham, 1999). Glycolic acid is oxidized to glyoxylic acid by glycolic acid oxidase and lactic dehydrogenase. Glyoxylic acid may be converted to formate and CO_2, or oxidized by glyoxylic acid oxidase to oxalic acid (Frantz et al., 1996). Metabolic acidosis in humans appears to be due largely to accumulation of glycolic acid (Jacobsen et al., 1984). Hypocalcemia can result from calcium chelation by oxalic acid to form calcium oxalate crystals. Deposition of these crystals in tubules of the kidney and small blood vessels in the brain is associated with damage of these organs. The actual mechanisms of cytotoxicity are poorly understood.


Figure 24-11. Metabolic pathway for oxidation of ethylene glycol.

Solid arrows represent steps that are quantitatively the most important in humans. Broken arrows indicate minor conversions. [Modified with permission from Wiener and Richardson (1988).]

EG appears to have limited chronic toxicity potential. TK studies in mice and rats have shown that EG is rapidly metabolized and eliminated (Frantz et al., 1996), so bioaccumulation should not occur upon repetitive exposures. DePass et al. (1986) observed that male F344 rats were more susceptible to nephrotoxicity than female rats or B6C3F1 mice of either sex fed EG at 1000 mg/kg/day for 2 years. Renal toxicity was not seen in animals ingesting 40 or 200 mg/kg/day. NTP (1993) found oxalate crystals in the renal tubules, urethra and/or bladder of male B6C3F1 mice consuming EG at 6000 mg/kg/day for 103 weeks. NOAELs were estimated to be 1500 and 6000 mg/kg/day for the male and female mice, respectively. There was no evidence of carcinogenicity in two lifetime dietary studies of EG in mice or rats (DePass et al., 1986; NTP, 1993).

EG does not appear to be a reproductive toxicant, but it can cause adverse developmental effects in rodents. Certain skeletal and soft tissue malformations, delayed ossification, and reduced body weight have been consistently observed in fetuses and pups of rodents given ³1000 mg/kg/day during gestation. Neeper-Bradley et al. (1995) reported oral NOAELs for developmental toxicity of 150 mg/kg for CD-1 mice and 500 mg/kg for CD rats. Dermal application of as much as ~3500 mg/kg/day under an occlusive dressing on days 6 to 15 of gestation was without observable maternal or fetal toxicity in CD-1 mice (Tyl et al., 1995). This lack of effect was attributed to the relatively poor percutaneous absorption of EG. Carney et al. (1999b) recently concluded that glycolic acid was the proximate developmental toxicant in EG-dosed rats. Metabolic acidosis was believed to exacerbate the teratogenicity of high doses of EG. The mechanism of the teratogenic action of glycolate is unknown.

Diethylene Glycol

Diethylene glycol (DEG) is used in industry as a solvent; a deicer; an additive for inks, lacquers, cosmetics and brake fluids; and as a textile finishing agent. DEG's use as an excipient in a liquid sulfanilamide preparation resulted in 105 deaths in the United States in 1937. This incident prompted passage of the Food, Drug and Cosmetic Act of 1938 (Wax, 1995). DEG is sometimes present as a contaminant of components of pharmaceuticals. Use of propylene glycol or glycerin contaminated with DEG has caused multiple fatalities from renal failure in Nigeria, Bangladesh, India, and Haiti. In the last incident, 109 cases of acute renal failure (with 88 deaths) were identified in children who received a locally manufactured acetaminophen syrup containing DEG-contaminated glycerin (O'Brien et al., 1998). The median lethal dose of DEG was estimated to be 1.34 mL/kg, with some victims receiving less than 1 mL/kg. Renal failure was the "hallmark" finding in these cases, but hepatitis, pancreatitis, and severe neurologic manifestations (e.g., encephalopathy, optic neuritis with retinal edema, unilateral facial paralysis) were frequently seen.

DEG toxicological data are limited. Oliguria or polyuria, proteinuria, and other manifestations of kidney injury were reported in rats given 5.0 or 7.5 mL DEG/kg ip (Kraul et al., 1991). The nephrotoxicity was maximally expressed 4 to 8 days after the single dose. Rats that consumed diets containing 1, 2, or 4 percent DEG (~1, 2, or 4 g/kg/day) exhibited dose-dependent hepatorenal injury (Fitzhugh and Nelson, 1946). Hellwig et al. (1995) did not find signs of maternal or fetal toxicity in rabbits given up to 1 g DEG/kg PO on days 7 to 19 postinsemination. Swiss CD-1 mice had to ingest as much as 6.1 g/kg/day for 14 weeks before their reproductive performance was diminished (Williams et al., 1990).

Relatively little information was located on the TK or mechanism of action of DEG. Heilmair et al. (1993) did find that doses of 1 and 5 mL/kg PO were rapidly and almost completely absorbed by male Sprague-Dawley (S-D) rats. ^{14}C-DEG was quickly distributed throughout the animals' bodies, and largely eliminated in the urine within 12 to 16 h. Wiener and Richardson (1989) identified a single urinary metabolite in DEG-dosed male Wistar rats, namely (2-hydroxyethoxy) acetic acid (HEAA). DEG, like EG, is oxidized in turn by alcohol dehydrogenase (ADH) and by aldehyde dehydrogenase. The ether linkage of DEG is not cleaved, as no EG or EG metabolites are formed from DEG. Lenk et al. (1989) observed that unchanged DEG, recovered in the urine of male S-D rats, constituted the majority (61 to 68 percent) of orally administered doses of 1, 5, and 10 mL/kg. HEAA accounted for 16 to 31 percent of these doses. DEG accelerated its own elimination by inducing osmotic diuresis at the two highest dosage levels. DEG's nephrotoxic moiety(ies) has (have) not been positively identified. Pretreatment of rats with pyrazole, an ADH inhibitor, did reduce the lethality of DEG in rats (Wiener and Richardson, 1989). Brophy et al. (2000) recently reported utilizing 4-methylpyrazole, an ADH inhibitor, and hemodialysis in the successful treatment of a 17-month-old girl who ingested DEG.

Propylene Glycol

Propylene glycol (PG) is used extensively as a solvent, coolant, antifreeze, and component of hydraulic fluids. As PG is "generally recognized as safe" by the FDA, it is a constituent of many cosmetics and processed foods. Furthermore, it serves as a solvent/diluent for a substantial number of oral, dermal, and intravenous drug preparations (ATSDR, 1997c).

PG has a very low order of acute and chronic toxicity (ATSDR, 1997c; LaKind et al., 1999). Extremely high doses can cause CNS depression, metabolic acidosis,

encephalopathy, and hemolysis in humans and laboratory animals. No accounts of human fatalities were located. Glover and Reed (1996) reported a typical clinical case in which a 2-year-old child experienced CNS depression and anion-gap acidosis after ingesting a hair gel containing PG. Christopher et al. (1990) noted that cats ingesting 1.6 g PG/kg/day exhibited increases in serum anion gap acidosis and in D-lactate over a period of 35 days. Cats fed 8 g/kg/day for 35 days developed depression and ataxia, consistent with their progressively elevated plasma lactate levels. No organ system has apparently been identified as a target for acute or chronic injury by PG (LaKind et al., 1999). Carcinogenic or non-carcinogenic effects have not been seen in chronic bioassays in a number of species (ATSDR, 1997c). PG has not been shown to be mutagenic or teratogenic, or to adversely affect fertility or reproduction in CD-1 mice (Morrissey et al., 1989).

The explanation for PG's low toxicity lies in its metabolism. PG is metabolized by alcohol dehydrogenase to lactaldehyde, which in turn is oxidized by aldehyde dehydrogenase to lactate (Morshed et al., 1988). Excessive lactic acid is primarily responsible for systemic metabolic acidosis. Lactate, of course, can be converted to pyruvate and glucose through gluconeogenic pathways. PG is readily absorbed from the GI tract and distributed throughout total body water. PG accumulation is reported to differ significantly among people maintained on a repetitive oral dosing schedule, due to intersubject variability in clearance (Yu et al., 1985).

GLYCOL ETHERS

If one of the alcohol residues of ethylene glycol (HO—CH$_2$—CH$_2$—OH) is replaced by an ether, the resulting compound is a monoalkyl glycol ether such as ethylene glycol monomethyl ether, also called 2-methoxyethanol (2-ME; **CH$_3$— O**—CH$_2$—CH$_2$—OH). If both alcohols are replaced by ethers, the result is a dialkyl glycol ether such as ethylene glycol dimethyl ether (**CH$_3$— O**—CH$_2$—CH$_2$—**O**—CH$_3$). The alkyl group at the end of the ether linkage may be a straight or branched short chain moiety (e.g., methyl, ethyl, *n*-propyl, isopropyl, or butyl). The latter results in one of the most widely used glycol ethers, 2-butoxyethanol (2-BE; **CH$_3$— CH$_2$— CH$_2$— CH$_2$— O**—CH$_2$—CH$_2$—OH). Acetates of monoalkyl ethers such as 2-ME acetate (**CH$_3$— CO— O**—CH$_2$—CH$_2$—O—CH$_3$) are also common solvents that undergo rapid ester hydrolysis in vivo, and are thus likely to exhibit the same toxicity profile as unesterified glycols. Glycol ethers exhibit properties of both alcohols and ethers and are thus soluble in water and most organic solvents. This dual solubility, along with a favorable evaporation rate, make glycol ethers very popular as solvents for surface coatings such as lacquers, varnishes, and latex paints. Glycol ethers also find use as solvents in paint thinners and strippers, inks, metal cleaning products, liquid soaps, household cleaners, and in the fabrication of semiconductors.

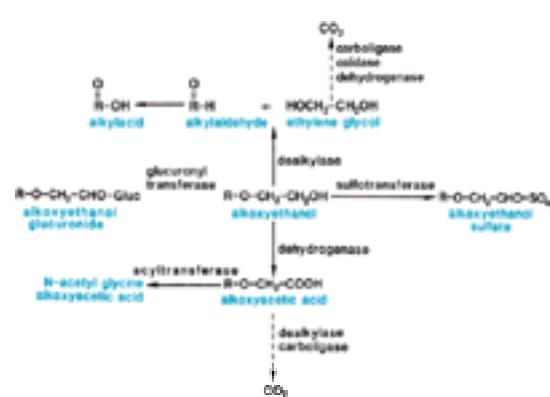
Although the metabolism of glycol ethers varies with the chemical structure, some generalizations are possible (Fig. 24-12). For ethylene glycol monoalkyl ethers, the major metabolic pathway is oxidation via alcohol and aldehyde dehydrogenases to alkoxyacetic acids. For example, 2-ME and 2-BE are metabolized to methoxyacetic acid (MAA; **CH$_3$— CO— O**—CH$_2$—O—CH$_3$) and butoxyacetic acid (BAA; **CH$_3$— CO— O**—CH$_2$—O—CH$_2$—CH$_2$—CH$_2$—CH$_3$), respectively. The competing *O*-dealkylase pathway results in the cleavage of the ether linkage to form ethylene glycol and an alkyl aldehyde. Medinsky et al. (1990) reported that the relative contribution of the oxidative pathway to metabolism of ethylene glycol ethers increases with increasing alkyl chain length, while that of the *O*-dealkylase pathway decreases. In contrast, the propylene series (e.g., propylene glycol monomethyl ether; PGME) is predominantly biotransformed to propylene glycol via *O*-dealkylation. Glycol ethers may also be conjugated with glucuronide or sulfate, but this is thought to occur mainly after saturation of the other metabolic pathways.


Figure 24-12. Metabolism of glycol ethers.

R denotes alkyl group of —CH$_3$, —CH$_2$—CH$_3$, or —CH$_2$—CH$_2$—CH$_2$—CH$_3$ for methoxy-, ethoxy-, or butoxyethanol, respectively. The formation of alkoxy glucuronide or sulfate conjugates has been identified only for butoxyethanol. [Reproduced with permission of Medinsky et al. (1990).]

The metabolism of glycol ethers is considered a prerequisite for their toxicity, as the alkoxyacetic acids are regarded as the ultimate toxicants. Their acetaldehyde precursors have also been implicated on occasion. Evidence for this comes from numerous in vitro and in vivo toxicity studies demonstrating that glycol ethers and their oxidative metabolites are reproductive, developmental, hematologic, and immunologic toxicants by all exposure routes. Additional evidence comes from: protection from toxicity afforded by inhibition of alcohol and aldehyde dehydrogenases; similar toxicity profiles of ethylene glycol ethers and their alkoxyacetic acid metabolites; and the differential toxicities of those glycol ethers metabolized via the oxidative and *O*-dealkylase pathways (Miller et al., 1984; Ghanayem et al., 1987).

Like glycol ether metabolism, glycol ether toxicity varies with chemical structure. With increasing alkyl chain length, reproductive and developmental toxicity decrease, whereas hematotoxicity increases (Ghanayem et al., 1989; Carney et al., 1999a). This demonstrates that structure-activity relationships are universally applicable across multiple toxicologic endpoints. Metabolic activation does not appear to be the sole determinant of the acute, oral lethality of ethylene glycol ethers. This was demonstrated by Tanii and coworkers (1992), who determined that LD$_{50}$s for ethylene glycol ethers in mice were highly correlated with their hydrophobicities. These researchers speculated that increasing hydrophobicity simply allowed the glycol ethers to more readily gain access to critical cellular targets.

Reproductive Toxicity

The reproductive toxicity of the glycol ethers is almost exclusively limited to reversible spermatotoxicity in males. Typical responses include testicular and seminiferous tubule atrophy, abnormal sperm head morphology, necrotic spermatocytes, decreased sperm motility and count, and infertility (Nolen et al., 1985; Heindel, 1990). Creasy and Foster (1984) noted a consistent order of spermatocyte susceptibility following oral administration of 2-ME or 2-EE to rats: dividing spermatocytes > early-pachytene spermatocytes > late-pachytene spermatocytes > mid-pachytene spermatocytes. Spermatocytes in the leptotene/zygotene stages of cell division, late-stage spermatids, and spermatogonia can be affected if the dose is increased and exposure prolonged. As for a mechanism of action, Beattie et al. (1984) reported that rates of lactate accumulation in cultured rat Sertoli cells were significantly decreased by MAA. Lactate is the preferred metabolic substrate of spermatocytes. Also, 2-EE has been shown to increase oxygen consumption and decrease ATP levels in pachytene spermatocytes in a manner consistent with an uncoupled oxidative state (Oudiz and Zenick, 1986). Mebus et al. (1989) demonstrated that serine, acetate, sarcosine, and glycine attenuated the spermatotoxicity of 2-ME in the rat, suggesting that MAA may interfere with the availability of one-carbon units for incorporation into purine and pyrimidine bases necessary for nucleic acid synthesis in pachytene spermatocytes. A mechanistic role for Ca^{2+} has been promoted by Ghanayem and Chapin (1990) who observed that a Ca^{2+} channel blocker afforded protection against 2-ME-induced pachytene spermatocyte cell death. These authors hypothesized that 2-ME perturbed Ca^{2+} homeostasis, which is consistent with observations of spermatocyte mitochondrial disruption. Involvement of Ca^{2+} is further suggested by observations that 2-ME induces spermatocyte apoptosis in both the rat and guinea pig, and activates or induces an endogenous endonuclease. An increase in intracellular Ca^{2+} is thought by many to be the trigger for endonuclease activation/induction and subsequent apoptotic cell death (Ku et al., 1995).

Testicular effects similar to those in rodents have been described for humans, in some cases at concentrations well below current OSHA PELs for 2-ME and 2-EE of 25 and 200 ppm, respectively. Men exposed to a mean level of 6.6 ppm 2-EE in a foundry had decreased numbers of sperm per ejaculate (Ratcliffe et al., 1989). Similarly, Welch et al. (1988) found that painters exhibited oligospermia and azoospermia following exposure to 2-EE and 2-ME at 2.7 ppm and 0.8 ppm on average, respectively. A large case-control study of male fertility clinic patients revealed a highly significant association between a diagnosis of impaired fertility and the detection of ethoxyacetic acid in urine (Veulemans et al., 1993). Significant associations between potential exposure to mixtures containing ethylene glycol ethers and increased risk for spontaneous abortion and subfertility have been observed in females. These results are interesting in light of findings that MAA increases progesterone production in human luteal cells (Almekinder et al., 1997).

Developmental Toxicity

Developmental toxicity has been described for several glycol ethers. Structural anomalies in rodents have included a variety of minor skeletal variations, hydrocephalus, exencephaly, cardiovascular malformations, dilatation of the renal pelvis, craniofacial malformations, and digit malformations (Hardin et al., 1986; Tyl et al., 1989). Electrocardiograms of fetal rats from dams treated with 2-ME during gestation showed persistent, aberrant QRS waves in the absence of structural defect, suggestive of an intraventricular conduction delay (Toraason and Breitenstein, 1988). Neurobehavioral changes and regional brain alterations of several neurotransmitters in the offspring of rats treated with 2-ME or 2-EE have been reported (Nelson and Brightwell, 1984). Ambroso et al. (1998) applied confocal laser scanning microscopy, classical histopathology, and in situ immunohistochemistry to demonstrate that 2-ME caused a dose-dependent increase and expansion of apoptosis in gestation day 8 mouse embryos that could underly 2-ME-induced neural tube defects. Such a mechanism has also been hypothesized for malformations induced by the prototypical teratogens, retinoic acid and ethanol.

A case-control study was conducted in Europe to determine whether maternal occupational exposure to glycol ethers in the first trimester was associated with congenital malformations (Cordier et al., 1997). The overall odds ratio of congenital malformations was 1.44 (95 percent CI = 1.10 to 1.90), with significant associations for glycol ether exposure with cleft lip and neural tube defects such as spina bifida. PBTK models have been applied to estimate inhaled concentrations of 2-EE, its acetate ester, and 2-ME in humans that would result in blood levels equivalent to those observed at the rat NOAELs and LOAELs for developmental effects (Gargas et al., 2000a, b). It is worthy of note that 2-ME has been largely removed from commerce due to its teratogenic potency.

Hematotoxicity

Some glycol ethers are hemolytic to red blood cells (RBCs). Typically, the osmotic balance of the cells is disrupted, they imbibe water and swell, their ATP concentration decreases, and hemolysis occurs. The swelling suggests that the erythrocyte membrane is the ultimate target (Ghanayem, 1989). Nyska et al. (1999) report that subchronic exposure to 2-BE causes disseminated thrombosis and bone infarction in female, but not male rats, likely due to the impedance of blood flow by intravascular hemolysis. It is thought that females might be susceptible, since they are less efficient at eliminating BAA and exhibit higher peak blood BAA levels. Young rats are more resistant to the hematologic effects of 2-BE than older rats, an observation attributed to depressed degradation and renal clearance of BAA in older rats. Hoflack et al. (1997) have shown 2-BE capable of inducing apoptosis in a human leukemia cell line and have hypothesized that the hematopoietic toxicity of 2-BE may be the result of its ability to induce cell death.

Species differ dramatically in their sensitivities to glycol ether–induced RBC deformity and hemolysis. Humans are less susceptible than rodents. This lower susceptibility applies even to RBCs from potentially sensitive subpopulations, such as the elderly and persons with hereditary blood disorders (Udden, 1994; Udden and Patton, 1994). A good example of using PBTK models in human risk assessment has been published by Corley et al. (1997). Based on comparisons of the model output with data collected by Udden et al. on levels of 2-BE required to affect osmotic fragility of human RBCs, Corley et al. (1997) concluded that humans are unlikely to achieve hemolytic blood levels of BAA, unless very large volumes of 2-BE are intentionally ingested.

Immunotoxicity/Carcinogenicity

It also appears that the immune system is a sensitive target of glycol ether oxidative metabolites. Exon et al. (1991) exposed male and female rats to high concentrations of 2-ME in drinking water for 21 days. Among the effects seen were thymic atrophy, increased natural killer cell cytotoxic activity, decreased antibody production, decreased splenocyte production of interferon-g, and a reduction in spleen cellularity. 2-ME-induced immunosuppression has also been reported by Kim and Smialowicz (1997). Interestingly, 2-methoxyacetaldehyde proved more immunotoxic than MAA in this study.

Chronic inhalation bioassays were recently conducted on 2-BE in F344 rats (0 to 125 ppm) and B6C3F1 mice (0 to 250 ppm) (NTP, 1998). Conclusions from the 2-year bioassay included: no evidence of carcinogenicity in male F344 rats; equivocal evidence of carcinogenicity in female F344 rats, based on the combined incidences of benign and malignant pheochromocytoma (mainly benign) of the adrenal medulla; and some evidence of carcinogenicity in male and female B6C3F1 mice, based on increased incidences of hemangiosarcoma of the liver and forestomach squamous cell papilloma or carcinoma (mainly papilloma), respectively. The genotoxicity of some of the glycol ethers and their metabolites has been evaluated, with most studies indicating a lack of genotoxic potential and with others yielding positive responses in certain tests. Therefore, the role of genetic toxicology in the toxicities discussed above cannot be summarily dismissed but is of unknown significance (Elliot and Ashby, 1997).

FUELS AND FUEL ADDITIVES

Automotive Gasoline

Automotive gasoline is a complex mixture of hundreds of hydrocarbons predominantly in the range of C_4 to C_{12}. The sheer number of people exposed in the manufacture, distribution, and use of gasoline make the characterization of its acute and chronic toxicities important. Generalizations regarding the toxicity of gasoline must be made with care, since its composition varies with the crude oil from which it is refined, the refining process, and the use of specific additives. Experiments conducted with fully vaporized gasoline may not be predictive of actual risk, since humans are exposed primarily to the more volatile components in the range of C_4 to C_5. These hydrocarbons are generally regarded as less toxic than their higher-molecular-weight counterparts. Concern for gasoline is fueled in part by the toxicities of its individual components, some of which are classified by the EPA as known or probable human carcinogens (e.g., benzene and 1,3-butadiene). The ACGIH has established a threshold limit value (TLV) for gasoline of 300 ppm to prevent ocular and upper respiratory tract irritation and a short-term exposure limit (STEL) of 500 ppm to avoid acute CNS depression.

Inhalation exposure to gasoline has been measured for service station attendants and self-service customers, for truck drivers and distribution workers, and for workers removing leaking underground storage tanks (Kearney and Dunham, 1986; Shamsky and Samimi, 1987). In one survey, short-term exposures to self-service customers averaged about 6 ppm. The TLV is rarely exceeded in occupationally exposed individuals, due in part to the use of vapor scavenging systems. Brief exposures in excess of the STEL have, however, been documented for workers engaged in bulk handling operations (Phillips and Jones, 1978). The most extreme exposures occur to those intentionally sniffing gasoline for its euphoric effects. Several case reports of acute and chronic encephalopathies, expressed as both motor and cognitive impairment, are testament to the dangers of this habit (Valpey et al., 1978; Fortenberry, 1985). In these cases, the identity of the offending agent(s) is often unclear. An all too common occurrence is the ingestion of gasoline during siphoning events. This is typically followed by a burning sensation in the mouth and pharynx, as well as nausea, vomiting, and diarrhea resulting from GI irritation. If aspirated into the lungs, gasoline may produce pulmonary epithelial damage, edema, and pneumonitis. Thus, emetic therapy for gasoline ingestion is usually contraindicated.

Reese and Kimbrough (1993), as well as Caprino and Togna (1998), have reviewed the acute toxicity of gasoline and its additives. Like some other solvents, gasoline can sensitize the heart to catecholamines, defat the skin upon repeated contact, and induce hepatic MFO and UDP-glucuronyltransferase activities (Poon et al., 1995). The issue of whether there is a "fetal gasoline syndrome" has been raised, although case reports offered in support of the affirmative are confounded by tetraethyl lead, alcohol abuse, and the possibility that an aberrant gene is distributed within the small Amerindian population where the cases reside (Hunter et al., 1979). There is a paucity of data on the reproductive toxicity of gasoline, but reports of enhanced estrogen metabolism and uterine atrophy among unleaded gasoline-treated mice suggest that this endpoint warrants investigation (Standeven et al., 1994a). The study of Lykke and Stewart (1978) is of interest, in the rats exposed to the modest concentration of 100 ppm leaded gasoline (one-third the current ACGIH TLV) 40 h/week for 6 to 12 weeks were observed to have a progressive interstitial fibrosis of the lungs associated with irregular alveolar collapse.

Prior to the identification of a_{2u}-globulin as the principal accumulating protein in the syndrome referred to as a a_{2u}-globulin nephropathy, Kuna and Ulrich (1984) reported regenerative epithelium and dilated tubules in the kidneys of male rats exposed to 1552 ppm unleaded gasoline for 90 days. At about the same time, a chronic inhalation study reported not only the nephropathy, but increased renal tumors in male rats (MacFarland et al., 1984). Subsequent studies by Halder et al. (1986) and Aranyi et al. (1986) showed that such nephropathy could not be produced by exposure of rats to a mixture of the butane and pentane components of gasoline or the 0° to 145°F gasoline distillation fraction. These are thought to be more representative of human occupational exposures than wholly vaporized gasoline. In addition, the authors of a gavage screening study of 15 pure hydrocarbons and gasoline fractions concluded that branched aliphatic alkane components were primarily responsible for the nephropathy (Halder et al., 1985).

Investigations of mechanisms of the nephropathy and renal tumors included an assessment of unscheduled (a measure of genotoxicity) and replicative DNA synthesis

(a measure of cell proliferation) in rat kidney cells exposed in vitro and in vivo to unleaded gasoline. No unscheduled DNA synthesis occurred, even at a tumorigenic dose, while a five- to eightfold increase in cell proliferation was observed (Loury et al., 1987). In a publication the same year by Olson et al. (1987), unleaded gasoline was reported to result in an increase in hyaline droplets harboring large accumulations of a $_{2u}$-globulin within proximal convoluted tubule epithelial cells. It was hypothesized that a$_{2u}$-globulin accumulated secondary to a defect in renal lysosomal degradation of the protein (Fig. 24-6). Supportive evidence for this hypothesis came from Olson et al. (1988), who demonstrated that inhibition of the lysosomal peptidase cathepsin B caused a rapid accumulation of phagolysosomes and a$_{2u}$-globulin in the kidney similar to that of gasoline.

Further progress in elucidating the mechanism of a$_{2u}$-globulin nephropathy came from the demonstration that the unleaded gasoline component, 2,2,4-trimethylpentane (TMP), itself an inducer of a$_{2u}$-globulin nephropathy, was metabolized to 2,4,4-trimethyl-2-pentanol (TMPOH), which was selectively retained by the kidney of male rats. Subsequently, it was demonstrated that the sex-specific retention of TMPOH in the kidney was due to reversible binding with a $_{2u}$-globulin. This binding rendered the protein less digestible by lysosomal enzymes, which accounted for its accumulation (Charbonneau and Swenberg, 1988). This accumulation, in turn, led to cellular degeneration and necrosis, primarily in the P $_2$ segment of the proximal tubule. In response, regenerative proliferation occurs and promotes formation of renal cell tumors by irreversibly "fixing" spontaneously altered DNA and clonally expanding initiated cells. The promotional effects of gasoline and TMP on atypical cell foci and renal cell tumors have been demonstrated in male rats following initiation with N-ethyl-N-hydroxyethylnitrosamine (Short et al., 1989). NCI-Black-Reiter male rats, the only rat strain not to synthesize a$_{2L}$-globulin, are resistant to gasoline- and TMP-induced nephropathy (Dietrich and Swenberg, 1991). Thus, gasoline and TMP have been of great value in elucidating the mechanism of a$_{2u}$-globulin nephropathy and shedding light on its implications for renal tumorigenesis. Most toxicologists, and indeed the EPA, have concluded that renal tumors secondary to a$_{2u}$-globulin nephropathy are of little relevance, because humans do not synthesize a$_{2L}$-globulin.

Chronic inhalation of gasoline has also resulted in increased hepatocellular adenomas and carcinomas in B6C3F1 female mice (MacFarland et al., 1984). This increase may have been due to the promotion of spontaneously initiated cells that occur with unusually high frequency in this mouse strain. Unleaded gasoline is a liver tumor promoter in N-nitrosodiethylamine–initiated female B6C3F1 mice (Standeven and Goldsworthy, 1993). Gasoline has been shown to induce cytochrome P450 activity and to produce hepatomegaly and a transient increase in hepatocyte proliferation, all of which are considered relevant to tumor-promoting activity (Moser et al., 1996a). An effort has been made to link gasoline's promoting effect to its antiestrogenicity (Standeven et al., 1994a, b). Unleaded gasoline has also been shown to induce unscheduled DNA synthesis in hepatocytes from male and female mice treated in vivo and in cultured mouse, rat and human hepatocytes (IARC, 1989). The epidemiologic evidence for an association between gasoline exposure and cancer in humans is inconclusive. IARC (1989) provides perhaps the best and least biased epidemiologic overview, from which they conclude that there is inadequate evidence for the carcinogenicity of gasoline in humans.

Methyl Tertiary-Butyl Ether

Methyl tertiary-butyl ether's (MTBE's) high octane rating made it a logical replacement for tetraethyl lead as an octane booster for gasoline, and later as a gasoline oxygenator. As an oxygenator, MTBE makes fuel combustion more complete, thereby reducing pollutant emissions from automobile exhaust. MTBE may be added to gasoline at levels up to 15 percent by volume in order to comply with the 1990 Amendments to the Clean Air Act. By 1997, it was being used at the rate of 10 million gal/day, with more than one-third of the usage in California. While routine, low-level exposure of customers occurs at self-service stations, heightened concern about MTBE has resulted primarily from its contamination of groundwater by leaking underground gasoline tanks. Water containing MTBE has an unpleasant taste and odor, which may alert consumers to the fact that their water is contaminated. Based on the results of studies of taste and odor thresholds for humans, an advisory guidance range of 20 to 40 mg/L has been set by the EPA to assure consumer acceptance and provide a large margin of safety from toxicity and carcinogenicity.

Comprehensive reviews of MTBE toxicity include those of the EPA and State of California in their Drinking Water Advisory and Public Health Goal documents, respectively (EPA, 1997; Wang et al., 1999). Scientists from three different federal government agencies have published a comprehensive review (Melnick et al., 1997), while the review of Borak et al. (1998) focuses upon the acute human health effects of MTBE. The conclusion of this latter work, based on 19 reports of inhalation exposure to MTBE alone or in gasoline and 12 reports of parenteral MTBE administration to dissolve cholesterol gallstones, is that no significant association exists between MTBE exposure and the acute symptoms commonly attributed to MTBE. These symptoms include headache, eye, nose and throat irritation, cough, nausea, dizziness, and disorientation. The ATSDR has published a Toxicological Profile for MTBE (ATSDR, 1996b).

In 1988, the EPA and industry developed a Testing Consent Order for MTBE under the Toxic Substances Control Act that precipitated investigations of MTBE's potential two-generation reproductive toxicity, developmental toxicity, in vivo mutagenicity, subchronic inhalation toxicity, oncogenicity, and neurotoxicity. Results of these studies are a major addition to the toxicity literature on MTBE and define several NOAELs (Bevan et al., 1997a, b; Bird et al., 1997; Daughtrey et al., 1997; Lington et al., 1997; McKee et al., 1997). The publication of Bird and colleagues is actually a recapitulation of reports by Chun et al. (1992) and Burleigh-Flayer et al. (1992), both of which are of particular value, as they represent two of only three MTBE cancer bioassays. In the Chun et al. study, male and female F344 rats were exposed to 0, 400, 3000, or 8000 ppm MTBE vapor 6 h/day, 5 days/week for 24 months. In the other inhalation study, Burleigh-Flayer et al. (1992) subjected male and female CD-1 mice to the same exposure regimen for 18 months. The only oral chronic bioassay is that by Belpoggi et al. (1995, 1997), who subjected male and female S-D rats by olive oil gavage to 0, 250, or 1000 mg/kg MTBE 4 days/week for 2 years. The results of the three MTBE animal cancer bioassays are presented in Table 24-4.

AUTHORS	ANIMAL STRAIN/BREED	EXPOSURE ROUTE	POSITIVE RESULTS
Chun et al. (1992)	Fischer 344 rats	Inhalation	Kidney and testicular tumors (males)
Burleigh-Flayer et al. (1992)	CD-1 mice	Inhalation	Liver adenomas (females)
Belpoggi et al. (1995)	Sprague-Dawley rats	Oral	Testicular tumors (males)
			Leukemia + lymphoma (females)

Table 24-4 Summary Results of MTBE Cancer Bioassays

Taken at face value, one might interpret these cancer bioassay findings as ample evidence of carcinogenicity in animals and suggestive of a cancer risk for humans. The relevance of these findings to humans, however, has been a source of debate among toxicologists. Critics have questioned these studies on the basis of (1) the appropriateness of a combined incidence category for leukemias and lymphomas; (2) the possibility that renal tumors were secondary to male rat–specific a $_{2u}$-globulin nephropathy; (3) the possibility that Leydig cell tumors were a function of abnormally low testicular tumor rates in control animals or increased survival time of treated rats; (4) the questionable relevance of testicular tumors in rats to humans, given the species' differential responses of Leydig cells to proliferative stimuli; (5) the possibility that liver and kidney tumors are the result of high dose-induced chronic cytotoxicity, cell death, and reparative cell proliferation; (6) the relevance of inhalation bioassays to prediction of drinking water risks; and (7) the use of an oil rather than a water dosing vehicle, which could unduly influence MTBE's oral TK. Some of these issues are discussed in more detail in Mennear's (1997) review and interpretation of the MTBE carcinogenicity studies.

As an outgrowth of the uncertainties surrounding MTBE's carcinogenicity, several mechanistic studies have been published. For example, after only 10 days of MTBE inhalation exposure, a strong positive linear relationship between renal a $_{2u}$-globulin concentration and cell proliferation was seen in the male F344 rat (Prescott-Matthews et al., 1997). This study, unlike the chronic bioassay of Chun et al. (1992), definitively identified the accumulating protein as a $_{2u}$-globulin (Fig. 24-6). The concentration of a$_{2u}$-globulin in kidney cytosol was measured with an enzyme-linked immunosorbent assay. MTBE has been shown to be a hepatic mitogen in the female mouse, but not a promoter of tumor formation in N-nitrosodiethylamine (DEN)-initiated female mouse liver (Moser et al., 1996b). It has been suggested in light of these findings, that MTBE may promote the growth of spontaneously initiated cell populations having genetic lesions different from those produced by DEN. Studies also indicate that MTBE causes endocrine dysregulation in rodents at high doses, suggesting that consideration be given to the possibility that MTBE-induced tumor formation is hormonally mediated (Moser et al., 1998; Williams et al., 2000). Although it has generally been accepted that MTBE's carcinogenicity in animals occurs through a non-genotoxic mechanism, MTBE has been shown to be moderately mutagenic in the Ames assay in the requisite presence of a functional excision

repair system (Williams-Hill et al., 1999).

Several mechanistic issues, including the contribution of MTBE's metabolites, *tert*-butyl alcohol and formaldehyde, to MTBE's toxicity have yet to be resolved. To this end, Casanova and Heck (1997) have reported a lack of concentration-, species-, and sex-dependence in the formation of formaldehyde-induced DNA-protein crosslinks and RNA-formaldehyde adducts in isolated female CD-1 mouse hepatocytes incubated with MTBE. As the cancer bioassay data suggest that hepatocarcinogenicity varies with all of these factors, these results do not support a role for formaldehyde in MTBE-induced liver tumor formation.

As a reflection of the paucity of data available, IARC (1999) has concluded that MTBE is not classifiable as to its carcinogenicity to humans (group 3), and the EPA has classified MTBE as a possible human carcinogen (group C), meaning limited evidence from animal studies and inadequate or no data in humans. Despite data limitations, the EPA Office of Water has calculated three cancer slope factors, one for each of the cancer bioassays, all using the linearized multistage model that assumes the absence of a threshold for tumor formation. California has derived both a cancer potency estimate and adopted a Public Health Goal of 13 ppb for MTBE in drinking water (Wang et al., 1999). There are advocates for the suspension of MTBE's use in reformulated gasoline, but such a decision should weigh the benefits against the risks associated with increased auto emissions of carcinogenic VOCs and the public health impact of increased CO_2 emissions and ozone formation. Two articles that discuss this subject in considerable detail are those of Spitzer (1997) and Erdal et al. (1997).

Jet Fuel

Jet propellant-8 (JP-8 jet fuel) is a complex, kerosene-like mixture of hundreds of aliphatic and aromatic hydrocarbons. It is now the recognized battlefield fuel for all NATO ground and air forces. Owing to slight differences in hydrocarbon composition and additives, JP-8's chemicophysical properties differ from those of its predecessor fuels in ways that impart added safety, enhance combat aircraft survivability, simplify battlefield logistics, and promote standardization with commercial jet fuel. Both civilian and military personnel are exposed to JP-8. For instance, ground crews have identified highly visible aerosol emissions during jet aircraft "cold starts," resulting in some crew members working behind the aircraft becoming "drenched" in fuel. Jet fuel can also be released into the environment by in-flight jettisoning and by spills or leaks to soil or water during use, storage, or transportation. In many cases, the United States Department of Defense (DoD) is ultimately responsible for the cost of remediating contaminated military sites and contractor facilities. Since toxicity is a primary determinant of the extent to which contaminated sites must be remediated, it is in DoD's interest to accurately characterize the toxicity of JP-8. Thus, much of the recent research on jet fuel toxicity has been conducted and/or funded by the military.

Toxicity data on jet fuels have recently been summarized (ATSDR, 1998a; IARC, 1989). There is no evidence that JP-8 or other jet fuels are a genetic risk. JP-8 was not teratogenic, based on a single study that identified a NOAEL of 1000 mg/kg/day for reduction in fetal body weight of rats (Cooper and Mattie, 1996). In a 90-day continuous inhalation study of JP-8 vapor, no treatment-related adverse effects other than a $_{2u}$-globulin nephropathy were seen in mice or rats (Mattie et al., 1991). Bruner et al. (1993) exposed rats and mice of each sex 6 h/day, 5 days/week to JP-4 vapors for 12 months. The main finding was renal toxicity and neoplasia in male rats consistent with a$_{2u}$-globulin nephropathy. Data suggest that the chronic dermal application of jet fuels can be carcinogenic to the skin of mice. It has been effectively argued, however, that the tumorigenic effect is secondary to chronic irritation (Nessel, 1999).

Some of the most interesting toxicity data on jet fuel have been published on the subject of JP-8-induced lung and immune dysfunction. In the first of this series of studies (Pfaff et al., 1995), the pulmonary effects of an aerosol/vapor mixture of JP-8 jet fuel (495–520 mg/m^3) were investigated in rats with nose only exposures for 1 h/day for 7 or 28 days to simulate military flightline exposures. Changes in pulmonary function, in the form of increases in pulmonary resistance and alveolar permeability, were accompanied by a decrease in the concentration of Substance P (SP) in bronchoalveolar lavage fluid. Pfaff et al. (1996) published another study in which reductions in SP were accompanied by pathological changes in lower pulmonary structures such as inflammation of the terminal bronchioles, degeneration of alveolar type II cells, disruption of terminal bronchial airway epithelium, interstitial and perivascular edema, thickened epithelium of the bronchioles, and minute irregular microvilli. Most interestingly, however, neutral endopeptidase (NEP), the enzyme most responsible for the metabolism of tachykinins such as SP in the lung, was increased by exposure and a significant inverse relationship between SP and NEP activity was demonstrated. Thus, JP-8 appears to exhibit a rather novel mechanism of lung injury that involves the reduction or depletion of SP due to its enhanced metabolism by NEP.

Because SP participates in the maintenance of airway epithelial cell competency, the effect of JP-8 and *n*-tetradecane (C$_{14}$), a primary constituent of JP-8, on epithelial barrier integrity was examined in vitro using paracellular mannitol flux in BEAS-2B human bronchial epithelial cells. Noncytotoxic concentrations of JP-8 and C$_{14}$ dose-dependently increased transepithelial mannitol flux that spontaneously reversed to control values over a 48-hr recovery period. This suggests that JP-8 and C$_{14}$ compromise the integrity of intercellular tight junctions that may precede and initiate the pathologic alterations observed in whole animal studies (Robledo et al., 1999). These same authors also have collected evidence that SP's protective affect on the lung is largely mediated through the plasma membrane bound neurokinin receptor, NK1, that is present on airway epithelium from the trachea to the respiratory bronchioles (Robledo and Witten, 1999). Further insight into the effects of JP-8 have come from the use of high resolution two-dimensional electrophoresis applied to samples of lung and kidney cytosol collected from JP-8 exposed mice. Both qualitative and quantitative changes were apparent in proteins, many of which were identified and related to impaired processes that could underlie the pathophysiological changes induced by JP-8 in the lung (Witzmann et al., 1999; Witzmann et al., 2000). It is conceivable that these altered proteins could one day serve as biomarkers of JP-8 exposure and effect in humans.

The immune system appears to be susceptible to insult at lower JP-8 concentrations than the lung. As reported by Harris et al. (1997a), mice were exposed nose-only to several concentrations of JP-8 aerosol/vapor mix (0-2500 mg/m^3) for 1 h/day for 7 days and sacrificed 24 h after the last exposure for immune assays. JP-8 exposure decreased spleen and thymus organ weights and cellularities and altered the number of viable immune cells of the lymph nodes, bone marrow, and peripheral blood. Depending upon the immune organ examined, different immune cell subpopulations were lost, including T and B cells and macrophages. In addition, JP-8 was found to affect immune function as demonstrated by a concentration-dependent suppression of T cell proliferation upon stimulation with the mitogen concanavalin A. As a follow-up study, Harris et al. (1997b) determined that JP-8-induced immunotoxicity persisted for at least 1 month after insult. Recently, these same authors have expanded the number of immune parameters examined and report that JP-8 exposure to mice (1 h/day for 7 days, 1000 mg/m^3) nearly completely ablated NK cell function, suppressed the generation of lymphokine-activated killer cell activity and cytotoxic T lymphocyte generation from precursor T cells, and inhibited helper T cell activity (Harris et al., 2000). Ullrich (1999) has demonstrated that the dermal application of JP-8 to mice also induces immune suppression. Ullrich found interleukin-10, a cytokine with potent immune suppressive activity, in the serum of JP-8 treated mice. He interpreted this as suggestive of an immune suppressive mechanism involving the upregulation of cytokine release. As in the case of JP-8-induced pulmonary toxicity, aerosolized SP afforded protection against JP-8 induced immunotoxicity, suggesting a key mechanistic role for the neuropeptide (Harris et al., 1997c).

The ATSDR has derived an intermediate MRL for JP-5 and JP-8 of 3 mg/m^3 from a study in which hepatocellular fatty vacuolization was observed in mice exposed to JP-5 at 150 mg/m^3 continuously for 5 days (ATSDR, 1998a). EPA has not verified a RfD or RfC for JP-5 or JP-8, but an EPA memorandum has detailed the derivation of provisional RfDs for JP-4 and JP-5 of 8×10^{-2} and 2×10^{-2} mg/kg/day, respectively (EPA, 1992).

Kerosene

In contrast to automobile gasoline and jet fuels that together account for about 60 percent of all United States refinery output, kerosene accounts for just 0.3 percent. Since the late 1970s, the demand for kerosene and its production have sharply declined. As a middle distillate consisting of C $_9$ to C$_{16}$ hydrocarbons, its make-up is very similar to that of jet fuel. Therefore, one might predict that its toxicity would resemble that of jet fuel. The majority of published literature on kerosene deals with localized effects at the portals of entry, mainly the skin and the lung. A comprehensive evaluation of the carcinogenic potential of middle distillate fuels has been recently published that focused on skin tumors secondary to chronic skin irritation (Nessel, 1999). A discussion of the toxicology of dermally applied middle distillates is also a recent addition to the literature (Koschier, 1999). For the most comprehensive review, see IARC's (1989) discussion of jet fuels and kerosene.

CARBON DISULFIDE

The majority of carbon disulfide (CS$_2$) is used in the production of viscose rayon and cellophane, CCl $_4$ and pesticides, and as a solubilizer for waxes and oils (ATSDR, 1996a). Exposure is predominantly occupational, but CS$_2$ has been identified at ~200 current or former EPA National Priority List hazardous waste sites (ATSDR, 1996a). As discussed in EPA's IRIS profile, a RfC of 0.7 mg/m^3 (~0.22 ppm) is based on reduced maximum motor conduction velocity in the peroneal nerves of viscose rayon workers exposed to CS$_2$. The RfD of 0.1 mg/kg/day is based on the teratogenic potential of CS$_2$ in rats and rabbits. For the protection of workers, OSHA has established a PEL of 20 ppm as an 8-h time-weighted average (TWA) and an acceptable ceiling concentration of 30 ppm. The ACGIH TLV is 10 ppm as an 8-h

TWA.

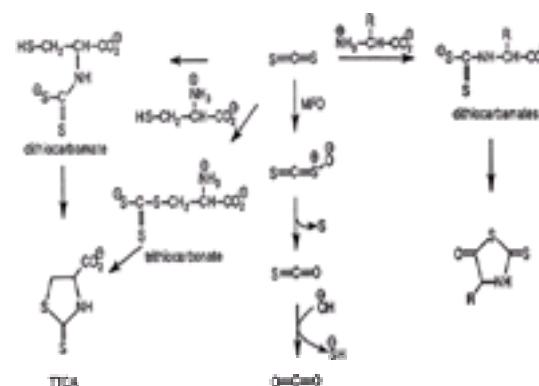
At present, the relative contributions of parent compound and metabolites to most CS_2-induced toxicities are unknown. Two distinct metabolic pathways for CS_2 exist: (1) the direct interaction of CS_2 with free amine and sulfhydryl groups of amino acids and polypeptides to form dithiocarbamates and trithiocarbonates and (2) microsomal metabolism of CS_2 to reactive sulfur intermediates capable of covalently binding to tissue macromolecules (Fig. 24-13). The conjugation of CS_2 with GSH results in the formation of 2-thiothiazolidine-4-carboxylic acid (TTCA), which is excreted in urine and has been frequently used as a biomarker of CS_2 exposure, especially among viscose rayon workers (Riihimaki et al., 1992; Lee et al., 1995). Several limitations of TTCA as a biomarker have been noted, and covalently cross-linked erythrocyte spectrin and hemoglobin have been discussed as potential alternatives (Valentine et al., 1993, 1998). Nonetheless, the current ACGIH Biological Exposure Index (BEI) for CS_2 is 5 mg of TTCA per g of creatinine for a urine sample collected at the end of a workshift. Commentary on the derivation of this BEI has been published by Cox et al. (1992).


Figure 24-13. Metabolism of carbon disulfide (CS$_2$).

CS_2 is metabolized by the MFO system to carbonyl sulfide, atomic sulfur and HS⁻. Reaction of CS_2 with sulfhydryls of cysteine or GSH yields trithiocarbonates, which can cyclize to form thiazolidine-2-thione-4-carboxylic acid (TTCA). Reaction of CS_2 with amino groups of amino acids results in dithiocarbamate derivatives, which can cyclize to yield 2-thio-5-thiazolidinones; reaction of cysteine amine could also produce TTCA. CS_2 is also metabolized in the liver by P450s to an unstable oxygen intermediate, which spontaneously generates atomic sulfur, carbonyl sulfide (COS), and CO_2. [Reproduced with permission of Graham et al. (1995).]

A few reviews of CS_2 toxicity appear in the literature (WHO, 1979; Beauchamp et al., 1983; ATSDR, 1996a). CS_2 targets multiple organ systems and has been associated with toxicities as diverse as ocular/auditory toxicity and spermatotoxicity. Two target organs have garnered the majority of attention, the nervous and cardiovascular systems. With regard to the former, CS_2 is associated with the following clinical syndromes as stated by Rosenberg (1995):

(1) acute and chronic encephalopathy (often with prominent psychiatric manifestations), (2) polyneuropathy (both peripheral and cranial), (3) Parkinsonism, and (4) asymptomatic CNS and PNS dysfunction....Pathologic changes occur in both the CNS and PNS...CNS pathology consists of neuronal degeneration throughout the cerebral hemispheres, wth maximal diffuse involvement in the frontal regions. Cell loss is also noted in the globus pallidus, putamen, and cerebellar cortex, with loss of Purkinje cells. Vascular abnormalities with endothelial proliferation of arterioles may be seen, sometimes associated with focal necrosis or demyelination. PNS changes consist primarily of myelin swelling and fragmentation and large focal axonal swellings, characteristic of distal axonopathy.

For those interested in the nervous system, the classic paper by Richter (1945), detailing his observations of chronic CS_2 poisoning in monkeys, is recommended. Much more recently, collaborative research by the NIEHS, EPA, and two universities was conducted. Studies were conducted to assess multiple biological and mechanistic endpoints at various times during subchronic exposure of F344 rats to a range of CS_2 concentrations. The endpoints included (1) TK in blood and urine; (2) assessment of covalently modified hemoglobin and nerve growth factor receptor mRNA as biomarkers of exposure and effect; (3) alterations in axon/Schwann cell interactions; (4) morphology of distal axonopathy; (5) nerve conduction velocity and compound nerve action potentials; and (6) a functional observational battery. The findings have been published as a series (Harry et al., 1998; Sills et al., 1998).

Neither the concentration nor the exposure duration required for CS_2-induced neurotoxicity in humans is known, although frequent and prolonged exposures over a course of months are likely required. Studies indicate that CS_2, like *n*-hexane, causes neurofilament-filled swellings proximal to nodes of Ranvier of distal axons. Distortions of nodal anatomy and demyelination occur, and some axons undergo degeneration distal to the neurofilamentous swellings. The success of regeneration of peripheral nerves is related to the severity of the loss of motor and sensory function, with greater degrees of recovery in those individuals with milder symptoms. While the primary clinical manifestations reflect changes in peripheral nerves, the axonopathy also involves the long axons in the CNS that cannot regenerate, particularly the ascending and descending tracks of the spinal cord and the visual pathways.

Several mechanisms for the disruption of neurofilament transport that underlies CS_2 axonopathy have been proposed including impaired energy metabolism, metal ion chelation by CS_2's dithiocarbamate derivatives, the induction of vitamin deficiency, neurofilament derivatization, and the disruption of cytoskeletal protein association by the increased phosphorylation of neurofilaments (Wilmarth et al., 1993; Graham et al., 1995). One mechanism has emerged as more plausible than the others, however, that of progressive cross-linking of neurofilaments by the reaction of electrophilic CS_2 metabolites with protein nucleophiles (Valentine et al., 1997).

Some epidemiology studies support an association between CS_2 exposure and cardiovascular disease in viscose rayon workers (Sweetnam et al., 1987; Peplonska et al., 1996; Kuo et al., 1997), but others do not (Drexler et al., 1996; Omae et al., 1998). Wronska-Nofer (1979) conducted studies in rats supporting a role for CS_2 in the elevation of blood cholesterol, and more recently Lewis et al. (1999) demonstrated that high doses of CS_2 in mice can induce the early lesions of atherosclerosis. Data were also presented in this study that suggest protein cross-linking may be involved in the atherosclerotic process. Egeland et al. (1992) reported a significant and positive linear trend in elevation of low-density lipoprotein cholesterol and diastolic blood pressure with increasing CS_2 exposure in a group of workers with average 8-h exposures from 0.6 to 11.8 ppm. This study seems contradictory to the conclusion of Price et al. (1997), that an association between CS_2 and ischemic heart disease mortality is meaningful only for workers exposed to extreme levels for many years. The general public may be exposed to low background concentrations of CS_2, as demonstrated by detection of CS_2 in all samples of breath and indoor and outdoor air surveyed in and around New York City (Phillips, 1992).

CHAPTER 25

TOXIC EFFECTS OF RADIATION AND RADIOACTIVE MATERIALS

Naomi H. Harley

INTRODUCTION

Among all the branches of toxicology, ionizing radiation provides the most quantitative estimates of health detriments for humans. Five large studies provide data on the health effects of radiation on people. These effects include those due to external x-rays and gamma-ray radiation and internal alpha radioactivity. The studies encompass radium exposures, including those sustained by radium dial painters, atom bomb survivors, patients irradiated with x-rays for ankylosing spondylitis, children irradiated with x-rays for tinea capitis (ringworm), and uranium miners exposed to radon and its short-lived daughter products. The only health effect subsequent to radiation exposure seen with statistical significance to date is cancer. The various types and the quantitative risks are described in subsequent sections.

All the studies provide a consistent picture of the risk of exposure to ionizing radiation. There are sufficient details in the studies of atom bomb, occupational, and medical exposures to estimate the risk from lifelong low-level environmental exposure. Natural background radiation is substantial, and only within the past two decades has the extent of the radiation insult to the global population from natural radiation and radioactivity been appreciated.

BASIC RADIATION CONCEPTS

The four main types of radiation are due to alpha particles, electrons (negatively charged beta particles or positively charged positrons), gamma rays, and x-rays. An atom can decay to a product element through the loss of a heavy (mass = 4) charged (+2) alpha particle (He $^{+2}$) that consists of two protons and two neutrons. An atom can decay by loss of a negatively or positively charged electron (beta particle or positron). Gamma radiation results when the nucleus releases excess energy, usually after an alpha, beta, or positron transition. X-rays occur whenever an inner-shell orbital electron is removed and rearrangement of the atomic electrons results, with the release of the element's characteristic x-ray energy.

There are several excellent textbooks describing the details of radiologic physics (Evans, 1955; Andrews, 1974; Turner, 1986, Cember 1996).

Energy

$$E = 1/2\ m\,V^2 \tag{1}$$

where m = mass of the particle
        V = velocity of the particle

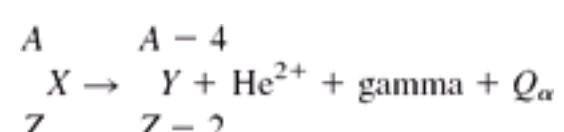
Alpha particles have a low velocity compared with the speed of light, and calculations of alpha particle energy do not require any corrections for relativity. Most beta particles (or positrons) have high velocity, and the basic expression must be corrected for their increased relativistic mass (the rest mass of the electron is 0.511 MeV). The total energy is equal to

$$E = 0.511/(1-v^2/c^2) + 0.511 \tag{2}$$

where v = velocity of the beta particle
        c = speed of light

Gamma rays and x-rays are pure electromagnetic radiation with energy equal to

$$E = hv \tag{3}$$

where h = Planck's constant (6.626×10^{-34} J s)
        v = frequency of radiation


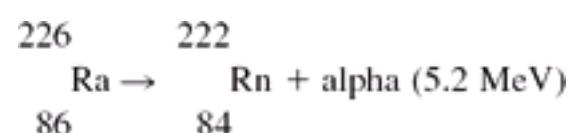
The conventional energy units for ionizing radiation are the electron volt (eV) or multiples of this basic unit, kiloelectron volts (keV) and million electron volts (MeV). The conversion to the international system of units, the Système Internationale (SI), is currently taking place in many countries, and the more fundamental energy unit of the Joule (J) is slowly replacing the older unit. The relationship is

$$1\ eV = 1y.6 \times 10^{-19}\ J$$

Authoritative tables of nuclear data such as those of Browne and Firestone (1986) contain the older but more widely accepted units of MeV for energy.

Alpha Particles

Alpha particles are helium nuclei (consisting of two protons and two neutrons), with a charge of +2, that are ejected from the nucleus of an atom. When an alpha particle loses energy, slows to the velocity of a gas atom, and acquires two electrons from the vast sea of free electrons present in most media, it becomes part of the normal background helium in the environment. All helium in nature is the result of alpha particle decay. The formula for alpha decay is

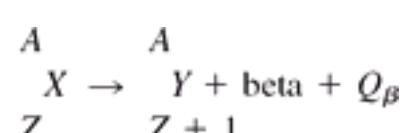
$$\begin{array}{c} A \\ X \\ Z \end{array} \rightarrow \begin{array}{c} A-4 \\ Y \\ Z-2 \end{array} + \text{He}^{2+} + \text{gamma} + Q_\alpha$$


where Z = atomic number
        A = atomic weight

The energy available in this decay is Q_a and is equal to the mass difference of the parent and the two products. The energy is shared among the particles and the

gamma ray if one is present.

An example of alpha decay is given by the natural radionuclide radium (^{226}Ra):

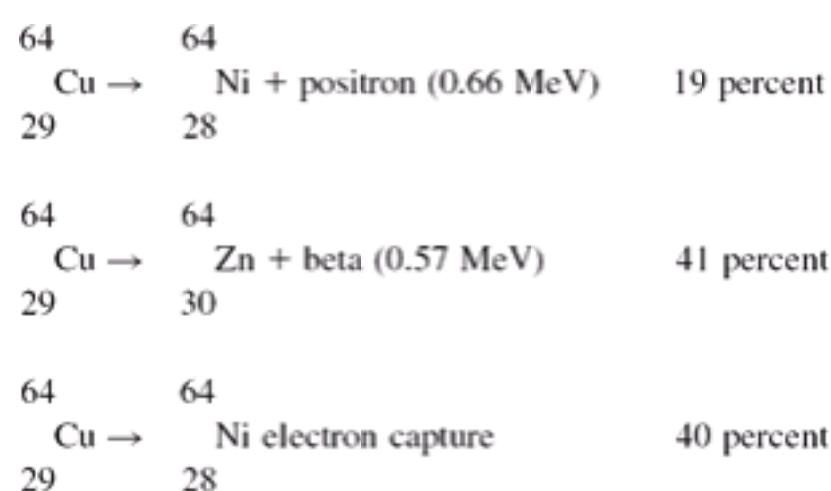
$$\underset{86}{\overset{226}{Ra}} \rightarrow \underset{84}{\overset{222}{Rn}} + \text{alpha (5.2 MeV)}$$


The energy of alpha particles for most emitters lies in the range of 4 to 8 MeV. More energetic alpha particles exist but are seen only in very short-lived emitters such as those formed by reactions occurring in particle accelerators. These particles are not considered in this chapter.

Although there may be several alpha particles with very similar energy emitted by a particular element such as radium, each particular alpha particle is monoenergetic, i.e., no continuous spectrum of energies exists, only discrete energies.

Beta Particles, Positrons, and Electron Capture

Beta particle decay occurs when a neutron in the nucleus of an element is effectively transformed into a proton and an electron. Subsequent ejection of the electron occurs, and the maximum energy of the beta particle equals the mass difference between the parent and the product nuclei. A gamma ray may also be present to share the energy, Q_b:

$$\underset{Z}{\overset{A}{X}} \rightarrow \underset{Z+1}{\overset{A}{Y}} + \text{beta} + Q_\beta$$


An example of beta decay is given by the natural radionuclide lead (^{210}Pb):

$$\underset{82}{\overset{210}{Pb}} \rightarrow \underset{83}{\overset{210}{Bi}} + \text{beta (0.015 MeV)} + \text{gamma (0.046 MeV)}$$

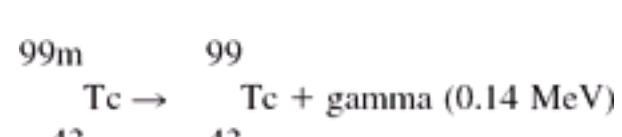
Unlike alpha particles in alpha decay, in which each alpha particle is monoenergetic, beta particles are emitted with a continuous spectrum of energy from zero to the maximum energy available for the transition. The reason for this is that the total available energy is shared in each decay or transition by two particles: the beta particle and an antineutrino. The total energy released in each transition is constant, but the observed beta particles then appear as a spectrum. The residual energy is carried away by the antineutrino, which is a particle with essentially zero mass and charge that cannot be observed without extraordinarily complex instrumentation. The beta particle, by contrast, is readily observed with conventional nuclear counting equipment.

Positron emission is similar to beta particle emission but results from the effective nucleon transformation of a proton to a neutron plus a positively charged electron. The atomic number decreases rather than increases, as it does in beta decay.

An example of positron decay is given by the natural radionuclide copper (^{64}Cu), which decays by beta emission 41 percent of the time, positron emission 19 percent of the time, and electron capture 40 percent of the time:

$$\underset{29}{\overset{64}{Cu}} \rightarrow \underset{28}{\overset{64}{Ni}} + \text{positron (0.66 MeV)} \qquad 19 \text{ percent}$$

$$\underset{29}{\overset{64}{Cu}} \rightarrow \underset{30}{\overset{64}{Zn}} + \text{beta (0.57 MeV)} \qquad 41 \text{ percent}$$

$$\underset{29}{\overset{64}{Cu}} \rightarrow \underset{28}{\overset{64}{Ni}} \text{ electron capture} \qquad 40 \text{ percent}$$


The energy of the positron appears as a continuous spectrum, similar to that in beta decay, where the total energy available for decay is again shared between the positron and a neutrino. In the case of positron emission, the maximum energy of the emitted particle is the mass difference of the parent and product nuclide minus the energy needed to create two electron masses (1.02 MeV), whereas the maximum energy of the beta particle is the mass difference itself. This happens because in beta decay, the increase in the number of orbital electrons resulting from the increase in atomic number of the product nucleus cancels the mass of the electron lost in emitting the beta particle. This does not happen in positron decay, and there is an orbital electron lost as a result of the decrease in atomic number of the product and the loss of the electron mass in positron emission.

Electron capture competes with positron decay, and the resulting product nucleus is the same nuclide. In electron capture, an orbiting electron is acquired by the nucleus, and the transformation of a proton plus the electron to form a neutron takes place. In some cases the energy available is released as a gamma-ray photon, but this is not necessary, and a monoenergetic neutrino may be emitted. If the 1.02 MeV required for positron decay is not available, positron decay is not kinetically possible and electron capture is the only mode observed.

Gamma-Ray (Photon) Emission

Gamma-ray emission is not a primary process except in rare instances, but it occurs in combination with alpha, beta, or positron emission or electron capture. Whenever the ejected particle does not utilize all the available energy for decay, the nucleus contains the excess energy and is in an excited state. The excess energy is released as photon or gamma-ray emission coincident with the ejection of the particle.

One of the rare instances of pure gamma-ray emission is technetium 99m (^{99m}Tc), which has a 6.0-h half-life and is widely used in diagnostic medicine for various organ scans. Its decay product, ^{99}Tc, has a very long half life (2.13 × 10^5 years), and as all ^{99}Tc is ultimately released to the environment, a background of this nuclide is emerging.

$$\underset{43}{\overset{99m}{Tc}} \rightarrow \underset{43}{\overset{99}{Tc}} + \text{gamma (0.14 MeV)}$$

In many cases, the photon will not actually be emitted by the nucleus but the excess excitation energy will be transferred to an orbital electron. This electron is then ejected as a monoenergetic particle with energy equal to that of the photon minus the binding energy of the orbital electron. This process is known as internal conversion. In tables of nuclear data such as those of Browne and Firestone (1986), the ratio of the conversion process to the photon is given as $e / y v$. For example, the e / v ratio for ^{99m}Tc is 0.11, and therefore the photon is emitted 90 percent of the time and the conversion electron is emitted 10 percent of the time.

INTERACTION OF RADIATION WITH MATTER

Ionizing radiation, by definition, loses energy when passing through matter by producing ion pairs (an electron and a positively charged atom residue). A fraction of

the energy loss raises atomic electrons to an excited state. The average energy needed to produce an ion pair is given the notation W and is numerically equal to 33.85 eV. This energy is roughly two times the ionization potential of most gases or other elements because it includes the energy lost in the excitation process. It is not clear what role the excitation plays, for example, in damage to targets in the cellular DNA. Ionization, by contrast, can break bonds in DNA, causing strand breaks and easily understood damage.

All particles and rays interact through their charge or field with atomic or free electrons in the medium through which they are passing. There is no interaction with the atomic nucleus except at energies above about 8 MeV, which is required for interactions that break apart the nucleus (spallation). Very high energy cosmic-ray particles, for example, produce ^{3}H, ^{7}Be, ^{14}C, and ^{22}Na in the upper atmosphere by spallation of atmospheric oxygen and nitrogen.

Alpha and beta particles and gamma rays lose energy by ionization and excitation in somewhat different ways, as described in the following sections.

Alpha Particles

The alpha particle is a heavy charged particle with a mass that is 7300 times that of the electrons with which it interacts. A massive particle interacting with a small particle has the interesting property that it can give a maximum velocity during energy transfer to the small particle of only two times the initial velocity of the heavy particle. In terms of the maximum energy that can be transferred per interaction, this is

$$E_{(maximum\ electron,} = 4/7300\ E_{(alpha\ particle)} \tag{4}$$

Although alpha particles can lose perhaps 10 to 20 percent of their energy in traveling 10 µm in tissue (1 cm in air), each interaction can impart only the small energy, given in the maximum, in Eq. (4). Thus, alpha particles are characterized by a high energy loss per unit path length and a high ionization density along the track length. This is called a *high linear-energy-transfer* (LET) or *high-LET* particle.

Hans Bethe (1953) derived an exact expression for the energy loss in matter, dE/dx or stopping power, with later modifications added by Bloch and others. For alpha energies between 0.2 and 10 MeV, the Bethe-Bloch expression can be simplified to

$$dE/dx = 3.8 \times 10^{-25}\ C\ NZ/E\ \ln\{548\ E/I\}\ \text{MeV} / \mu\text{m}^{-1} \tag{5}$$

where N = number of atoms cm^{-3} in medium
Z = atomic number of medium
I = ionization potential of medium
E = energy of alpha particle
C = charge correction for alpha particles with energy below

1.6 MeV

A simple rule of thumb derived by Bloch may be used to estimate the ionization potential of a compound or element,

$$I = 10(Z) \tag{6}$$

or the Bragg additivity rule (Attix et al., 1968) may be used for compounds when the individual values of ionization potential for the elements are available. A tabulation of values of ionization potential is given in ICRU 37 (ICRU, 1984), and the stopping power in all elements has been calculated in ICRU 49 (ICRU, 1993) and by Ziegler (Ziegler, 1977).

When alpha particles are near the end of their range, the charge is not constant at +2 but can be +1 or even zero as the particle acquires or loses electrons. A correction factor, C, is needed for energies between 0.2 and 1.5 MeV to account for this effect. Whaling (1958) published values for the correction factor by which Eq. (4) should be multiplied. These factors vary from 0.24 at 0.2 MeV, 0.75 at 0.6 MeV, 0.875 at 1.0 MeV, up to 1.0 at 1.6 MeV.

For the case of tissue, Eq. (5) reduces to

$$dE/dx_{tissue} = [0.126\,C/E]\ \ln \{7.99\ E\}\ \text{MeV} / \mu\text{m}^{-1} \tag{7}$$

Example 1 Find the energy loss (stopping power) of a 0.6 and a 5-MeV alpha particle in tissue.

dE/dx= 0.126 (0.75)/0.6 ln (7.99 × 0.6)
= 0.25 MeV / μm^{-1}
= 0.126 (1.0)/5.0 ln (7.99 × 5.0)
= 0.093 MeV /μm^{-1}

The significance of this energy loss is seen in that it requires 33.85 eV to produce an ion pair; therefore, a 5-MeV alpha particle can produce $(0.25 \times 10^{6}\ \text{eV}/\mu\text{m}^{-1})$ / (33.86 ev / ion pair) = 7400 ion pairs in 1µm, or enough damage to cause a double-strand break.

Beta Particles

The equations for beta particle energy loss in matter cannot be simplified, as in the case of alpha particles, because of three factors:

1. Even at low energies of a few tenths of an MeV, beta particles are traveling near the speed of light and relativistic effects (mass increase) must be considered.
2. Electrons are interacting with particles of the same mass in the medium (free or orbital electrons), so large energy losses per collision are possible.
3. Radiative or bremsstrahlung energy loss occurs when electrons or positrons are slowing down in matter. Such a loss also occurs with alpha particles, but the magnitude of this energy loss is negligible.

Including the effects of these three factors, the energy loss for electrons and positrons has been well quantitated. Tabulations of energy loss in various media have been prepared with the ionization energy loss and the radiative loss detailed. Tables of energy loss for electrons in tissue and many other substance as a function of electron energy can be found in ICRU 37 (1984).

Gamma Rays

Photons do not have a mass or charge, as do alpha and beta particles. The interaction between a photon and matter therefore is controlled not by the electrostatic Coulomb fields but by interaction of the electric and magnetic field of the photon with the electron in the medium. There are three modes of interaction with the medium.

The Photoelectric Effect The photon interaction with an orbital electron in the medium is complete, and the full energy of the photon is given to the electron.

The Compton Effect Part of the photon energy is transferred to an electron, and the photon scatters (usually at a small angle from its original path) (Evans, 1955) with reduced energy. The governing expressions are

$$E' = E\ 0.511/(1 + 1/a - \cos q) \tag{8}$$
$$T = E\ a(1 - \cos q)/[1 + a(1 - \cos q)]$$

where E, E' = initial and scattered photon energy in MeV
   T = kinetic energy of electron in MeV
   a = E/0.511
   q = angle of photon scatter from its original path

Pair Production Pair production occurs whenever the photon energy is greater than the rest mass of two electrons, 2(0.511 MeV) = 1.02 MeV. The electromagnetic energy of the photon can be converted directly to an electron-positron pair, with any excess energy above 1.02 MeV appearing as kinetic energy given to these particles.

The loss of photons and energy loss from a photon beam as it passes through matter are described by two coefficients. The attenuation coefficient determines the fractional loss of photons per unit distance (usually in normalized units of g/cm^2, which is the linear distance times the density of the medium). The mass energy absorption coefficient determines the fractional energy deposition per unit distance traveled. The loss of photons from the beam is given by

$$i/I_0 = \exp(-\mu / r\ d) \tag{9}$$

where i = intensity of photon beam (numbers of photons)
   I_0 = beam intensity
   μ / r = attenuation coefficient in medium for energy considered (in m^2 kg^{-2})
   d = thickness of medium in superficial density units kg m^{-2} (thickness in m times density in kg m^{-3})

Superficial density is convenient in that it normalizes energy absorption in different media. For example, air and tissue have approximately the same energy absorption per kg m^{-2}, whereas in linear dimension, the energy absorption, say, per meter, is vastly different. The energy actually deposited in the medium per unit distance is calculated using the mass energy absorption coefficient as opposed to the overall attenuation coefficient and the energy loss is given by

$$DE = (\mu_{en} / r)E_0 \tag{10}$$

where DE = energy loss in medium per unit distance (in MeV m^2 kg^{-1})
   μ_{en} / r = mass energy absorption coefficient (m^2 kg^{-2})
   E_0 = initial photon energy

The values for μ_{en} / r as a function of gamma-ray energy are shown in Table 25-1 for air and muscle. Energy loss can then be expressed per unit linear distance by multiplying by the density of the medium (kg m^{-3}).

Table 25-1 Mass Energy Absorption Coefficients for Air and Water

ABSORBED DOSE

Dose and Dose Rate

Absorbed dose is defined as the mean energy, e, imparted by ionizing radiation to matter of mass m (ICRU, 1993):

$$D = e/m \tag{11}$$

where D = absorbed dose
   e = mean energy deposited in mass
   m = mass

The unit for absorbed dose is the gray (Gy), which is equal to 1 J kg^{-1}. The older unit of dose is the rad, which is equal to 100 erg g^{-1}, a value numerically equal to 100 times the dose in gray. The conversion between the two units is 100 rad = 1 Gy.

For uncharged particles (gamma rays and neutrons), kerma (kinetic energy released in matter) is sometimes used. It is the sum of the initial kinetic energies of all the charged ionizing particles liberated in unit mass. The units of kerma are the same as those for dose.

Exposure often is confused with absorbed dose. Exposure is defined only in air for gamma rays or photons and is the charge of the ions of one sign when all electrons liberated by photons are completely stopped in air of mass m:

$$X = Q/m \tag{12}$$

where X = exposure
   Q = total charge of one sign
   m = mass of air

The unit of exposure is coulombs per kilogram of air. The older unit of exposure is the roentgen, which is equal to 2.58 × 10^{-4} C kg^{-1} of air.

Exposure and dose are used interchangeably in some publications, even though this is not correct. The reason is that the older numerical values of dose in rad and exposure in roentgen are similar. Although they are similar numerically, they are fundamentally different in that exposure is ionization (only in air) and dose is absorbed energy in any specified medium:

1 roentgen = 0.87 rad (in air)

The SI units are not numerically similar:

$$1 \text{ C kg}^{-1} = 33.85 \text{ Gy}$$

Dose Rate

Dose rate is the dose expressed per unit time interval. The dose rate delivered to the thyroid by ^{99m}Tc for a nuclear medicine scan, for example, diminishes with time because of the 6.0-h half-life of the nuclide. The total dose is a more pertinent quantity in this case because it can be related directly to risk and compared with the benefit of the thyroid scan. The total dose over all time is expressed by

$$D = D_0 \times \{T_{\text{eff}}\}/\ln2$$

where D_0 = dose rate at time zero
$\quad\quad T_{\text{eff}}$ = effective half-life = $\{ T_t + T_b \} / \{ T_r \times T_b \}$
$\quad\quad T_t$ = radiologic half-life
$\quad\quad T_b$ = biological half-life

In general, substances in the body are removed through biological processes as well as by radioactive decay; therefore the effective half-life is shorter than the radiologic half-life.

The dose rate from natural body ^{40}K in all living cells, by contrast, is relatively constant throughout life and is usually expressed as the annual dose rate.

Equivalent Dose

Ionizing radiation creates ion pairs in a substance such as air or tissue in relatively dense or sparse distribution depending upon the particle. Alpha particles with large mass produce relatively intense ionization tracks per unit distance relative to beta particles, and beta particles produce more dense ionization than gamma-rays. The ability to produce more or less ionization per unit path in a medium is quantitated by the LET. The linear energy transfer in a substance such as water is readily calculated.

The calculated LET from alpha and beta particles is therefore much greater than it is for gamma rays. In considering the health or cellular effects of each particle or ray, it is necessary to normalize the various types of radiation. For a particular biological endpoint, such as cell death in an experiment with mouse fibroblasts, it is common to calculate a relative biological effectiveness (RBE). This is defined as the ratio of gamma ray dose that yields the same endpoint to the dose from the radiation under study, for example, cell death.

Although giving the same dose to an organ from alpha particles as opposed to gamma rays would result in greater effects from the alpha particles, such refinement in the normalization of endpoints (cancer) in the human is not possible with the available data. An attempt to normalize human health effects from different types of radiation, i.e., to calculate an "equivalent" dose is made through the values for LET of the various types of radiation in water. The ratio of the LET for gamma to the radiation in question is defined as a *radiation weighting factor, w_r* (formerly Q), and the normalized (or weighted) dose is called the *equivalent dose.* The unit for the equivalent dose is the sievert (Sv), and the older unit is the rem:

$$H = Dw_r \tag{13}$$

where H = equivalent dose in sievert (older unit rem)
$\quad\quad D$ = dose in gray (older unit rad)
$\quad\quad w_r$ = radiation weighting factor

Table 25-2 gives the values of LET for different particles or rays and is reproduced from the National Council on Radiation Protection (NCRP, 1993) and the International Commission on Radiation Protection (ICRP, 1990).

TYPE OF RADIATION	APPROXIMATE W_r
X-rays, gamma rays, beta particles, and electrons	1
Thermal neutrons	5
Neutrons (other than thermal ≫100 kev to 2 Mev), protons, alpha particles, charged particles of unknown energy	20

SOURCE: NCRP, 1993, and ICRP, 1990.

Table 25-2 Recommended Values of W$_r$ for Various Types of Radiation

Example 2 Find the equivalent dose (in sievert) for a dose to lung from an internal emitter of 0.01-Gy alpha particles and 0.01 Gy from external gamma-ray radiation.

Alpha, *H* = 0.01 (20) = 0.20 Sv
Gamma, *H* = 0.01 (1) = 0.01 Sv

Effective Dose and Cancer Risk

The term *effective dose* (ED) (formerly *effective dose equivalent*) was introduced formally by the ICRP in 1977 to allow addition or direct comparison of the cancer and genetic risk from different partial-body or whole-body doses. A partial-body gamma-ray dose to the lung, for example, is thought to give 0.0064 cancers over a lifetime per sievert, whereas a whole-body dose of 1 Sv would result in 0.056 total cancers and early genetic effects over the same lifetime interval. Both values are derived from the human A-bomb follow-up data. The ratio 0.0064/0.056 was defined as a tissue weighting factor, w_t, for lung and is numerically equal to 0.12.

The effective dose, H_E, is defined as a doubly weighted dose, weighted for radiation type and the tissue at risk.

$$H_E = w_t \times (Dw_r) \tag{14}$$

This concept is useful in the case of occupational exposure, because H_E values from different sources to different organs can be summed to yield a direct estimate of total cancer and genetic risk.

Table 25-3 is taken from ICRP (1990) and gives the values of w_t for various organs.

TISSUE OR ORGAN	TISSUE WEIGHTING FACTOR, w_t
Gonads	0.20
Bone marrow (red)	0.12
Colon	0.12
Lung	0.12
Stomach	0.12
Bladder	0.05
Breast	0.05
Liver	0.05
Esophagus	0.05
Thyroid	0.05
Skin	0.01
Bone surface	0.01
Remainder	0.05*†

Table 25-3 Recommended Values of the Weighting Factors, w_t, for Calculating Effective Dose

The occupational guideline for H_E is 20 mSv per annum (NCRP, 1987; ICRP, 1990). This requires that the sum of all H_E be less than or equal to this value:

$$H_E = \sum w_t H \leq 20 \text{ mSv} \tag{15}$$

In 1990, the ICRP revised its 1977 estimates of risk and adopted and published Publication 60. This document includes new estimates of risk for both fatal and nonfatal cancer and new guidelines for the exposure of workers to external and internal radiation. The risk estimates are based largely on the analysis of Japanese A-bomb survivors. The occupational guidelines for radiation protection developed from the 1990 document are 100 mSv in 5 years (average, 20 mSv per year) with a limit of 50 mSv in any single year. This is compared with the 1977 limit of 50 mSv per year.

The ICRP document (ICRP, 1990) is a response to the increase in lifetime cancer risk from ionizing radiation observed in A-bomb survivors. Mental retardation for those exposed in utero is a finding in the A-bomb survivor cohort and is now included in the risk estimates.

The overall risk per unit exposure for adult workers and the risk for the whole population given in the ICRP (1990) are shown in Table 25-4. The risk of fatal cancer is adopted as 0.04 per sievert [4 percent per sievert (100 rem)] for adult workers and 0.05 per sievert [5 percent per sievert (100 rem)], for the whole adult population.

Table 25-4 Nominal Probability Coefficients for Individual Tissues and Organs

The NCRP (1993) chose to limit exposure to 20 mSv per year with a lifetime limit of (age × 10 mSv). The ICRP had been criticized for excluding the effects of nonfatal cancer in previous documents. An attempt to correct this omission was made in ICRP 60 (1990). An attempt was made to calculate the total detriment and is given the notation *aggregated detriment*. The aggregated detriment is the product of four factors: the probability of attributable fatal cancer, the weighted probability of nonfatal cancer, the weighted probability of severe hereditary effects, and the relative length of life lost. The nominal probability of fatal cancer per sievert, F, and the aggregated detriment are shown in Table 25-4. The computation of the aggregated detriment proceeds as follows. A cancer lethality fraction, K (the fraction of total cancer that is lethal), is used as a weighting factor for nonfatal cancers. The total number of cancers (fatal plus nonfatal) Sv^{-1} will be F/K. The total number of nonfatal cancers is $(1 - K)F/K$. The total weighted detriment is then

$$F + K(1 - K)F/K = F(2 - K)$$

The aggregated detriment is then the product of $F(2 - K)$ times the relative length of life lost, l/l_{av}, for a particular cancer. The average length of life lost, l_{av}, is 15 years per cancer. The aggregated detriment is tabulated as 7.3×10^{-2} Sv^{-1} for the whole adult population and $\times 10^{-2}$ 5.6 Sv^{-1} for the working population.

In assessing radiation risk from low-dose, low-dose-rate, low-LET radiation using risk coefficients derived from high-dose, high-dose-rate exposures, a dose rate–reduction factor (DREF) must be applied. NCRP (1980) and the United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR) (1988, 1993) have shown that the human data cover a range for the DREF of 2 to 10. That is, the original risk coefficients derived from the high-dose data are divided by the DREF factor to obtain the best estimate of effects at typical low-dose exposures. ICRP has used 2.5 as the adopted DREF; however, in ICRP (1990) a DREF of 2.0 was used, and this is incorporated in the nominal probability coefficients in Table 25-4. Table 25-4 is used universally to assess the effects of occupational exposure.

The overall objective of both NCRP and ICRP dose limitation recommendations is to control the lifetime risk to maximally exposed individuals. ICRP (1990) limits the lifetime occupational effective dose to (20 mSv × 50 years) = 1000 mSv. In 1993, NCRP (1993) reduced the U.S. Recommendation for Lifetime Exposure to (age × 10 mSv) or approximately 700 mSv, with an average annual limit of 20 mSv and a maximum annual limit of 50 mSv.

The dose to members of the public is also considered by ICRP and NCRP. For continuous exposure to human-made sources, i.e., other than medical or natural, it is recommended that the annual effective dose not exceed 1 mSv (100 mrem), and for infrequent exposures the annual effective dose should not exceed 5 mSv (500 mrem).

Committed Equivalent Dose

A problem arises with internal emitters in that once they are ingested, there is an irreversible dose that is committed because of the biokinetics of the particular element. The absorbed dose depends on the biological and physical half-times of the element in the body. For this reason, the concepts of committed equivalent dose and committed effective dose were derived to accommodate the potential for the dose to be delivered over long periods after incorporation in the body. The committed dose is taken over a 50-year interval after exposure and is equal to

$$H_{T,50} = \int_{t_0}^{t_0 + 50} \dot{H}_t \, dt \tag{16}$$

where $H_{T,50}$ = 50-year dose to tissue T for a single intake at time t_0

$\dot{H}_t$ = equivalent dose rate in organ or tissue T at time t

The NCRP (1987, 1993) recognizes that for radionuclides with half-lives ranging up to about 3 months, the committed equivalent dose is equal to the annual dose for

the year of intake. For longer-lived nuclides, the committed equivalent dose will be greater than the annual equivalent dose and must be calculated on an individual basis. ICRP Publication 30 (ICRP, 1978) provides the details of this calculation for all nuclides.

Negligible Individual Risk Level (Negligible Dose)

The current radiobiologic principle commonly accepted is that of linear, nonthreshold cancer induction from ionizing radiation. Thus, regardless of the magnitude of the dose, a numerical cancer risk can be calculated. For this reason, the NCRP proposed the negligible individual risk level (NIRL) and defined it as "a level of annual excess risk of fatal health effects attributable to irradiation below which further effort to reduce radiation exposure to the individual is unwarranted."

The NCRP emphasized that the NIRL is not to be confused with an acceptable risk level, a level of significance, or a limit.

The NCRP recommended an annual effective equivalent dose limit for continuous exposure of members of the public of 1 mSv (0.1 rem). This value is in addition to that received from natural background radiation (about 2 mSv). In this context, the NIRL was taken to be 0.01 mSv (1 mrem). In NCRP (1993) the notation used currently is negligible individual dose (NID).

MECHANISMS OF DNA DAMAGE AND MUTAGENESIS

Energy Deposition in the Cell Nucleus

DNA is a double-helical macromolecule consisting of four repeating units: the purine bases adenine (A) and guanine (G) and the pyrimidine bases thymine (T) and cytosine (C). The bases are arranged in two linear arrays (or strands) held together by hydrogen bonds centrally and linked externally by covalent bonds to sugar-phosphate residues (the DNA "backbone"). The adenine base pairs naturally with thymine (A:T base pair), while guanine pairs with cytosine (G:C base pair), so that one DNA strand has the complementary sequence of the other. The sequence of the bases defines the genetic code; each gene has a unique sequence, but certain common sequences exist in control and structural DNA elements. Damage to DNA may affect any one of its components, but it is the loss or alteration of base sequence that has genetic consequences (UNSCEAR, 2000).

Ionizing radiation loses energy and slows down by forming ion pairs (a positively charged atom and an electron). Different ionization densities result from gamma rays, beta particles, and alpha particles. Their track structure is broadly characterized as from sparsely ionizing, (or low-LET), to densely ionizing (high-LET) radiation. Each track of low-LET radiation, resulting from x-rays or gamma rays, consists of a few ionizations across an average-sized cell nucleus (e.g., an electron set in motion by a gamma ray crossing an 8-μm-diameter nucleus gives an average of about 70 ionizations, equivalent to about 5 mGy (500 mrad) absorbed dose. Individual tracks vary widely about this value because of the stochastic nature of energy deposition, i.e., variability of ion pars per μm and path length through the nucleus. A high-LET alpha particle produces many thousands of ionizations and gives a relatively high dose to the cell. For example, a 4-MeV alpha-particle track yields on average, about 30,000 ionizations (3 Gy, 300 rad) in an average-sized cell nucleus. However, within the nucleus even low-LET gamma radiation will give some microregions of relatively dense ionization over the dimensions of DNA structures due to the low-energy electrons set in motion (UNSCEAR, 2000).

Direct and Indirect Ionization

Radiation tracks may deposit energy directly in DNA (direct effect) or may ionize other molecules closely associated with DNA, hydrogen or oxygen, to form free radicals that can damage DNA (indirect effect). Within a cell, the indirect effect occurs over very short distances, of the order of a few nanometers. The diffusion distance of radicals is limited by their reactivity. Although it is difficult to measure accurately the different contributions made by the direct and indirect effects to DNA damage caused by low-LET radiation, evidence from radical scavengers introduced into cells suggests that about 35 percent is exclusively direct and 65 percent has an indirect (scavengeable) component (Reuvers et al., 1973).

It has been argued that both direct and indirect effects cause similar early damage to DNA; this is because the ion radicals produced by direct ionization of DNA may react further to produce DNA radicals similar to those produced by water-radical attack on DNA (Ward, 1975).

DNA Damage

Ionization frequently disrupts chemical bonding in cellular molecules such as DNA. If the majority of ionizations occur as single isolated events (low-LET radiation), the disruptions are readily repaired by cellular enzymes. The average density of ionization by high-LET radiations is such that several ionizations may occur as the particle traverses a DNA double helix. Therefore, much of the damage from high-LET radiations, as well as a minority of the DNA damage from low-LET radiations, will derive from localized clusters of ionizations that can severely disrupt the DNA structure (Goodhead, 1992; Ward, 1994). While the extent of local clustering of ionizations in DNA from single tracks of low and high-LET radiations will overlap, high-LET radiation tracks are more efficient at inducing larger clusters and hence more complex damage. Also, high-LET radiations will induce some very large clusters of ionizations that do not occur with low-LET radiations; the resulting damage may be irreparable and may also have unique cellular consequences (Goodhead, 1994). When a cell is damaged by high-LET radiation, each track will give large numbers of ionizations, so that the cell will receive a relatively high dose, as noted in the calculation above, and there will be a greater probability of correlated damage within a single DNA molecule. As a consequence, the irradiation of a population of cells or a tissue with a "low dose" of high-LET radiation results in a few cells being hit with a relatively high dose (one track) rather than in each cell receiving a small dose. In contrast, low-LET radiation is more uniformly distributed over the cell population. At doses of low-LET radiation in excess of about 1 mGy (for an average-size cell nucleus of 8 μm in diameter), each cell nucleus is likely to be traversed by more than one sparsely ionizing track.

The interaction of ionizing radiation with DNA produces numerous types of damage; the chemical products of many of these have been identified and classified according to their structure. These products differ according to which chemical bond is attacked, which base is modified, and the extent of the damage within a given segment of DNA. Table 25-5 lists some of the main damage products that can be measured following low-LET irradiation of DNA, with a rough estimate of their abundance (UNSCEAR, 2000). Attempts have also been made to predict the frequencies of different damage types from the knowledge of radiation track structure, with certain assumptions about the minimum energy deposition (number of ionizations) required. Interactions can be classified according to the probability they will cause a single-strand DNA alteration (e.g., a break in the backbone or base alteration) or alterations in both strands in close proximity in one DNA molecule (e.g., a double-strand break), or a more complex type of DNA damage (e.g., a double-strand break with adjacent damage). Good agreement has been obtained between these predictions and direct measurements of single-strand breaks, but there is less agreement for other categories of damage. While complex forms of damage are difficult to quantify with current experimental techniques, the use of enzymes that cut DNA at sites of base damage suggests that irradiation of DNA in solution gives complex damage sites consisting mainly of closely spaced base damage (measured as oxidized bases of abasic sites); double-strand breaks were associated with only 20 percent of the complex damage sites (Sutherland et al., 2000). It is expected that the occurrence of more complex types of damage will increase with increasing LET, and that this category of damage will be less repairable than the simpler forms of damage. Theoretical simulations have predicted that about 30 percent of DNA double-strand breaks from low-LET radiation are complex because of additional breaks (Nikjoo et al., 1977) and that this proportion rises to more than 70 percent, and the degree of complexity increases, for high-LET particles (Goodhead and Nikjoo, 1997).

TYPE OF DAMAGE	YIELD (NUMBER OF DEFECTS PER CELL Gy^{-1})
Single-strand breaks	1000
Base damage[a]	500
Double-strand breaks	40
DNA protein cross-links	150

[a] Base excision enzyme-sensitive sites or antibody detection of thymine glycol.
source: UNSCEAR, 2000.

Table 25-5 Estimated Yields of DNA Damage in Mammalian Cells Caused by Low-LET Radiation Exposures

Some of the DNA damage caused by ionizing radiation is chemically similar to damage that occurs naturally in the cell. This "spontaneous" damage arises from the thermal instability of DNA as well as endogenous oxidative and enzymatic processes. Several metabolic pathways produce oxidative radicals within the cell, and these radicals can attack DNA to give both DNA base damage and breakage, mostly as isolated events. The more complex types of damage caused by radiation may not occur spontaneously, since localized concentrations of endogenous radicals are less likely to be generated in the immediate vicinity of DNA (UNSCEAR, 2000).

HUMAN STUDIES OF RADIATION TOXICITY

There have been five major studies of the health detriment resulting from exposure of humans to ionizing radiation. Other studies of large worker populations exposed to very low levels of radiation and environmental populations exposed to radon are ongoing, but they are not expected to provide new data on the risk estimates from ionizing radiation. These worker or environmental populations are studied to ensure that there is no inconsistency in the radiation risk data in extrapolating from the higher exposures. The basic studies on which the quantitative risk calculations are founded include radium exposures, A-bomb survivors, underground miners exposed to radon, patients irradiated with x-rays for ankylosing spondylitis, and children irradiated with x-rays for tinea capitis (ringworm).

Radium Exposures ([226,228]Ra)

Radium was discovered in the early part of the twentieth century. Its unique properties suggested a potential for the healing arts. It was incorporated into a wide variety of nostrums, medicines, and artifacts. The highest exposure occurred in the United States among radium dial painters who ingested from 10s to 1000s of micrograms (microcuries). These exposed groups, including patients, chemists, and dial painters, have been studied for over 60 years to determine the body retention of radium and the health effects of long-term body burdens.

The only late effect of ingestion of [226,228]Ra seen is osteogenic sarcoma. It is significant that no study has identified a statistically significant excess of leukemia after even massive doses of radium. This implies that the target cells for leukemia residing in bone marrow are outside the short range of the radium series alpha particles (70 µm). Several thousand people were exposed to radium salts either as part of the modish therapies using radium in the era from 1900 to 1930 or occupationally in the radium dial–painting industry around 1920. Radium therapy was accepted by the American Medical Association, and in around 1915 advertisements were common for radium treatment of rheumatism and as a general tonic and in the treatment of mental disorders. Solutions were available for drinking containing 2 µg/60 cm^3 as well as ampoules for intravenous injection containing 5 to 100 µg radium (Woodard, 1980). Luminous paint was developed before World War I, and in 1917 there were many plants in New England and New Jersey painting watch dials, clocks, and military instruments (Woodard, 1980).

The first large studies on osteogenic sarcoma in radium-exposed people were done by Martland (1931) and Aub and associates (1952), who found 30 cases of bone sarcoma; Evans and associates (1969) with 496 cases of sarcoma out of 1064 studied at the Massachusetts Institute of Technology; and Rowland et al. (1978), with 61 cases out of 1474 female dial painters (Woodard 1980).

Radium, once ingested, is somewhat similar to calcium in its metabolism and is incorporated on bone surfaces into the mineralized portion of bone. The long half-life of [226]Ra (1600 y) allows distribution throughout the mineral skeleton over life. The target cells for osteogenic sarcoma reside in marrow on endosteal surfaces at about 10 µm from the bone surface. At long times after exposure, target cells are beyond the range of alpha particles from radium not on bone surfaces.

The loss of radium from the body by excretion was determined to follow a relatively simple power function (Norris et al., 1955):

$$R = 0.54\ t^{-0.52} \tag{17}$$

where R = total body retention
t = time in days

Other models to fit the data were developed as more information became available, the most recent being that of Marshall et al. (1972). The entire body of radium data and the various models are shown in Fig. 25-1. It can be seen that the Norris function fits the observed data well except at very long times after exposure. A simplified form of the more complex later model of Marshall and associates (1972) which fits the human data over all observed times is

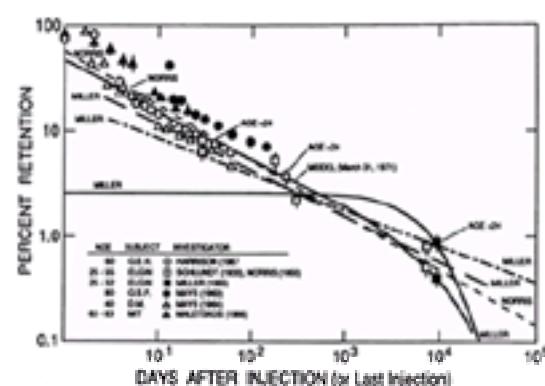
$$R = 0.8t^{-0.5}\ (0.5e^{-\lambda t} + 0.5e^{-4\lambda t}) \tag{18}$$


Figure 25-1. Whole-body radium retention in humans. Summary of all available data for adult humans. (From Marshall et al., 1972, with permission.)

where R = whole body retention
λ = rate of bone apposition or resorption = 0.0001 day^{-1}
t = time in days

For most purposes, the Norris formula is applicable. It can be seen from Fig. 25-1 for the Norris equation that even 1 year after exposure, only about 2 percent of the radium is retained in the body but that after 30 years, about 0.5 percent still remains. The risk of osteogenic bone cancer after radium exposure has been summarized in the National Academy of Sciences report BEIR IV (NAS, 1988).

Equations were proposed by Rowland and coworkers (1978) for the annual risk of sarcoma (including the natural risk), and expressed as a function of either radium intake or dose from [226,228]Ra. Risk per unit intake is

$$I = [0.7 \times 10^{-5} + (7 \times 10^{-8})\ D^2]\ \exp[-(1.1 \times 10^{-3})\ D] \tag{19}$$

where I = total bone sarcomas per person year at risk
D = total systemic intake of [226]Ra plus 2.5 times total systemic intake of [228]Ra, both in microcuries

Risk per unit dose is

$$I = [10^{-5} + (9.8 \times 10^{-6})D^2]\ \exp(-1.5 \times 10^{-2}\ D) \tag{20}$$

where I = total bone sarcomas per person year at risk

D = total mean skeletal dose in Gray from ^{226}Ra plus 1.5 times mean skeletal dose from ^{228}Ra

Raabe and associates (1980) modeled bone sarcoma risk in the human, dog, and mouse and determined that there is a practical threshold dose and dose rate (a dose low enough so that bone cancer will not appear within the human life span). The dose rate is 0.04 Gy per day or a total dose of 0.8 Gy to the skeleton. This practical threshold for bone cancer has useful implications in considering health effects from exposures to environmental radioactivity.

Radium Exposure (^{224}Ra)

In Europe, ^{224}Ra was used for more than 40 years in the treatment of tuberculosis and ankylosing spondylitis. The treatment of children was abandoned in the 1950s, but the ability to relieve debilitating pain from ankylosing spondylitis in adults has prolonged its use. ^{224}Ra is different from ^{226}Ra in that it has a short half-life (3.62 days) and the alpha dose is delivered completely while the radium is still on bone surfaces.

Spiess and Mays (1970) and Mays (1988) studied the health of 899 German patients given ^{224}Ra therapeutically. The calculated average mean skeletal dose was 30 Gy (range, 0.06 to 57.5 Gy) with injection time spans ranging from 1 to 45 months. There were two groups—juveniles and adults—and the bone sarcoma response was not significantly different for the two. There were 60 patients who developed bone sarcoma (Gossner 1999), 46 have been studied for histologic type. Further study of this group revealed other solid tumors with statistically significant excesses of male and female breast cancer, thyroid cancer and liver cancer (Nekolla et al., 1999).

In a second cohort, Wick and colleagues (1986 , 1999) studied 1432 adult patients treated for ankylosing spondylitis with an average skeletal dose of 0.65 Gy. This study was originally started by Otto Hug and Fritz Schales and has been continued since their deaths. Four patients in this group have developed osteogenic sarcoma, and one in the control group.

Spiess and Mays (1973) found that the observed effectiveness of the ^{224}Ra in their cohort in producing bone sarcomas increased if the time span of the injections was long. Injections were given in 1, 10, or 50 weekly fractions. They developed an empiric expression to estimate the added risk from this protracted injection schedule:

$$I = \{0.003 + 0.014\,[1 - \exp(0.09m)]\}D \tag{21}$$

where I = cumulative incidence of bone sarcomas after most tumors have appeared (25 years)
m = span of injections in months
D = average skeletal dose in Gy

Chemelevsky and coworkers (1986) analyzed the Spiess data and developed an equation for the total cumulative sarcoma risk from ^{224}Ra:

$$R = (0.0085D + 0.0017D^2)\exp(-0.025D) \tag{22}$$

where R = cumulative risk of bone sarcoma
D = average skeletal dose in Gy

These two equations for risk predict 5.7 and 5.8 bone sarcomas in the second series of (spondylitis) patients, with 2 actually observed.

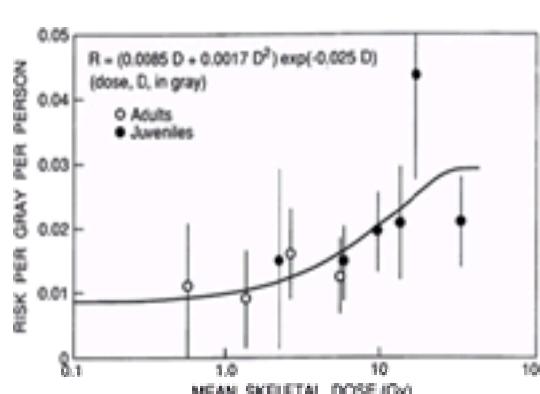
Chemelevsky and coworkers (1986) also showed that in the Spiess study, linearity (sarcoma response with dose) could be rejected. For example, equation 22 results in a lifetime risk of sarcoma of 0.02 Gy^{-1} at an average skeletal dose of 10 Gy but 0.01 Gy^{-1} at 1 Gy. Also, there was no difference in sarcoma response between juveniles and adults. These data are presented in Fig. 25-2. Again, no excess leukemia was found in either series of ^{224}Ra patients.


Figure 25-2. Lifetime risk per gray versus mean skeletal dose in ^{224}Ra exposed subjects. (From Chemelevsky et al., 1986, with permission.)

Atomic Bomb Survivors

On August 6, 1945, the U.S. military dropped an atomic bomb on the city of Hiroshima, Japan. Three days later a second bomb was dropped on Nagasaki which effectively ended World War II. The weapons were of two different types, the first being ^{235}U and the second a ^{239}Pu device.

Within 1 km of the explosions in both cities, a total of 64,000 people were killed by the blast and the thermal effects and as a result of the instantaneous gamma and neutron radiation released by the weapons. Others between 1 and 2 km from the hypocenter (the point on earth directly below the detonation point in air) received radiation doses up to several gray.

Within a few years it was decided to follow the health of the people in both cities over their lifetime to determine quantitatively the effects of external ionizing radiation. The study of prospective mortality of A-bomb survivors was initiated by the Atomic Bomb Casualty Commission (ABCC) in 1950 and is ongoing by the Radiation Effects Research Foundation (RERF). The main study, called the Life Span Study (LSS), included 92,228 people within 10,000 m of the hypocenter and 26,850 people who were not in either city at the time of bombing (ATB). The most recent reports of the RERF (1987) are follow-up of the cancer mortality of a subcohort (DS86 subcohort) of 75,991 persons over the periods 1950–1985, and 1950–1990 (Pierce and Preston 1993).

In 1978, questions arose that the original dose estimates for persons in the LSS might be somewhat in error and that an effort should be made to improve the dose estimates. This study was published in a United States–Japan joint reassessment of dose called DS86—Dosimetry System 1986 (RERF, 1987).

Dose estimation by reconstruction of the event is always problematic, but direct computation of dose to about 18,500 persons in the LSS with detailed shielding information is complete. The remaining DS86 dose values for 57,000 individuals without detailed shielding information are also incorporated into the mortality study by various estimation techniques. Of the 75,991 persons in the DS86 subcohort, 16,207 were within 2000 m of the hypocenter, and these are the individuals who received a substantial exposure.

Previous reports of cancer risk estimates were based on the air dose (gamma ray plus neutron tissue kerma in air) adjusted for shielding by structures or terrain. The 1987 and 1988 reports also include DS86 organ dose estimates, and these are about 80 percent of the shielded kerma (Shimizu et al., 1988).

The dose from fallout at Hiroshima and Nagasaki has not been included in the health effects studies. Fallout was found in certain restricted localities in Nagasaki and Hiroshima. The absorbed dose from gamma rays at Nagasaki for persons continuously in the fallout area from 1 h on ranged from 0.12 to 0.24 Gy. The absorbed

doses at Hiroshima ranged from 0.006 to 0.02 Gy. Because the region of fallout was quite limited, the total contribution of fallout to survivor dose was probably negligible in Hiroshima but may have been significant for a limited number of survivors in Nagasaki, where an exposure of one-fifth the maximum extends over some 1000 hectares. Estimates of internal dose from ingested ^{137}Cs yield about 0.0001 Gy integrated over 40 years (Harley, 1987; RERF, 1987).

Complete mortality data and the dose estimates are reported in RERF Technical Reports 5-88 (RERF, 1988) and were updated by Pierce and Preston (1993) and in UNSCEAR (2000). The projected lifetime cancer risks as of the follow-up through 1990 are reported in UNSCEAR (2000), and these data are summarized in Table 25-6.

Table 25-6 Observed and Expected Cases of Cancer in A-Bomb Survivors with DS86 Dose Estimate and Projections of Lifetime Cancer Incidence from Radiation for a Dose of 0.1 Sv

No statistically significant excess cancer of the gallbladder, bone, pancreas, uterus, or prostate or of malignant lymphoma has been seen in the LSS to date.

It is of interest to consider the effect of smoking, as it is the most important factor in assessing lung cancer risk. The analysis performed by Shimuzu and associates (1988) examined the interaction of smoking and radiation in detail. The results showed no interaction indicating that smoking and the atom bomb radiation act independently rather than multiplicatively in lung cancer induction.

It is also possible to model the risk over the full life if a projection model is assumed. RERF has preferred a constant relative risk model (radiation mortality is a constant fraction of the baseline age-specific mortality per gray) for this purpose. There is evidence in the atom bomb mortality and in several other studies discussed later (ankylosing spondylitis patients, uranium miners) that the constant relative risk model is not appropriate but that the risk coefficient decreases with time subsequent to exposure. In most cases this also means that the absolute excess cancer risk (risk above that expected) declines with time. This is a biologically plausible model suggesting the loss or repair of the damaged stem cell population.

The estimates of lifetime risk of cancer may increase somewhat with time, but given the present age of the population, the final values are unlikely to be significantly higher than the values in Table 25-6.

Tinea Capitis (Ringworm) Irradiation

During the period 1905–1960, x-ray epilation in the treatment of tinea capitis was performed regularly in children. The treatment was introduced by Sabouraud in 1904 and was standardized by Kienbock (1907) and Adamson (1909). Over the half century it was used, as many as 200,000 children worldwide may have been irradiated (Albert et al., 1986).

No follow-up studies of the long-term effects of irradiation were performed until Albert and Omran (1968) reported on 2200 children irradiated at the Skin and Cancer Unit of New York University Hospital during 1940–1959. Subsequent publications on this group have appeared at regular intervals (Shore et al., 1976, 1984, 1990).

Since the New York University (NYU) study, a follow-up of 11,000 children irradiated in Israel was performed (Ron and Modan, 1984; Ron et al. 1991).

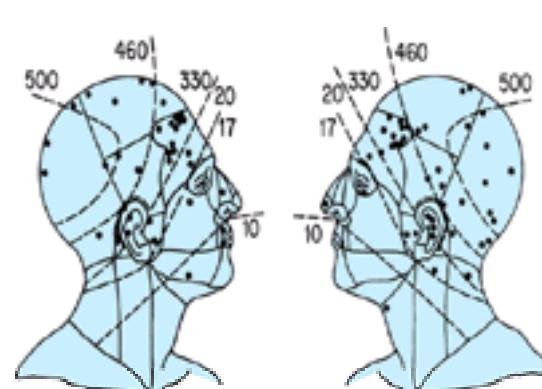
The mean age of children irradiated in both the New York and Israeli studies was between 7 and 8 years. Dose reconstruction in the NYU series was performed using a head phantom containing the skull of a 7-year-old child covered with tissue-equivalent material (Schulz and Albert, 1963; Harley et al., 1976, 1983). The doses to organs in the head and neck for a typical Adamson-Kienbock five-field treatment of the scalp are shown in Table 25-7, and the dose to the skin is shown in Fig. 25-3.


Figure 25-3. X-ray dose in rads for the Adamson-Kienbock five-field tinea capitis treatment and locations of basal cell lesions. (From Shore et al., 1984, with permission.)

ORGAN	AVERAGE DOSE AT 25 cm TREATMENT DISTANCE, rad
Scalp	220–540
Brain	140
Eye	16
Internal ear	71
Cranial marrow	385
Pituitary	49
Parotid gland	39
Thyroid	6
Skin (eyelid)	16
Skin (nose)	11
Skin (midneck)	9

Table 25-7 Average Dose to Organs in the Head and Neck from Measurements Performed with a Phantom for a Child's Head

In the NYU series there were 2 thyroid cancers with 1.4 expected cases. In the Israeli series there were 43 thyroid cancers with 10.7 expected cases. In the NYU series there are 83 skin lesions, predominantly basal cell carcinoma, with 24 expected cases, in 41 persons. Fairness of skin is an important factor in the appearance of skin cancer (Shore et al., 1984, 1990). Skin cancer was found only in whites even though 25 percent of the study population consisted of blacks. This and the fact that there appears to be a much lower dose response on the hair-covered scalp than on the face and neck (Harley et al., 1983) suggest that the promotional effects of UV radiation play an important role in skin cancer.

The dose estimate for the thyroid in the Israeli study is 0.09 Gy compared with 0.06 Gy in the NYU study.

A risk projection model was used to estimate the lifetime risk of basal cell carcinoma (BCC) for facial skin and for the hair-covered scalp after x-ray epilation in whites. The model used was a cumulative hazard plot which assumes that the BCC appearance rate in the exposed population remains constant over time (Harley et al., 1983). The result of this risk projection for BCC is shown in Table 25-8.

	TOTAL INCIDENCE, RISK Gy^{-1}	MORTALITY, RISK Gy^{-1}
Skin malignancies (NYU study)		
BCC (facial skin)	0.32	
BCC (hair-covered scalp)	0.04	
Thyroid malignancies (Israeli study)		
Male	0.04	0.001
Female	0.04	0.004

Table 25-8 Estimated Lifetime Risk Estimates for Basal Cell Carcinoma (BCC) and Thyroid Cancer after X-Ray Irradiation for Tinea Capitis

The small numbers of tumors other than skin cancers in the NYU study make it of dubious value in estimating the lifetime risk per Gy although an excess is appearing. The tinea capitis studies are prospective, and sound numerical values are forthcoming as these populations age. These are particularly important studies because children were the exposed group and because only partial body irradiation was involved. The temporal pattern of appearance of these tumors is also important. The dose was delivered over a short time interval (minutes at NYU and 5 days in Israel), and lifetime patterns will be indicative of the underlying carcinogenic mechanisms.

Skin and thyroid cancers are of importance in documenting health effects from ionizing radiation. However, both types of cancer are rarely fatal. NCRP (1985) reported that about 10 percent of thyroid cancer is lethal. It is estimated that the fatality rate of skin cancer is 1 percent (NCRP, 1990). The lifetime risk per gray derived by NCRP for total thyroid cancer incidence (0.003 for females and 0.0014 for males for external x-ray or gamma radiation for persons under 18 years of age) is about a factor of 10 lower than that reported by Ron and Modan (1984, 1991) in tinea capitis irradiations. However, the tinea irradiations were given to children with a mean age of about 7 years, also in the Israeli study there is apparently an increased sensitivity resulting from ethnicity.

The effect of ethnicity and sex is also suggested by NCRP (1985) for thyroid cancer. The incidence rates of spontaneous thyroid cancer for persons of Jewish origin in Europe and North America are three to four times that for other racial groups. There is an obvious susceptibility of women for thyroid cancer and adenomas in both the NYU and Israeli tinea capitis studies.

Chernobyl and Radioactive Iodine (^{131}I)–Induced Thyroid Cancer

The Chernobyl accident (April 26, 1986) was the result of efforts to conduct a test on the electrical control system, which allows power to be provided in the event of a station blackout. The details of the accident have been published in a report of the International Atomic Energy Agency (IAEA 1992), and UNSCEAR (2000). Basically, there was a rapid increase in the reactor power. Part of the fuel in the pressurized water reactor was vaporized, resulting in an explosion that blew the reactor core apart and destroyed much of the containment building. The estimates of the significant radionuclides for health effects released during the accident are 1800 PBq (4.9 × 10^7 Ci) ^{131}I and 85 PBq (2.3 × 10^6 Ci) ^{137}Cs, and 10 PBq (2.7 × 10^5 Ci) ^{90}Sr (UNSCEAR, 2000).

The accident caused the deaths within days or weeks of 30 power plant employees and firemen (including 28 deaths that were due to radiation exposure). During 1986, 220,000 people were evacuated from areas surrounding the reactor, and, after 1986, of about 250,000 people were relocated from what were at that time three constituent republics of the Soviet Union: Belarus, the Russian Federation, and Ukraine. Large areas in these three republics were contaminated, and deposition of fission product radionuclides was measurable in all countries of the northern hemisphere. In addition, about 240,000 workers, termed "liquidators," were mobilized in 1986 and 1987 to take part in major mitigation activities at the reactor and within the 30-km zone surrounding the reactor. Residual mitigation activities continued until 1990. In all, about 600,000 persons received the special status of "liquidator."

The radiation exposures resulting from the Chernobyl accident were due initially to ^{131}I and short-lived radionuclides and subsequently to radiocesium (^{134}Cs and ^{137}Cs) from both external exposure and the consumption of foods contaminated with these radionuclides. UNSCEAR (1988) estimated that, outside the regions of Belarus, the Russian Federation, and Ukraine, thyroid doses averaged over large portions of European countries were 25 mGy for 1-year-old infants. However, the dose distribution was very heterogeneous, especially in countries near the reactor site. For example, in Poland, although the countrywide population-weighted average thyroid dose was estimated to be 8 mGy, the mean thyroid doses for the populations of particular districts ranged from 0.2 to 64 mGy. Individual dose values for about 5 percent of the children were 200 mGy. UNSCEAR (1988) estimates that effective dose averaged over large portions of European countries were 1 mSv or less in the first year after the accident and approximately two to five times the first-year dose over a full lifetime.

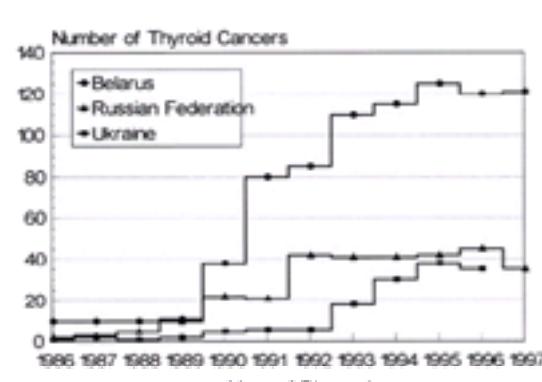
To date there is a significant increase in the number of thyroid cancers in the three territories. Approximately 1600 thyroid cancers have been identified in children under the age of 17 at the time of the accident. The expected number of thyroid cancer cases is not known, but is evidently a small fraction of those observed. No solid tumors other than thyroid cancer have been identified resulting from the accident. Figure 25-4 shows the sequential increase in the number of thyroid cancers in children under the age of 14 at the time of the accident. It is well established that release of ^{131}I presents the major health effect in a nuclear accident. Many countries prepare for such accidents and have ready a large supply of potassium iodide (KI), which effectively blocks the thyroid uptake of radioactive iodine. Had this been available in time, it is questionable whether the large number of tumors seen would have occurred.


Figure 25-4. Thyroid cancer in children under 14 at the time of the Chernobyl accident. (From UNSCEAR, 2000.)

Medical Administration of ^{131}I Iodine-131 is given medically in three ways. Very large quantities, 3.7×10^9 Bq (100 mCi) or more are administered to ablate the thyroid in thyroid cancer, lesser quantities (about 10 mCi or 3.7×10^8 Bq) are given for hyperthyroidism, and the lowest quantity given (0.1 mCi or 3.7×10^6) is for diagnostic purposes (UNSCEAR, 1993). Individuals have also been exposed to ^{131}I as a result of nuclear weapons testing. Very few thyroid cancers have been found subsequent to these exposures, with the exception of the 243 Marshall Island inhabitants who received a large dose from a mixture of radionuclides (^{131}I, ^{132}I, ^{133}I, ^{134}I, and ^{135}I), tellurium, and gamma-ray radiation from the 1954 Bravo thermonuclear test (Conard, 1984) in the Pacific. The mean thyroid dose was estimated as 3 to 52 Gy in children and 1.6 to 12 Gy in adults. Over a 32-year follow-up period, 7 of 130 women and 2 of 113 men developed thyroid cancer.

Attempts have been made to relate external gamma-ray radiation and ^{131}I exposure. The NCRP (NCRP, 1985) estimated from human data that the effectiveness ratio of ^{131}I/gamma-ray radiation is between 0.1 and 1.0. In a more recent review of the human data, Shore (1992) found 8.3 observed excess cancers derived from all ^{131}I studies and 37 cases based on risk estimates from external exposure. The ratio 8.3/37 yields an estimate for the effectiveness ratio of 0.22. The protracted dose to the thyroid during the decay of ^{131}I may explain the difference; however, the nonuniform distribution of ^{131}I in the thyroid also may be a factor (Sinclair et al., 1956).

It is evident that ^{131}I can expose large populations after nuclear weapons testing or nuclear accidents. Generally, it is the ingestion pathway that is most significant. Iodine is ingested quickly either from surface deposition on edible plants or from pasture grass to the cow, to milk, and to the thyroid. A large body of data exists on the transfer coefficients, P_{24} (intake to the body per unit deposition), P_{45} (effective dose per unit intake), and P_{25} ($P_{25} = P_{24} \times P_{45}$) = effective dose per unit deposition). UNSCEAR (1993) reported the transfer coefficients for ^{131}I to be

$P_{24} = 0.07$ Bq per Bq m^{-2}
$P_{45} = 61$ nSv per Bq intake (effective dose for the thyroid)
$P_{25} = P_{24} \times P_{45} = 4.2$ nSv per Bq m^{-2} (effective dose for the thyroid)

Ankylosing Spondylitis

About 14,000 persons, mostly men, were treated with x-rays for ankylosing spondylitis at 87 radiotherapy centers in Great Britain and Northern Ireland between 1935 and 1954. Court Brown and Doll (1957) were the first to report that these patients had a leukemia risk substantially in excess of that for the general population. Subsequent publications have developed the time pattern of appearance not only of leukemia but also of solid tumors (Court Brown and Doll, 1959, 1965; Smith and Doll, 1978, 1982; Smith, 1984; Darby et al., 1985, 1987; Weiss et al., 1994).

A group was selected consisting of 11,776 men and 2335 women all of whom had been treated with x-rays either once or twice. About half the total group received a second x-ray treatment or treatment with thorium. The reports on the ankylosing spondylitis patients attempt to consider health effects from only the first x-ray treatment. For this reason, an individual receiving a second treatment is included in their follow-up only until 18 months after the second course (a short enough time so that any malignancies in this interval cannot be ascribed to the second x-ray treatment).

The appearance of excess leukemia is now well documented, and solid tumors are also apparent in the population. The part of the body in the direct x-ray beam (spine) received the highest dose, but it is thought that other sites received substantial radiation from scatter or from the beam itself.

The importance of this study lies in the health effects of partial body exposure and in the temporal pattern of appearance of solid tumors in irradiated adults. Smith and Doll (1978, 1982), Darby et al. (1985, 1987), and Weiss et al. (1994, 1995), in the most recent follow-up publications concerning these patients, have shown that the excess risk for solid tumors diminishes with time since exposure, with maximum appearance 5 to 20 years after exposure. This has significant implications for risk projection modeling. Many projection models assume a constant rate of appearance either as an absolute number of tumors per person per unit exposure (constant absolute risk) or as a fraction of the baseline age-specific cancer mortality rate (constant relative risk). The emerging pattern is that constant risk models, either absolute or relative, are not correct for certain cancers, such as lung cancer. Thirty-five years after the first treatment, excess lung cancer had completely disappeared.

The dosimetry was redone in 1988 (Lewis et al., 1988), and although better estimates of dose are now available, it is still the dose that is most uncertain for the cohort. No details about the x-ray machines used to deliver the exposures, such as output, kilovoltage, and half-value layer, are reported.

The excess cancers and the estimate of lifetime cancer risk at three sites in the ankylosing spondylitis cohort are shown in Table 25-9. For the purpose of calculating lifetime risks as of the time of follow-up, the number of persons used here as the individuals at risk is the number actually receiving only one x-ray treatment (6158). This assumes that those followed for 18 months after the second treatment do not contribute significantly to the malignancies.

Table 25-9 Excess Cancer in 6158 Ankylosing Spondylitis Patients Given a Single X-Ray Treatment as of the Last Follow-up

The relatively low risk for leukemia (compared with atom bomb survivors) has been suggested to be due to cell sterilization at the high dose delivered. It is also possible that the low risk is due to partial irradiation of the skeletal red marrow. The volume of bone marrow irradiated in the spine, rib, and pelvis is much less than 50 percent of that in whole-body irradiation.

The deaths resulting from causes other than neoplasms in the total cohort are about 30 percent higher than expected. This higher total mortality is of significance in risk modeling as the premature deaths resulting from competing causes decrease the observed fractional cancer mortality. Thus, the lifetime risk in this population probably underestimates the risk when projecting the effects of exposure in a healthy population.

Uranium Miners

Radon is ubiquitous on earth. It is found outdoors and in all dwellings as a result of the decay of the parent ^{226}Ra, which is present in all of earth's minerals.

Although the risk of developing lung cancer from radon exposure among underground miners is firmly documented and quantitative risk estimates are available, the current interest lies in whether this risk carries over into environmental situations. Radon levels in homes that are comparable to those in mines surely confer risks to the residents. The question remains: Can the risks in mines for exposures at higher concentrations over short time periods be used to model risks at lower environmental levels over a lifetime?

Radon Exposure in Underground Mines There are 11 large follow-up studies of underground miners exposed to high concentrations of radon and radon decay products, and the documentation of excess lung cancer is convincing (NCRP, 1984; NAS, 1988 NIH, 1994; NAS, 1998). The carcinogen in the case of radon is

actually the alpha-emitting short-lived decay products of radon, ^{218}Po, and ^{214}Po. The decay scheme for the entire uranium series, including radon and the daughter species, is shown in Fig. 25-5. The decay products or daughter products are solids and are deposited on the bronchial airways during inhalation and exhalation according to the laws of diffusion. As the airway lining (bronchial epithelium) is only 40 μm thick, the alpha particles emitted are able to reach and transfer a significant amount of energy to all the cells implicated in lung cancer induction. Although the daughters are the carcinogen, the term *radon* is here used interchangeably for *radon decay products,* because without the parent radon, the daughters could not exist longer than a few hours. The measurements in mines were usually of the daughter species rather than radon, and the term *working level* (WL) was adopted for occupational exposure. It indicated the total potential energy content in 1 L of air for complete decay of the short-lived daughters.* The exposure attributed to miners was developed in working-level months (WLMs), which is the numerical value of WL times the time exposed in multiples of a working month of 170 h (Holaday et al., 1957).

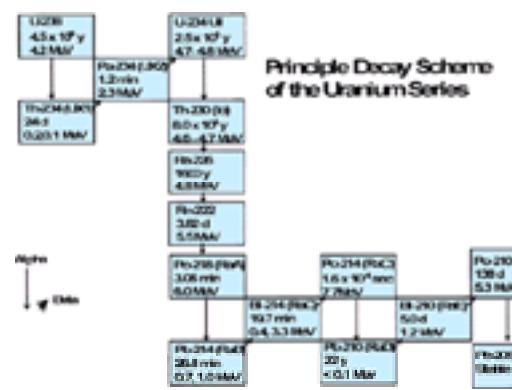
$$\text{WLM} = \text{WL (hours exposed / 170).}$$


Figure 25-5. Uranium-238 decay series. (From NCRP, 1987.)

Estimating Lung Cancer Risk from Underground Miner Epidemiology The follow-up studies from 11 large underground mining cohorts in Australia, Canada, Czechoslovakia, France, Sweden, and the United States have all produced data that show that the excess lung cancer risk from exposure to radon is about 1 to 3 per 10,000 persons per WLM exposure (Radford and Renard, 1984; Hornung and Meinhardt, 1987; Sevc et al., 1988; Muller et al., 1989; Howe et al., 1986, 1987; Tirmarche et al., 1993; Woodward et al., 1991; NCRP 1984, NIH, 1994, NAS 1998). Expressed another way, radon exposure increases the normal age-specific lung cancer risk by about 0.5 percent for each WLM exposure. This way of expressing risk leads to the concept that many epidemiologists prefer—that the lung cancer risk is proportional to the normal baseline risk. This means, for example, that the lifetime excess lung cancer risk from radon is different for smokers and nonsmokers (NAS, 1988; NIH, 1994).

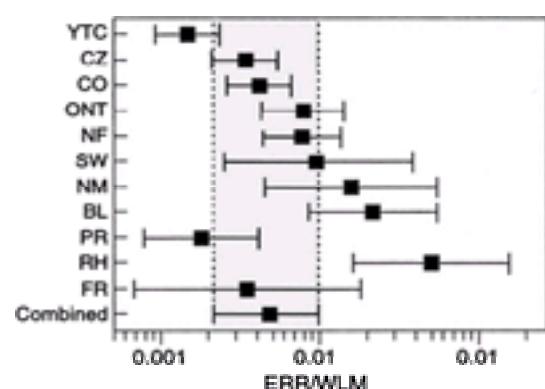
The actual data from the underground studies are not clear-cut with regard to the effect of smoking, and it is apparent from more recent analyses that radon exposure does not simply multiply the baseline risks of the population by a constant factor. This is considered in the discussion of risk, earlier in this chapter. The excess lung cancer risk in each of the exposure cohorts for the 11 major mining populations as of the date of the last published follow-up is summarized in Fig. 25-6. It can be seen in the figure that the range of risks for the same exposure varies by about a factor of 10 among the different studies. The differences are likely accounted for by errors in measuring and estimating total exposure. However, the Czech mine atmosphere contained arsenic as well as radon, and the arsenic contributed to the excess lung cancers observed. A maximum value of 50 percent lung cancer risk is the highest value ever observed in a mining population and was reported in mines in Saxony at the turn of the century (Muller, 1989). These mines are thought to have had about 100,000 Bq m^{-3} of radon. It is noteworthy that concentrations this high have been reported in a few homes in the United States. In Fig. 25-6, the lowest (well-documented) exposures were in the Ontario mines, and a mean exposure of 29 WLM has given an excess lung cancer risk of about 1 percent.


Figure 25-6. Excess relative risk (ERR) of lung cancer per working-level month (WLM) for each of the 11 cohorts studied.

RRs plotted per WLM exposure. YTC, Yunnan China Tin miners; CZ, Chechoslovakian uranium miners; CO, Colorado uranium miners; ONT, Ontario uranium miners; NF, Newfoundland fluorspar miners; SW, Swedish iron miners; NM, New Mexico uranium miners; BL, Beaverlodge, Canada, uranium miners; PR, Port Radium, Canada, uranium miners; RH, Radium Hill, Australia, uranium miners; FR, French uranium miners. (From NIH, 1994.)

To date, the most comprehensive epidemiologic analysis of underground miners exposed to high concentrations of ^{222}Rn is a joint analysis of 11 underground mining studies conducted by the National Cancer Institute (NIH, 1994), and updated by NAS (1998). The study encompasses the Chinese, Czechoslovakian, Colorado, Ontario, Newfoundland, Swedish, New Mexico, Beaverlodge, Port Radium, Radium Hill, and French mining data. Domestic studies do not prove useful in obtaining risk estimates for radon. This is because the effects of ^{222}Rn in the environment are obscured by typical low exposure rates and the large numbers of lung cancers caused by smoking. In mines, the average concentration can be thousands of Bq m^{-3} compared with less than 100 Bq m^{-3} in a typical domestic environment. The occupational exposure in mines is relatively short compared with that over a full life in homes. Although the time exposed in mines is shorter, the cumulative exposure in mines is generally many times that in homes. The joint analysis of the 11 cohorts (NIH, 1994) focused on 10 variables:

1. The estimation of excess relative risk per working level month (ERR/WLM) and the form of the exposure response
2. The variation of ERR/WLM with attained age
3. The variation of ERR/WLM with duration of exposure, considering total exposure as well as exposure rate
4. The variation of ERR/WLM with age at first exposure
5. The variation of ERR/WLM as a function of time after exposure ceased
6. The evaluation of an optimal exposure lag interval, that is, the interval before lung cancer death during which ^{222}Rn exposure has no effect
7. The consistency among the 11 cohorts
8. The joint effect of smoking and ^{222}Rn exposure
9. The role of exposure to other airborne contaminants in mines
10. The direct modeling of the relative risk of lung cancer with duration and rate of exposure

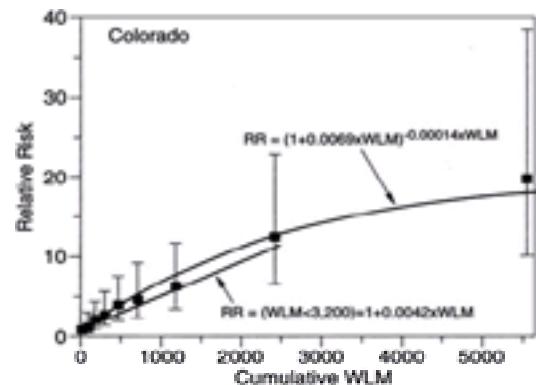
The relative risk of lung cancer for the Colorado uranium miners is shown in Fig. 25-7 and that for all 11 cohorts—showing only the data for exposures below 400 WLM—is shown in Fig. 25-8.


Figure 25-7. Excess relative risk per unit exposure for the Colorado mining cohort. (From NIH, 1994.)
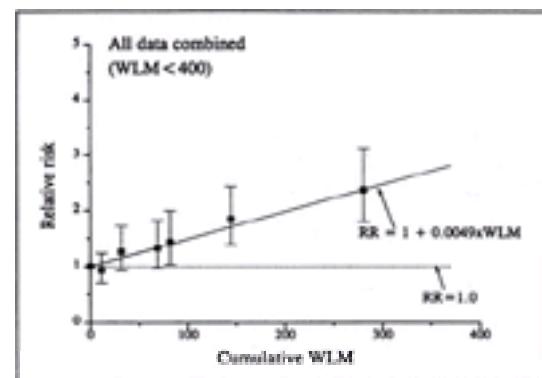

Figure 25-8. Relative risk (RR) of lung cancer by cumulative working-level month (WLM) and fitted linear excess RR model for each cohort and for all data combined (WLM < 400).

The pooled cohorts included 2620 lung cancer deaths among 60,570 exposed miners, accumulating 1.2 million person-years of observation. The excess relative risk of lung cancer is seen in Fig. 25-7 to be linearly related to the cumulative radon decay product exposure in units of WLM. The exception is at the highest exposures, where a clear reduction in excess relative risk is evident. This is often noted as an *inverse dose rate effect*. Confusion exists concerning the inverse dose rate effect in that the relative risk is not *higher at lower dose rates* but is *lower at higher dose rates,* in agreement with cell killing and removal of damaged cells from the pool of cells that are potential sites of malignant transformation. This effect is seen in all studies of radiation damage at high dose.

Data on tobacco use were available in six of the cohorts. The ERR/WLM was not related to age at first exposure in this analysis. The joint effect of smoking and ^{222}Rn exposure did not show a clear pattern except that the risk was consistent with a relationship that was intermediate between additive and multiplicative.

Lung (Bronchial) Dose from Radon Exposure When radon gas decays to its solid decay products, some 8 to 15 percent of the ^{218}Po atoms do not attach to the normal aerosol particles. This ultrafine species (unattached fraction) is deposited with 100 percent efficiency on the upper bronchial airways. In mines the unattached fraction is low (4 to 5 percent) because of the normal aerosol loading. The rest of the decay products attach to the ambient aerosol of about 100-nm average diameter (George and Breslin, 1980) and only a few percent of this aerosol is deposited on these airways. Measurements in mines have mostly involved the short-lived radon daughters, as they are the easiest to measure rapidly. The alpha dose from radon gas itself is very low in comparison with that from the daughters, as the daughters deposit and accumulate on the airway surfaces. The upper airways of the bronchial tree are the region where almost all the lung cancers appear. This is true in general, not only for miners exposed to radon daughters but also for smokers.

The alpha dose from radon daughters therefore must be calculated in these airways, not in the pulmonary or gas-exchange regions. Although the dose to the pulmonary region should not be neglected, it is about 15 percent of that to the airways (Saccomanno et al., 1995). Several calculations regarding the absorbed alpha dose exist for radon daughters (NCRP, 1984; ICRP, 1987; Harley, 1987, 1989; Harley et al., 1996, NRC, 1991). The authors make different assumptions about the atmospheric and biological parameters that go into the dose calculation, and this can cause discrepancies among the models. The most significant variables are the particle size of the ambient aerosol, the assumed breathing rate, and the target cells considered.

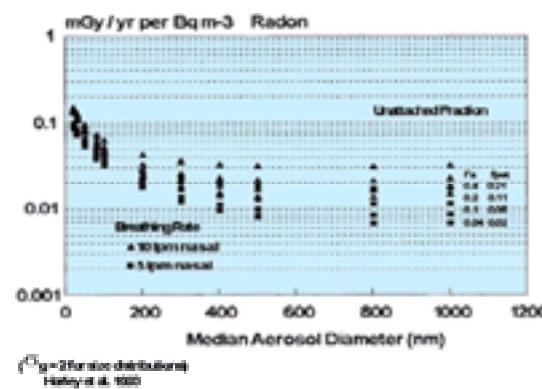
Very small particles deposit more efficiently in the airways. Therefore if small particles, such as those from open burning flame (Tu and Knutson, 1988), contribute to the atmosphere, the dose delivered to the bronchial epithelium can be higher per unit WLM exposure than is the dose predicted from an average particle size. Conversely, a hygroscopic particle can increase in size in the humid environment of the bronchial airways, and deposition will be diminished. The particle size of the aerosol in mines is somewhat larger than that for environmental conditions (200 to perhaps 600 nm versus 100 nm) (George et al., 1975). Figure 25-9 shows the alpha dose per unit exposure as it is related to the variables (particle size, unattached fraction, breathing rate) known to affect dose.


Figure 25-9. Radon decay product bronchial dose as a function of inhaled aerosol diameter, breathing rate, and unattached fraction. (Breathing rates from Ruzer et al., 1995; target cells from Robbins and Meyers, 1995, with permission.)

As carcinogenesis is related to absorbed alpha dose, Fig. 25-9 shows that particle size is an important determinant of risk. The average dose per unit exposure in WLM for miners in Fig. 25-9 is about the same as that for average environmental conditions, assuming 100 nm aerosol in homes and 200 to 600 nm aerosol in mines.

Radon can deliver a greater or lesser carcinogenic potential by about a factor of 2 over the range of realistic indoor conditions (average particle size ranging from 80 to 300 nm). The allowable effective dose for continuous exposure of the population in the United States is 1 mSv/year (100 mrem/year) (NCRP, 1993). This limit would be delivered by exposure to 10 Bq m^{-3} of radon, or one-quarter the actual average measured indoor concentration in most countries where measurements have been made. Thus, the guidelines for exposure to radon cannot be set in the usual way from dosimetric considerations.

LIFETIME ENVIRONMENTAL LUNG CANCER RISK PROJECTIONS FOR RADON EXPOSURE

There are at present six sets of models based on the underground miner epidemiology that provide risk projection calculations for exposure to radon daughters in the

home. The following sections describe each in detail.

National Council on Radiation Protection and Measurements

In 1984, the NRCP on Protection and Measurements (NCRP, 1984) developed a model to project the risk derived from miner studies to whole-life risk in the environment. It is a modified absolute risk model that reduces the risk subsequent to exposure with a half-life of 20 years. Risk is not accumulated until after age 40, the time when lung cancer normally appears in the population. There is no indication that early exposure produces any significant shift to younger ages, even for young miners exposed at significantly higher concentrations. This model was the first to incorporate a time since exposure reduction in risk.

National Academy of Sciences

The National Academy of Sciences report in 1988 (BEIR IV) developed a model based on examination of the raw data from five mining cohorts (NAS, 1988). The data indicated that the highest risk appears from 5 to 15 years after exposure. After 15 years, the risk is one-half that of the 5- to 15-year risk (per unit exposure), and this risk was assumed to persist to the end of life. Again, no significant risk appears before 40, the usual age for the appearance of lung cancer. The NAS model also included a correction for attained age (at age 65, the risk is 0.4 of that for ages 55 to 64). The BEIR IV committee assumed a relative risk model (risk is proportional to the normal age-specific lung cancer risk per unit radon exposure), but with risk dependent on time from exposure. This was the first modified relative risk model. This means that the risk for smokers and nonsmokers differs because of their different baseline lung cancer values. Although the miners' epidemiology did not support this strictly multiplicative relationship, the NAS chose the relative risk model as a conservative one. Its analysis supported the risk reduction subsequent to exposure by using a two-step risk reduction window.

NAS 1998 (BEIR VI) expanded on the models developed in NAS (1988) using 11 underground mining cohorts rather than 4. The models for the 11 cohorts were developed first by NIH (1994), see below, and updated for the NAS report.

International Commission on Radiation Protection

The IRCP (ICRP, 1987) developed two risk projection models: one was based on a constant relative risk and the other was a constant absolute risk model. Although neither risk model is correct because of the temporal reduction pattern of lung cancer subsequent to the cessation of exposure, the numerical values obtained for the lifetime risk of lung cancer from radon exposure are not significantly different from those in other models. Later follow-up of the Czechoslovakian underground uranium miners presented by Kunz and Sevc (1988) indicates that the excess lung cancer risk may actually be reduced to zero 35 years after exposure. If this factor were included in the NAS model (zero risk after 35 years), it would reduce those values by about a factor of 2. The risk values obtained from the various models are shown in Table 25-10. In 1993, ICRP simply adopted a lifetime lung cancer fatality coefficient of 3×10^{-4} per WLM.

Table 25-10 Lung Cancer Risk for Continuous Whole-life Exposure to 4 pCi/L (150 Bq m^{-3} or 0.58 WLM per year at Indoor Conditions) as Predicted by Various Models of Domestic Exposure*

NIH Joint Analysis of 11 Underground Mining Cohorts

The pooled analysis from the 11 underground mining cohorts was used to develop two models for full-life risk projection (NIH, 1994). The models are similar to the model used by the NAS (1988), utilizing time since exposure reduction and reduction with attained age. Three time windows for reduction of risk with time since exposure are used instead of two. Also, an additional parameter is incorporated; one model decreases the risk with increasing exposure rate, and the other decreases the risk with decreasing exposure duration. The lifetime domestic risk for lifetime exposure to unit concentration was not reported. However, the ratio of the relative risk of lung cancer for the BEIR IV and joint analysis model was given as 0.9 for continuous exposure to 4 pCil^{-1} (1 WLM per year) for the model incorporating exposure duration as a parameter. The joint analysis estimated that there are 15,000 lung cancer deaths in the United States attributable to ^{222}Rn: 10,000 in smokers and 5000 in those who have never smoked.

BEIR VI (NAS 1998) updated these two models and increased the calculated risk in the United States to 15,400 or 21,800 per year for ever smokers and never smokers for the two model values. The BEIR VI best annual estimate of deaths for ever smokers is stated to be 11,000 per year with 2100 or 2900 calculated deaths for never smokers, depending upon the model chosen.

ENVIRONMENTAL EPIDEMIOLOGY

The Environmental Studies

There are at least 24 published studies that attempt to define or detect the effect of radon exposure in the environment. Most are summarized by Borak and Johnson (1988), Neuberger (1989, 1992), and Samet and associates (1991). A study in the United States was performed in 1989 by the New Jersey Department of Health (NJDOH) (Schoenberg and Klotz, 1989; Schoenberg et al., 1990). This is a case-control study of women, 433 lung cancer cases and 402 controls with yearlong measurements of radon in the homes where the individuals lived for 10 or more years. This study devoted considerable effort to quality control concerning the exposure measurements. The results of this study are slightly positive, suggesting an association of radon and lung cancer even at concentrations of 80 Bq m^{-3}, but the results are not statistically significant. A case-control study of 538 nonsmoking women (1183 controls) in Missouri with an average exposure of 70 Bq m^{23} also showed no statistically significant increase in lung cancer (Alavanja et al., 1994).

The largest case-control study to date concerning the effects of residential ^{222}Rn exposure was conducted nationwide in 109 municipalities in Sweden. It included all subjects 35 to 74 years old who had lived in one of the 109 municipalities at some time between January 1980 and December 31, 1984, and who had been living in Sweden on January 1, 1947. Fifty-six of the municipalities were known to have elevated ^{222}Rn concentrations on the basis of earlier measurements.

Thus, an attempt was made to study a large group of persons living in a known area of greater than average ^{222}Rn and to estimate their exposure over a large fraction of life (34 years). The primary aim of the study was to narrow the uncertainty in the estimation of lung cancer risk.

The environmental epidemiologic studies conducted before this study suffered from the small numbers of persons observed and relatively low ^{222}Rn exposures. For this reason, although the risk in underground miners was seen clearly, the outcome regarding the lung cancer risk from residential exposure has been ambiguous. All the existing domestic studies, including the measurement protocols, have been reviewed (Neuberger, 1992, 1994; Samet, 1989; Samet et al., 1991, 1989; Lubin et al., 1990).

Pershagen and coworkers (1994) included 586 women and 774 men with lung cancer diagnosed between 1980 and 1984. For a comparison control population, 1380

women and 1467 men were studied.

The ^{222}Rn concentration in 8992 homes was measured for 3 months during the heating season. The geometric and arithmetic mean concentrations were 1.6 and 2.9 pCi L[21] (60 and 106 Bq m^{-3}). The cumulative exposure since 1947 was estimated for each subject by the addition of the products of concentration by the length of time the subject lived in each residence.

The data were reported in terms of the relative risk (RR) of lung cancer (ratio of observed to expected lung cancer) normalized to a relative risk of 1.0 for persons who never smoked and who had radon exposure below 50 Bq m^{-3}. The excess risk due to smoking could be seen easily. Smokers smoking less than or more than 10 cigarettes per day with a radon concentration of << 50 Bq m^{-3} had RR of 6.2 (with a confidence interval from 4.2 to 9.2) and 12.6 (CI from 8.7 to 18.4), respectively.

The only statistically significant lung cancer excess resulting from ^{222}Rn was seen in those who smoked fewer than 10 cigarettes per day and had a time-weighted mean ^{222}Rn concentration >400 Bq m^{-3}. Their relative risk was 25.1 (CI 7.7 to 82.4). For those smoking more than 10 cigarettes per day, the relative risk compared with those who had never smoked and had ^{222}Rn concentrations <50 Bq m^{-3} was 32.5 (CI 10.3 to 23.7). Although this relative risk appears higher than that for those smoking <10 cigarettes per day, the result is not statistically signficant. If the effect of ^{222}Rn alone is examined by comparing the risk only among smokers, that is, those with <50 Bq m^{-3} against smokers having >400 Bq m^{-3}, the relative risk due to ^{222}Rn alone is 3.7 (CI 1.1 to 11.7) for those smoking less than 10 cigarettes per day and 2.5 (CI 0.8 to 7.9) for those smoking more than 10 cigarettes per day (Pershagen et al., 1994). Because the confidence interval includes 1.0, it cannot be stated with statistical certainty that there was increased lung cancer caused by ^{222}Rn exposure although the point estimate RR = 2.5 suggests at least an upper bound of risk.

The analysis was done for the combined group of men and women (Pershagen et al., 1994). There were no details given concerning lung cancer and sex difference. However, the preliminary report (Pershagen et al., 1994) suggested that women may indeed have had less lung cancer than men for the same exposure conditions. Also of interest in the study of Pershagen and associates (1994) was the relative risk of lung cancer by histological type. In the >400 Bq m^{-3} group, only small cell carcinoma and adenocarcinoma had a statistically significant increased risk.

The pattern emerging from the domestic studies indicates that the lung cancer risk from ^{222}Rn exposure is difficult to determine with accuracy or precision. This is mostly due to the high background lung cancer mortality caused by smoking.

Among the 24 published domestic studies, 13 are ecologic and 11 are case-control (Neuberger 1989). Ecologic studies depend on relating the disease response of a population to some measure of a suspected causative agent. There usually are not enough data on all the variables involved in the disease to infer any reliable associations. Ecologic studies are the weakest type of epidemiologic exploration. Unless a biological marker for radon-induced lung cancer is found, it is unlikely that environmental epidemiology will be effective in assessing risk. The effects of radon in the environment are subtle compared with the overwhelming lung cancer mortality that results from smoking.

Meta-analysis of Environmental Epidemiology

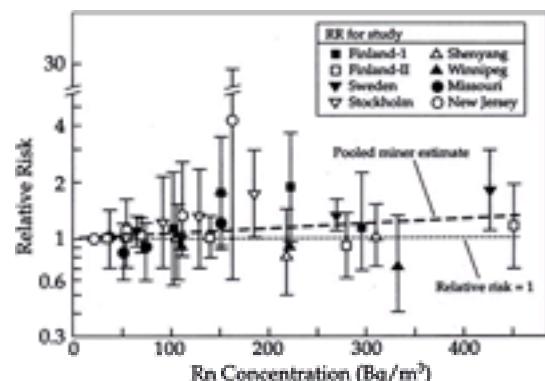
In an attempt to combine the largest domestic studies to determine whether any risk from radon exposure in the home was apparent, Lubin and Boice (1997) performed a meta-analysis of 8 domestic case control studies. A meta-analysis combines the published information from several studies into one study without actually having the raw data available. The results are shown in Fig. 25-10. The data showed that essentially no study found statistically significant cancer deaths due to radon, but the authors state that the combined trend in the relative risk with increasing exposure was statistically significant, with an estimated RR of 1.14 (95 percent CI = 1.0 to 1.3) at an exposure of 150 Bq m^{-3} (4 pCiL^{-1}).


Figure 25-10. Meta-analysis of eight domestic radon case-control studies. sg = 2 for size distributions. (From Harley et al., 1993, with permission.)

What Is Known about Radon Exposure in the Home

Four concepts have emerged from the radon research so far:

1. The mining epidemiology indicates that short exposure to high levels of radon and daughters produces a clear excess of lung cancer.
2. Particle size can change the actual dose delivered by radon to bronchial tissue, with small particles giving a substantially higher dose per unit exposure. The use of open flames, electric motors, and the like indoors produces a higher dose per unit exposure.
3. Smokers are at higher risk from radon per unit exposure than are nonsmokers. The relative risk for nonsmokers is about three times that for smokers, but their age-specific lung cancer mortality is about ten times lower than that for smokers. Thus, the overall lifetime lung cancer risk is three times higher for smokers.
4. Urban areas almost universally have low radon, and apartment dwellers removed from the ground source have particularly low radon exposure at home.

The miners' data show clearly that there is a risk of lung cancer from exposure to high concentrations of radon delivered over short periods. Comparable exposures delivered over a lifetime in the home have not produced statistically significant increases in lung cancer mortality except among smokers in one large study in Sweden. The risk can still exist, but the confounding effects of other carcinogens, such as smoking and urbanization, make it impossible to extract the more subtle impact of radon in existing studies.

NATURAL RADIOACTIVITY AND RADIATION BACKGROUND

The occupational, accidental, and wartime experiences detailed in the preceding sections have provided the bases for all the current radiation risk estimates. For many years, the radioisotopes deposited internally were compared with ^{226}Ra to evaluate the maximum permissible body burden for a particular emitter. The present limits for external and internal radiation are based on dose estimates that, in turn, can be related to cancer risks. One standard of comparison has always been the exposure from natural background, and this source is assessed here.

Background radiation from all sources is described in detail in NCRP report 94 (1987b), and some of the information is summarized here.

The risk estimates in the previous sections must be placed in context with the radiation dose received by all humans from natural background radiation. A substantial dose is received annually from cosmic radiation and from external terrestrial radiation present from uranium, thorium, and potassium in the earth's crust. Internal emitters are present in the body as a consequence of dietary consumption and inhalation. For example, potassium is a necessary element in the body and is under homeostatic control. Radioactive ^{40}K constitutes a constant fraction of all natural potassium. Potassium delivers the largest internal dose from the diet of 0.15 mSv per year. However, the data are scanty on the dietary intake of other radionuclides in the U.S. population. Given the usual distribution of intakes across a large

population, it is probable that other emitters, notably ^{210}Pb, could deliver a significant dose to a fraction of the population.

The largest dose received by the population is from the inhaled short-lived daughters of radon. These are present in all atmospheres because radon is released rather efficiently from the ^{226}Ra in rock and soil. The short-lived daughters, ^{218}Po, ^{214}Pb, ^{214}Bi-^{214}Po, have an effective half-life of 30 min, but the 3.8-day parent radon supports their presence in the atmosphere. Figure 25-5 shows the entire uranium series decay.

Average outdoor concentrations in every state in the United States have been measured and summarized as 15 Bq m^{-3}, and indoors, as 40 Bq m^{-3} (NAS, 1999). A structure such as a house prevents the rapid upward distribution of radon into the atmosphere, and substantial levels can be built up indoors. The source of radon is the ground; therefore levels in living areas above the ground are generally one-third to one-fifth the concentrations measured in basements. An effective barrier across the soil-building interface also inhibits the entry of radon to buildings. Ventilation with outdoor air reduces indoor radon. For this reason, industrial buildings with more substantial foundations and higher ventilation rates tend to have lower radon concentrations than do single-family (or detached) houses. Apartments above ground level have radon concentrations about half the average of those in single-family dwellings.

It is of significance that an average radon concentration indoors of 40 Bq m^{-3} results in an equivalent dose to bronchial epithelium of 24 mSv/year or an effective dose of 2 mSv per year.

The equivalent doses for the major natural internal emitters are shown in Table 25-11. These are reproduced from NCRP (1987).

	Equivalent Dose Rate, mSv yr⁻¹			
RADIONUCLIDE	BRONCHIAL EPITHELIUM	SOFT TISSUE	BONE SURFACE	BONE MARROW
^{14}C	—	0.10	0.06	0.30

Table 25-12 Estimated Total Effective Dose Rate for a Member of the Population in the United States and Canada from Various Sources of Background Radiation

The lifetime dose from natural emitters is shown in Table 25-13, assuming an average exposure from birth to a full life of 85 years. It should be recognized that the actual dose accumulated by an individual depends on dietary habits, location (Denver, for example, at an altitude of 1.6 km, has double the average cosmic-ray exposure), and the dwelling. An apartment dweller would accumulate approximately half the dose from inhaled radon daughters as would a person living in a single-family dwelling. Table 25-13 is informative in considering the effects of radiation exposure from other than natural sources. For example, in assessing an occupational dose, which might add, say, 10 mSv effective dose equivalent, natural background would be a strong confounder. Any health detriment would have to be calculated rather than observed directly. No study would be able to detect an increase in health effects from 10 mSv above the average whole-life natural background of 260 mSv.

LOCAL ENVIRONMENTAL RELEASES

Large- and small-scale accidents will undoubtedly occur that release radioactivity into the environment. The accident at the Windscale nuclear power reactor in 1957 was a local incident in Great Britain. The nearby population has been studied for over 30 years without the appearance of significant health effects.

The nuclear power accident at Three Mile Island caused enormous financial damage, but the containment vessel was not breached and virtually no radioactivity escaped.

The accident at the Chernobyl nuclear power plant was another such occasion, and in this case containment did not exist and some of the radioactivity was widespread over Europe. The United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR, 1988, 1993) has summarized the committed dose from measurements made in the affected countries from various releases, and these are shown in Table 25-14. Table 25-14 includes environmental releases from most known sources.

Table 25-14 Estimates of Radionuclide Released and Collective Effective Dose from Human-Made Environmental Sources of Radiation

Highly radioactive emissions from industrial sources that are "lost," such as the ^{60}Co in Goiania or Thailand, do harm to the few persons involved, often with a few deaths due to very high radiation exposure and dose.

The criticality accident on September 30, 1999, at a fuel reprocessing facility in Tokai-Mura, Japan, resulted in the death of two workers and caused neighbors to receive a small local dose of about 2 mSv (Komura et al 2000).

Local exposures and doses from accidents can only be anticipated to increase, as the use of radioactive materials industrially is widespread.

SUMMARY OF HUMAN CANCER RISKS FROM RADIATION

The details of the five major studies have been given in the preceding sections. The data are summarized in Table 25-15. This table shows the lifetime cancer risks that are significant. The risks are given in units of per gray (or per Sievert where appropriate for alpha emitters).

Table 25-15 Lifetime Cancer Mortality per Gray from Five Major Epidemiologic Studies (in parentheses, risk per sievert for alpha emitters, w_r = 20)*

Within the table, leukemia and cancers of the lung and female breast are the most critical. Osteogenic sarcoma is seen in the radium exposures. There is no clear linear dose response for ^{224,226}Ra. This has been attributed to the existence of an apparent threshold. The cancer risk to individual organs from different study groups is in general agreement regardless of radiation type or whole- or partial-body exposure.

*One working level (WL) is any combination of short-lived daughters in 1 L of air that will result in 1.3 × 10^5 MeV of alpha energy when complete decay occurs. One working level is approximately equal to 7400 Bq m^{-3} (200 pCi/L) in a home and 11,000 Bq m^{-3} (300 pCi/L) in a mine.

TOXIC EFFECTS OF TERRESTRIAL ANIMAL VENOMS AND POISONS

Findlay E. Russell

Toxinologists generally separates the "venomous" animals from those termed "poisonous." The former are those animals capable of producing a poison in a highly developed secretory gland or group of cells and that can deliver their toxin during a biting or stinging act. Poisonous animals, by contrast, are generally regarded to be those whose tissues, either in part or in their entirety, are toxic. These latter animals have no mechanism or structure for the delivery of their poisons, and poisoning usually takes place through ingestion (Russell, 1965). Venomous or poisonous animals are found in every phylum, even the birds. For the most part, they are widely distributed throughout the animal kingdom, from the unicellular protistan *Alexandrium (Gonyaulax)* to certain of the mammals, including the platypus and the short-tailed shrew. There are at least four hundred species of snakes considered to be of a danger to humans. The number of venomous and poisonous arthropods must be countless, while toxic marine animals number approximately 1500 species and are found in almost every sea and ocean (Halstead, 1965–1970; Russell, 1965, 1984; Russell and Nagabhushanam, 1996).

An animal's venom may have one or several functions. It may play a role in offense, as in the capture and digestion of food, or it may contribute to the animal's defense, as in protection against predators or aggressors. It can also serve both functions. In the snake, the venom provides a food-getting objective. Its secondary function is in its defensive stature. The presence of a toxic venom in the snake is a superior modification to the animal's speed, size, concealment, or strength. In the venomous spiders, the toxin is used to paralyze the prey before it extracts the hemolymph and body fluids. The venom is not primarily designed to kill the prey, only to immobilize the organism for feeding. The same can be said for the scorpions, although they do use their venom in defense. In the fishes, such as the scorpionfishes and stonefishes, and in elasmobranches, such as the stingray, the venom apparatus is generally used in the animal's defense. There does not appear to be any evidence that it is employed in a food-getting capacity, nor would the chemistry or pharmacology so indicate. Venoms used in an offensive posture are generally associated with the oral pole, as in the snakes and spiders, while those used in a defensive function are usually associated with the aboral pole or with spines, as in the stingrays and scorpionfishes. The poisonous animals, on the other hand, usually derive their toxins through the food chain, and as such the poison is often a product of metabolism, sometimes concentrated as it passes through the food chain from one animal to another.

PROPERTIES OF ANIMAL TOXINS

The use to which an animal puts its toxin courses the nature of its chemistry and pharmacology. Whether, in its evolution, the process proceeds by trial and error or by some other means cannot be said. Venoms contain both high- and low-molecular-weight proteins, including polypeptides and enzymes. There may also be amines, lipids, steroids, aminopolysaccharides, quinones, glucosides, and free amino acids as well as 5-hydroxytryptamine (5-HT), histamine, and other substances. Questions then arise as to why and how these substances, most of which are common components of most living tissues, are found in the venom glands, how they came to concentrate there, and why the amounts are sufficient to make them toxic or venomous. It has become apparent that venoms—some snake venoms, for instance—may consist of more than a hundred proteins. Why are there so many? What synergistic and antagonistic mechanisms may be involved, and what autopharmacological phenomena can take place?

One might ask: What is the relationship between the in vitro and in vivo experiment? There is, of course a relationship, but we are finding that putting a single venom component on an isolated tissue preparation (often in far larger amounts than would ever reach that activity site in vivo) does not give us the precise mechanism of action of the full venom; in fact, the data may mislead us, particularly with respect to therapeutics. There is another unfortunate fact in studying the chemistry, pharmacology, and toxicology of venoms in that their structure and function are researched by taking the venoms apart. This has two shortcomings: first, a destructive process is used in attempting to understand what must have been a constructive one; second, the essential quality of the venom may be destroyed before suitable acquaintance of the full toxin has been made. Often, the technology becomes so exacting that the end as to the venom's function is lost sight of in our preoccupation with the means of the examination. Most venoms probably exert their effects on almost every cell and tissue, and their principal pharmacologic properties are usually determined by the amount of a fraction that accumulates at an activity site.

It seems advisable to suggest some general principles on what occurs to a venoms as it passes through the numerous tissues in order to reach an activity site or be metabolized or excreted. The bioavailability of a venom is determined by its composition, molecular size, amount or concentration gradient, solubility, degree of ionization, and the rate of blood flow into that tissue as well as the properties of the engulfing surface itself. The venom can be absorbed by active or passive transport, facilitated diffusion, or even pinocytosis, among other physiologic mechanisms. The role of surface integrins has not been determined for venom components.

In the case of active transport, the cell expends energy and substrates may be accumulated intracellularly against a concentration gradient. In facilitated diffusion, it has been suggested that a "carrier component" combines reversibly with the venom molecule at the membrane's outer surface, and that the carrier-substrate complex can then diffuse more rapidly across the membrane, releasing the molecule (or toxin) to the membrane's inner surface. For some substances it is known that the process of facilitated diffusion is highly selective, accepting only those components that have a relatively specific molecular configuration. There is some evidence to suggest that some fractions of venoms are transported across a membrane by pinocytosis—a process by which a cell engulfs particles or fluids by invaginating and forming a vesicle that later buds off within the interior cell. The venom is then transmitted into the vascular bed, sometimes directly or sometimes through lymphatic channels. This may be determined by the molecular size of its components, by water-oil (or other) partition coefficients, or by some other process causing its movement to the various receptor sites.

The role of the lymphatics and the characteristics in the transport and absorption of snake venom is a much neglected subject in toxicology and toxinology. The lymph circulation not only carries surplus interstitial fluid produced by the venom but also transports the larger molecular components and other particulates back to the bloodstream. Thus, the larger toxins of snake venoms, particularly those of Viperidae, probably enter the lymphatic network preferentially and then transported to the central venous system in the neck. Because lymphatic capillaries (i.e., initial lymphatics), unlike blood capillaries, lack a basement membrane and have fibroelastic "anchoring filaments," they can readily adjust their shape and size, facilitating absorption of excess interstitial fluid along with macromolecules of a venom. Unlike blood flow, which is propelled by a powerful pump, namely the heart, lymph is propelled for the most part by intrinsic segmental contractions of the large and small trunks (lymphangions). With a well-developed intraluminal valve system, the volume of tissue, fluid, and venom components transported is enhanced by both increased rate and greater stroke volume of the lymphangion micropumps (Witte and Witte, 1997).

The receptor sites appear to have highly variable degrees of sensitivity. It is well known that the differences in the rate of metabolism of a venom at a receptor site can

vary considerably in mammals. The differences observed in effective amounts of venom between human and laboratory animals does not necessarily reflect any increased sensitivity on the part of the human's target organs but may be directly related to the differences in specific rates of metabolism for the venom as well as the amount of the poison that actually reaches that site. A toxin will produce its pharmacologic effect when the quantity attains a critical minimum concentration at the receptor site. In the case of such complex mixtures as snake venoms, there may be several if not many receptor sites. There is also considerable variability in the sensitivity of those sites for the different components of a venom.

The site of action and metabolism of a venom is dependent on its diffusion and partitioning along the gradient between the plasma and the tissues where the components are deposited. In the case of most snake venoms and fractions so far studied, the distribution is rather unequal, being affected by protein binding, variations in pH, and membrane permeability, among other factors. Once the toxin reaches a particular site, its entry to that site is dependent upon the rate of blood flow into that tissue, the mass of the structure, and the partition characteristics of the toxin between the blood and that particular tissue. Some venom components have a high affinity for certain tissues and exert their most deleterious effects at these sites. This observation has given rise to such terms as *neurotoxin, cardiotoxin, myotoxin,* etc. In such cases the principal effector site may be the nerve, heart, or muscle, but evidence is lacking that these same venoms or fractions do not exert additional deleterious effects, sometimes serious, on other if not most tissues. Then, there is always the problem of how to label a fraction that affects the atrioventricular node. Is this neurologic or cardiovascular? It may seem unwise, in view of our meager knowledge, to claim an understanding of how a venom exerts its exact deleterious effects. One way is to refer to its injurious property, calling it, if we must, neurotoxic, cardiotoxic, or myotoxic, but even those terms circumvent the science of being physiopharmacologically exact.

In addition to the receptor sites, a venom may also be metabolized in several or many different tissues. This is important in considering the pharmacologic activity of a venom or venom fraction, for some components are metabolized distant to the receptor site(s) and may never reach the primary receptor in a quantity sufficient to affect that site. The amount of a toxin that tissues can metabolize without endangering the organisms may also vary. It would be wise, as has been done in some venom studies, to examine tissue slices or homogenates and subcellular fractions of different tissues to determine their metabolic coefficient. In evaluating such data, however, it must be remembered that organs or tissues may contain enzymes that catalyze a host of reactions, including deleterious ones. Enzymes that oxidize venom components by oxygenase mechanisms are for the most part localized in the parenchymal cells of the liver, while other enzymes are found somewhat unevenly distributed throughout many tissues. Again, it should be remembered that these cell types can and do differ between human and other mammals, and particularly the lower animals.

Once a venom component is metabolized or in some way altered, the end substance is excreted, principally through the kidneys. The intestines play a minor role, and what contribution the lungs and biliary system may make has not been determined. Excretion may be complicated by the direct action of the venom on the kidneys themselves, causing an inflammatory reaction that may produce gaps between the endothelial fenestrae, very small pores, so they are more permeable than skeletal muscle capillaries. Intestinal, salivary, and sweat gland capillaries also contain fenestrae. Indeed, the author has been impressed by the damage to the kidneys in humans seen on postmortem examination following crotalid and viperid bites. Although no generalization concerning the damage wrought by a snake venom on the organ systems of humans can be made (as compared with other mammals), the changes in the kidneys would seem only secondary to those occurring in the heart, and of course, the blood vessels (Russell, 1980a, 1980b, 1983). To sum up, applying a venom or venom fraction directly to an isolated tissue preparation of the mouse or other small mammal may provoke a quite different physiopharmacologic response, both qualitatively and quantitatively than the same toxin produces *in vivc* in the human.

ARTHROPODS

There are more than a million species of arthropods, generally divided into 25 orders, of which at least 12 are of importance to humans from an economic standpoint. Medically, however, only about 10 orders are of significant venomous or poisonous importance. These include the arachnids (scorpions, spiders, whipscorpions, solpugids, mites, and ticks); the myriapods (centipedes and millipedes); the insects (water bugs, assassin bugs, and wheel bugs); beetles (blister beetles); Lepidoptera (butterflies, moths, and caterpillars), and Hymenoptera (ants, bees, and wasps). In each of these groups and perhaps in some others, there are additional creatures that have been implicated in poisonings, but in most cases the clinical evidence or chemical nature of the toxin appears to be relatively circumstantial to properly implicate their dangerousness to humans. As noted by many authors, most arthropods do not have fangs or stings long or strong enough to penetrate the human skin.

In treating the subject of venomous arthropods the writer has not included those bites that, because of the trauma of their injury, may be painful. I have also needed to exclude those creatures that are vectors for certain bacterial, viral, or rickettsial disease and those bites or stings that give rise to allergic reactions. There are numerous texts and papers that deal with the general characteristics of venomous and poisonous arthropods. These inlcude those of Minton (1968), Eberling (1975), Maretic and Lebez (1979), Harwood and James (1979), Nutting (1984), and Smith (1997).

The number of deaths from arthropod stings and bites is not known. Most countries do not keep records of the incidence of such deaths or injuries. In Mexico, parts of Central and South America, North Africa, and India, deaths from scorpion stings, for instance, exceed several thousand a year. Spider bites probably do not account for more than 200 deaths a year worldwide. A common problem faced by physicians in suspected spider bites relates to the differential diagnosis. Of approximately 600 suspected spider bites seen in one series of cases, 80 percent were found to be caused by arthropods other than spiders or by other disease states (Russell and Gertsch, 1983). The arthropods most frequently involved in the misdiagnoses were ticks (including their embedded mouthparts), mites, bedbugs, fleas (infected flea bites), Lepidoptera insects, flies, vesicating beetles, water bugs, and various stinging Hymenoptera. Among the disease states that were confused with spider or arthropod bites or stings were erythema chronicum migrans, erythema nodosum, periarteritis nodosum, pyroderma gangrenosum, kerion cell–mediated response to a fungus, Stevens-Johnson syndrome, toxic epidermal necrolysis, herpes simplex, and purpura fulminans.

As with the snake, a spider or any other arthropod may bite or sting and not eject venom. The author has seen many such cases. Finally, some arthropod venom poisonings give rise to the symptoms and signs of an existing undiagnosed subclinical disease. The problem of diverse disease states following bites or stings of various venomous animals has been recognized (Russell, 1979), and when a case of poisoning appears to persist, the patient should be reexamined for the possible presence of some undiagnosed disease. In some cases, stings or bites may induce stress reactions that bring the unrecognized disease to the surface.

ARACHNIDA

Scorpions

The scorpions are said to be the oldest known terrestrial arthropods. There are at least a thousand species, among which the stings of more than 75 can be considered of sufficient importance to warrant medical attention. Scorpions spend the daylight hours under cover or in burrows. They emerge at night to ambush other arthropods or even small rodents, capture them with their pincers, sting and paralyze them, or tear them apart and digest their body fluids. Because they are carnivorous, the larger ones often feed on the smaller. Scorpions live from 2 to 10 years, although there are reports of a 25-year life span. Some of the more important of these species are noted in Table 26-1. In addition, members of the genera *Pandinus, Hadrurus, Vejovis, Nebo,* and some of the others are capable of inflicting painful and often erythematous lesions. In the United States the sting of *Centruroides exilicauda (sculpturatus)* is dangerous, and in Mexico there were 20,352 deaths over two 9-year periods, chiefly in children less than 3 years of age. It has been said that the total number of scorpion stings per year in Mexico at present may be as high as 250,000, with perhaps 200 deaths. Working in Mexico in 1953, this writer estimated that there were over 40,000 stings that year, of which 10,000 were treated or reported. The total number of deaths appeared to be less than 1500.

GENUS	DISTRIBUTION
Androctonus species	North Africa, Middle East, Turkey
Buthus species	France and Spain to Middle East and north Africa, Mongolia, China
Buthotus species	Africa, Middle East, central Asia
Centruroides species	North, Central, South America
Heterometrus species	Central and southeast Asia
Leiurus species	North Africa, Middle East, Turkey
Mesobuthus species	Turkey, India
Parabuthus species	Southern Africa
Tityus species	Central and South America

Table 26-1 Medically Important Scorpions

The dangerous bark scorpion *Centruroides exilicauda,* so called because of its preference for hiding under the loose bark of trees or in dead trees or logs, often frequents human dwellings. Its general color is straw to yellowish-brown or reddish-brown, and it is often easily distinguishable from other scorpions in the same habitat by its long, thin telson, or tail, and its thin pedipalps, or pincerlike claws. Adults of this genus show a considerable difference in length. *Centruroides exilicauda* in the southwestern United States and adjacent Mexico reaches a length of approximately 5.5 cm, while *Centruroides vittatus* of the Gulf states and adjacent Mexico is generally slightly larger. *Centruroides suffusus,* a particularly dangerous Mexican species, may attain a length of 9 cm, but *Centruroides noxius,* another important species, seldom exceeds 5 cm in length. Excellent reviews on scorpions have been provided by Keegan (1980) and Polis (1990).

Many scorpion venoms contain low-molecular-weight proteins, peptides, amino acids, nucleotides, and salts, among other components. The neurotoxic fractions are generally classified on the basis of their molecular size, the short-chain toxins being composed of 30 to 40 amino acid residues with three or four disulfide bonds and appear to affect potassium or chloride channels; while the long-chain toxins have 60 to 70 amino acid residues with four disulfide bonds and affect mainly the sodium channels. These particular toxins may have an effect on both voltage-dependent channels. The amino acid content is known for more than 90 species, and there appears to be a high degree of cysteines in most of these venoms. The toxins can selectively bind to a specific channel of excitable cells, thus impairing the initial depolarization of the action potential in the nerve and muscle that results in their neurotoxicity. It appears that the way that some scorpion venoms differently affect mammalian, as opposed to insect tissues is related to the structural basis of the gates in the two organisms. Not all scorpions, however, have fractions that affect neuromuscular transmission. The venoms of most scorpions may be deleterious to other arthropods, but they exert no significant systemic effects on humans. The American scorpion *Vejovis spinigerus* has no effect on mammalian neurotransmission, reflex discharge, or antidromic inhibition, but at high doses it can provoke systemic arterial, venous, and cisternal changes in mammals (Russell, 1968).

The symptoms and signs of scorpion envenomation differ considerably depending on the species. In the United States, the most common offenders are members of the family Vejovidae, generally found in the southwestern and western states as well as in Mexico, Central America, and South America. Their sting gives rise to localized pain, swelling, tenderness, and mild parasthesia. Systemic reactions are rare, although weakness, fever, and muscle fasciculations have been reported. These same findings have been reported for the stings of the giant hairy scorpion, *Hadrurus,* another member of the Vejovidae. Envenomations by some members of the genus *Centruroides* are clinically the most important, particularly in the western United States, where *C. exilicauda* is found. In children, their sting produces initial pain. However, some children do not complain of pain and are unaware of the injury. The area becomes sensitive to touch, and merely pressing lightly over the injury will elicit an immediate retraction. Usually there is little or no local swelling and only mild erythema. The child becomes tense and restless and shows abnormal and random head and neck movements. Often the child will display roving eye movements. In their review of *Centruroides sculpturatus* stings, Rimsza and coworkers (1980) noted visual signs, including nystagmus roving eye and oculogyric movements, in 12 of 24 patients stung by this scorpion. Loud noises, such as banging the examination table behind the child's back, often cause the patient to jump. Tachycardia is usually evident within 45 min as well as some hypertension. Although this is not seen in children as early or as severely as in adults, it is often present within an hour following the sting. Respiratory and heart rates are increased, and by 90 min the child may appear quite ill. Fasciculations may be seen over the face or large muscle masses, and the child may complain of generalized weakness and display some ataxia or motor weakness. Opisthotonos is not uncommon. The respiratory distress may proceed to respiratory paralysis. Excessive salivation is often present and may further impair respiratory function. Slurring of speech may be present, and convulsions may occur. If death does not occur, the child usually becomes asymptomatic within 36 to 48 h.

In adults the clinical picture is somewhat similar, but there are some differences. Almost all adults complain of immediate pain after the sting, regardless of the *Centruroides* species involved. Adults do not show the restlessness seen in children. Instead, they are tense and anxious. They develop tachycardia and hypertension, and respirations are increased. They may complain of difficulties in focusing and swallowing, as may children. In some cases, there is some general weakness and pain on moving the injured extremity. Convulsions are very rare, but ataxia and muscle incoordination may occur. Most adults are asymptomatic within 12 h but may complain of generalized weakness for 24 h or more.

As noted elsewhere (Russell, 1996), a review of the therapy for scorpion stings will provide a fascinating mixture of mythology, folklore, hunches, and a list of all sorts of therapeutic devices from electroshock to mechanical compression. Measures such as bed rest, positive-pressure breathing, mild sedation with diazepam and antihypertensive drugs may be helpful when high blood pressure is a problem. An antivenom produced by Arizona State University for *C. exilicauda* stings is available and approved by the state, but does not have the approval of the U.S. Food and Drug Administration (FDA). An F(ab)$_2$ polyvalent antivenom is produced in Mexico, but the former is preferred for U.S. species. Recently, the continuous infusion of midazolam has been used with considerable success in serious *C. exilicauda* stings in Arizona (Jones et al., 1988).

Spiders

Of the 30,000 or so species, at least 200 have been implicated in significant bites on humans. Some of the more medically important of these spiders are noted in Table 26-2. Spiders are predaceous, polyphagous arachnids that generally feed on insects or other arthropods. A more complete review of spider bites can be found in the excellent work of Kaston (1978), Maretic and Lebez (1979), Gertsch (1979), and the lesser contributions of Southcott (1976) and Russell and Gertsch (1983). It is not possible to describe the chemistry, pharmacology, or immunology of the hundreds (perhaps thousands) of spider venoms that are toxic. Discussed here are only a few that appear to be clinically more important in the United States. There are, however, bites by species of *Pheostica, Pamphobeteus, Bothriocyrtum, Ummidia, Phoneutria, Cupiennius, Lycosa, Heteropoda, Misumenoides, Liocranoides, Neoscona, Araneus, Argiope, Peucetia, Agelenopsis,* and *Tegenaria.* Whether native or imported, all have all been implicated in bites on humans in the United States.

Table 26-2 Genera of Spiders for Which Significant Bites on Humans are Known

Spider venoms are very complex and have been studied extensively, even as sources for new drugs (Coombs, 1992). From a neuroactive standpoint, the widow and

grass spiders, with their neurotranmitter release and channel-affecting properties; the jumping spiders, with their Ca^{2+}–channel blocking activity; and the argiope and orb spinners, with their glutamate and Ca^{2+}–channel blocking activities appear to show much promise as tools in studying neurologic phenomena and perhaps for clinical use.

Latrodectus Species (Widow Spiders) In the United States, these spiders are commonly known as the black widow, brown widow, or red-legged spider. They, however, have many other common names in English: hourglass, poison lady, deadly spider, red-bottom spider, T-spider, gray lady spider, and shoebutton spider. Widow spiders are found almost circumglobally in all continents with temperate or tropical climates. In the United States, there are at least five species, including the native *L. mactans, L. bishopi, L. variolus, L. hesperus,* and the imported *L. geometricus.* Although both male and female widow spiders are venomous, only the female has fangs large and strong enough to penetrate the human skin. Mature *L. mactans* females range in body length from 10 to 18 mm, whereas males range from 3 to 5 mm. These spiders have a globose abdomen varying in color from gray to brown to black, depending on the species. In the black widow, the abdomen is shiny black with a red hourglass or red spots and sometimes white spots on the venter.

Through the years, one of the difficulties in determining the composition of spider venoms, particularly that of *Latrodectus* spp., has been the procedure of grinding up the venom glands and preparing a homogenate of the glands and then attributing the chemistry or toxicology to that of the actual venom. The manifestations of the poisoning from the glands do not reflect those found in the in vivo state. A family of high-molecular-weight proteins, latrotoxins, have been described in *Latrodectus* venoms. These are proteins of about 1000 amino acid residues (Grishin, 1999). Alpha-latrotoxin is a presynaptic toxin which is said to exert toxic effects on the vertebrate central nervous system in depolarizing neurons by increasing [Ca^{2+}]i and by stimulating uncontrolled proteins described in *Latrodectus* venom. These are proteins of about 1000 amino acid residues (Grishin, 1999). Alpha-latrotoxin is a presynaptic toxin that is said to exert its toxic effects on the vertebrate central nervous system in depolarizing neurons by increasing [Ca^{2+}]i, and by exocytosis of neurotransmitters from nerve terminals (Holz and Habener, 1998). Along with the known GTP-binding protein-coupled receptors, five latroinsectotoxins affecting neurotransmitter release from the presynaptic endings of insects and one latrocrustatoxin have been isolated, and a alpha-latrotoxin preparation showed a low-molecular-weight protein structurally related to crustacean hyperglycemic hormones (Greshin, 1998). By thin-layer chromatography (TLC) on silica gel, it was shown that the venom kininase was a thiol endopeptidase (Akhunov et al., 1996).

Clinical Problem Bites by the black widow are described as sharp and pinprick-like, followed by a dull, occasionally numbing pain in the affected extremity and by pain and cramps in one or several of the large muscle masses. Rarely is there any local skin reaction except during the first 60 min following the bite, but piloerection in the bite area is sometimes seen. Muscle fasciculations frequently can be seen within 30 min of the bite. Sweating is common, and the patient may complain of weakness and pain in the regional lymph nodes, which are often tender on palpation and occasionally are enlarged; lymphadenitis is frequently observed. Pain in the low back, thighs, or abdomen is a common complaint, and rigidity of the abdominal muscles is seen in most cases in which envenomation has been severe. Severe paroxysmal muscle cramps may occur, and arthralgia has been reported. Hypertension is a common finding, particularly in the elderly after moderate to severe envenomations. Blood studies are usually normal.

There is no effective first-aid treatment. In most cases, intravenous calcium gluconate will relieve muscle pain, but this may have to be repeated at 4- to 6-h intervals for optimum effect. Muscle relaxants such as methocarbamol 5 to 10 mg can be used. Acute hypertensive crises may require intravenous nitroprusside. The use of antivenom (antivenin, *L. mactans*) should be restricted to more severe cases and when other measures have proved unsuccessful. One ampule administered intravenously is usually sufficient. In patients who are under 16 or over 60 years, have any history of hypertension or hypertensive heart disease, or who show significant symptoms and signs, the use of antivenom seems warranted; it also is appropriate in cases involving pregnancy.

Loxosceles Species (Brown or Violin Spiders) These primitive spiders are variously known in North America as the fiddle-back spider or the brown recluse. There are over 100 species of *Loxosceles.* Twenty of these species range from temperate South Africa northward through the tropics into the Mediterranean region and southern Europe. Another 84 species are known from North, Central, and South America and the West Indies. The most widely distributed is *Loxosceles rufescens,* the so-called cosmopolitan species. It is found in the Mediterranean area, southern Russia, most of north Africa including the Azores, Madagascar, the Near East, Asia from India to southern China and Japan, parts of Malaysia and Australia, some islands of the Pacific, and North America. *Loxosceles laeta* is mostly South American, but it has been introduced into Central America; small areas in Cambridge, Massachusetts; Sierra Madre and Alhambra, California; and the zoology building of the University of Helsinki. The abdomen of these spiders varies in color from grayish through orange and reddish-brown to blackish and is distinct from the pale yellow to reddish-brown background of the cephalothorax. This spider has six eyes grouped in three dyads. Females average 8 to 12 mm in body length, whereas males average 6 to 10 mm. Both males and females are venomous. The most important species in the United States are *Loxosceles reclusa* (brown recluse spider), *Loxosceles deserta* (desert violin spider), and *Loxosceles arizonica* (Arizona violin spider).

The chemistry and toxicology of *Loxosceles* venom were first described by Schenone and Suarez (1978). Early work indicated that the amount of venom protein per spider was about 68 mg. Although the venom is said to contain phospholipase, protease, esterase, collagenase, hyaluronidase, deoxyribonuclease, ribonuclease, dipeptides, dermanecrosis factor 33, dermonecrosis factor 37, the most important factor is sphingomyelinase D. The relationship between these various fractions is not clear, but most recent works treat with the sphingomyelinase D. In *Loxosceles intermedia* a the toxic effects appear to be associated with a 35-kDa protein (1735) which demonstrates a complement-dependent hemolytic activity and a dermonecrotic-inducing factor (Andrade et al., 1998). ^{31}P-Nuclear magnetic resonance assay of the four bands representing proteins, measuring 34 kDa in the venom, produced three proteins with sphingomyelinase D activity (Merchant et al., 1998). An endotoxemic-like shock, showing eosinophilic material in the proximal and distal tubules and tubular necrosis, were the most common histopathologic findings, preceded in mice by prostration, acute cachexia, hypothermia, neurologic changes, and hemoglobinuria (Tambourgi et al., 1998). In Brazil, the sandwich-type enzyme-linked immunosorbent assay (ELISA) for the detection of venom antigens for *L. intermedia* in both animal and human envenomations has been shown to be a useful diagnostic procedure (Chavez-Olortegui et al., 1998). The venom has coagulation and vasoconstriction properties. It causes selective damage to the vascular endothelium. There are adhesions of neutrophils to the capillary wall with sequestration and activation of passing neutrophils by the perturbed endothelial cells (Patel et al., 1994). When the venom is injected into mammals, it produces, in addition to the local tissue reaction, varying degrees of thrombocytopenia, some intravascular hemolysis, and hemolytic anemia.

Clinical Problem The bite of this spider produces about the same degree of pain as does the sting of an ant, but sometimes the patient may be unaware of the bite. In most cases, a local burning sensation, which may last for 30 to 60 min, develops around the injury. Pruritus over the area often occurs, and the area becomes red, with a small blanched area surrounding the reddened bite site. Skin temperature usually is elevated over the lesion area. The reddened area enlarges and becomes purplish during the subsequent 1 to 8 h. It often becomes irregular in shape, and as time passes, hemorrhages may develop throughout the area. A small bleb or vesicle forms at the bite site and increases in size. It subsequently ruptures and a pustule forms. The red hemorrhagic area continues to enlarge, as does the pustule. The whole area may become swollen and painful, and lymphadenopathy is common. During the early stages the lesion often takes on a bull's-eye appearance, with a central white vesicle surrounded by the reddened area and ringed by a whitish or bluish border. The central pustule ruptures, and necrosis to various depths can be visualized. Not all bites, however, take this course, some producing no more than localized pain, slight redness, and minimal swelling (Russell, 1996).

In serious bites, the lesion can measure 8 by 10 cm with severe necrosis invading muscle tissue. On the face, large lesions resulting in extensive tissue destruction and requiring subsequent plastic surgery sometimes are seen after bites by *L. laeta* in South America. Systemic symptoms and signs include fever, malaise, stomach cramps, nausea and vomiting, jaundice, spleen enlargement, hemolysis, hematuria, and thrombocytopenia. Fatal cases, while rare, usually are preceded by intravascular hemolysis, hemolytic anemia, thrombocytopenia, hemoglobinuria, and renal failure. There have been no deaths in the United States from the bites of this spider, contrary to reports in the media.

There are no first-aid measures of value. In fact, all first-aid procedures should be avoided, as the natural appearance of the lesion is most important in determining the diagnosis. A cube of ice may be placed on the wound. At one time, excision of the bite area with ample margins was advised when this could be done within an hour or so of the bite and when *Loxosceles* was definitely implicated. The value of steroids has been questioned. This writer, however, has had seemingly good results with steroids following bites by *L. deserta, L. arizonica, and L. russelli.* The patient should be placed on a corticosteroid such as intramuscular dexamethasone, 4 mg every 6 h during the acute phase. Subsequent doses were determined by clinical judgment, followed by decremental doses over a 4-day period. Antihistamines are of questionable value. The use of dapsone was suggested by King and Rees (1983). The results have been encouraging, but care must be exercised with this drug. If skin grafting becomes necessary, the procedure is best deferred for 4 to 6 weeks after the injury. Systemic manifestations should be treated symptomatically. Antivenom is not commercially available but has been used in Tennessee (King, personal correspondence, 1990).

Steatoda Species The cobweb spiders, *Steatoda* spp., are variously known as the false black widow, combfooted, or cupboard spiders. They are thought to have reached the Americas through trading sources. These spiders are often mistaken for black widow spiders, and indeed the first clinical case of *Steatoda grossa* envenomation directed to the author in 1961 was thought to be caused by *L. mactans.* The female of *S. grossa* differs from *L. mactans* and *L. hesperus* in having a purplish-brown abdomen rather than a black one. It is less shiny, and its abdomen is more oval than round. It may have pale yellow or whitish markings on the dorsum of the abdomen, and no markings on the venter. The abdomen of some species is orange, brown, or chestnut in color and often bears a light band across the anterior

dorsum.

Cavalieri et al. (1987) state that the venom of *Steatoda paykulliana* had little effect on guinea pigs and no proteolytic activity was noted, but high concentrations of the venom stimulated release of transmitter substances similar to *Latrodectus* venom. A high-molecular-weight protein was toxic to houseflies. The venom is said to form ionic channels permeable for bi- and monovalent cations. It was found that the living time in the open state depended on the membrane potential (Sokolov et al., 1984). According to Mareti^{c} and Lebez (1979), *S. paykulliana* venom gives "strong motor unrest, clonic cramps, exhaustion, ataxia and then paralysis in guinea pigs." Bites by *S. grossa* or *Steatoda fulva* in the United States have been followed by local pain, often severe; induration; pruritus; and the occasional breakdown of tissue at the bite site. Warrell et al. (1991) report a bite by *Steatoda nobilis* with unpleasant local and systemic "symptoms," but whether the envenomation can be termed "neurotoxic" in humans remains questionable. In none of the seven *S. grossa* cases seen by the writer was there any strong evidence of neurotoxicity. Perhaps there is a significant difference in the venoms of the various species. Wounds should be debrided and covered, and signs should be treated symptomatically.

***Cheiracanthium* Species (Running Spiders)** The 160 species of this genus have an almost circumglobal distribution, although only four or five species have been implicated in bites on humans. Mareti^{c} and Lebez (1979) named *Cheiracanthium punctorium, Cheiracanthium inclusum, Cheiracanthium mildei,* and *Cheiracanthium diversum* as the spiders most often implicated in envenomations. In Japan, however, *Cheiracanthium japonicum* is a common biting spider. The abdomen is convex and egg-shaped and varies in color from yellow, green, or greenish-white to reddish-brown; the cephalothorax is usually slightly darker than the abdomen. The chelicerae are strong, and the legs are long, hairy, and delicate. The spider ranges in length from 7 to 16 mm. Like *Phidippus* but even more so, *Cheiracanthium* tends to be tenacious and sometimes must be removed from the bite area. For that reason there is a high degree of identification following the bite of these spiders. The most toxic fraction of the venom is said to be a protein of 60 kDa, and the venom is high in norepinephrine and serotonin.

The author's experiences with seven bites by *C. inclusum* have been very similar; the following description is based on those experiences. The patient usually describes the bite as sharp and painful, with the pain increasing during the first 30 to 45 h. The patient complains of dull pain over the injured part. A reddened wheal with a hyperemic border develops. Small petechiae may appear near the center of the wheal. Skin temperature over the lesion is often elevated, but body temperature is usually normal. Lymphadenitis and lymphadenopathy may develop. In Japan, *C. japonicum* produces more severe manifestations than we have seen with the American or European species. These include severe local pain, nausea and vomiting, headache, chest discomfort, severe pruritus, and shock in addition to the local findings.

***Phidippus* Species (Jumping Spiders)** These spiders, variously known as crab spiders and eyebrow spiders, are usually less than 20 mm in length and have a somewhat elevated, rectangular cephalothorax that tends to blunt anteriorly. The abdomen is often oval or elongated. There is a great deal of variation in the color of these spiders. In the female, the cephalothorax may be black, brown, red, orange, or yellowish-orange and the abdomen tends to be slightly lighter in color. In most species there are various white, yellow, orange, or red spots or markings on the dorsum of the abdomen. These spiders are thought to have the sharpest of vision, thus their hunting excellence. They have four large eyes on the face and four smaller eyes on the dorsum of the head. The larger pair of eyes on the face apparently serve for the sharpest vision.

A computer-aided key based on electromorph patterns for five enzyme systems has been developed to determine specific species of *Phidippus*. Digitized, and the gels graphed, the system provides a ready identification of seven species of the spider (Terranova and Roach, 1989). In their comprehensive study of the venom of 26 spider species belonging to 15 families, it was found that the toxic effect of the venom was dramatic with respect to its cytotoxic effect on cultured cells, where there was a dramatic, instantaneous disruption of cell membranes, resulting in the collapse of the neuroblastoma cells (Cohen and Quistad, 1998).

The bite of this spider produces a sharp pinprick of pain, and the area immediately around the wound may become painful and tender. The pain usually lasts 5 to 10 min. An erythematous wheal slowly develops. In cases seen by the author, the wheal measured 2 to 5 cm in diameter. A dull, sometimes throbbing pain may subsequently develop over the injured part, but it rarely requires attention. A small vesicle may form at the bite site. Around this is an irregular, slightly hyperemic area, which in turn may be surrounded by a blanched region that is tender to touch and pressure. Generally, there is only mild lymphadenitis. Swelling of the part may be diffuse and is often accompanied by pruritus. The symptoms and signs usually abate within 48 h. There is no specific treatment for the bite of this spider (Russell, 1970).

Ticks

Tick paralysis is caused by the saliva of certain ticks of the families Ixodidae and Argasidae and perhaps others. An excellent review on the subject has been published by Gregson (1973), while a more recent, shorter review is that of Smith (1997). Tick paralysis is known for both domestic animals and humans, being noted in humans since 1912, although it was known to the American Indians as pajaroella , due to *Ornithodoros corisceus,* long before that time. There are said to be at least 60 species of ticks that have been implicated in paralysis-producing disorders. With respect to tick paralysis rather than tick toxicosis, one must consider the rickettsial, spirochetal, and microbacterial organisms transmitted by ticks (or mites) that cause neurologic disorders similar to those produced by the organism's saliva. Among the diseases due to organisms transmitted by ticks are Lyme disease, Rocky Mountain spotted fever, babesiosis, leptospirosis, Q fever, ehrlichiosis, typhus, tick-borne encephalitis, and others.

The saliva of *Ixodes holocyclus* appears to have been most often studied and has yielded a number of substances that may cause paralysis and, at high doses, death. Peak paralytic activity was found between 60 to 100 kDa, and a lethal nonparalytic fraction was found at 20 kDa. In *Argas* paralysis, the action appears to be directed toward polyneuropathy, with only slight afferent pathways. Respiration is affected and acetylcholine release is reduced, while sensitivity at the neuromuscular junction is affected. Conduction in motor fibers is said to be affected, with a functional deficiency in afferent fibers. It has been suggested that in *Dermacentor andersoni* paralysis, the paralysis represents lower motor neuron injury and irritation of the posterior root of the spinal cord (Amese and Lyday, 1939), while Rose (1954) has provided evidence that the block is at the neuromuscular junction. It must be concluded that the exact mechanism of the paralysis has yet to be determined.

Clinical Problem Except for some species, tick bites are often not felt; the first evidence of envenomation may not appear until several days later, when small macules develop. The macules are 3 to 4 mm in diameter and surrounded by erythema and swelling, often displaying a hyperemic halo. The patient often complains of difficulty with gait, followed by paresis and eventually locomotor paresis and paralysis. Problems in speech and respiration may ensue and lead to respiratory paralysis if the tick is not removed. Since the tick is often in the hair, it may remain unseen, thus confusing the differential diagnosis. Removal of the tick usually results in a rapid and complete recovery, although regression of paralysis may resolve slowly.

It seems probable that the ticks that cause the paralysis in humans and domestic animals may be the same, and that it is the length of the exposure to the feeding tick that determines the degree of poisoning. Obviously, the first signs of poisoning are less likely to be observed in cattle, sheep, dogs, and cats than in humans; as for symptoms (what the patient tells the physician), such reports are not likely to be made. Treatment consists of removal of the tick, using a formamidine derivative or petroleum product, washing with soap and water, and treating specifically for the paralysis or other manifestation. It should be pointed out, again, that these comments are specific only for tick venom poisoning and not for allergic reactions, transmission of disease states, or other complications of tick bites.

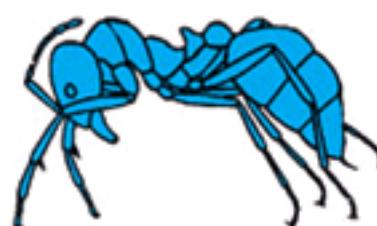
CHILOPODA (CENTIPEDES)

These elongated, many-segmented brownish-yellow arthropods are found worldwide. With a pair of walking legs on most segments, they are fast-moving, secretive, and nocturnal. They feed on other arthropods and even small vertebrates and birds; they are cannibalistic. The first pair of legs behind the head are modified into poison jaws or maxillipeds. Centipedes range in length from 3 to almost 300 mm. In the United States, the prevalent biting genus is a *Scolopendra* species. The venom is concentrated within the intracellular granules, discharged into vacuoles of the cytoplasm of the secretory cells, and moved by exocytosis into the lumen of the gland; from thence ducts carry the venom to the jaws (Ménez et al., 1990).

The venoms of centipedes contain high-molecular-weight proteins, proteinases and esterases, 5-hydroxytrptamine, histamine, lipids, and polysaccharides. In humans, such a venom produces cardiovascular changes and changes associated with acetylcholine release. It produces immediate bleeding, redness, and swelling often lasting 24 h. Localized tissue changes and necrosis have been reported, and severe envenomations may cause nausea and vomiting, changes in heart rate, vertigo, and headache. In the most severe cases, there can be mental disturbances. Treatment is nonspecific, but washing and the application of a cream containing hydrocortisone, diphenhydramine, and tetracaine (Itch Balm Plus, Sawyer) is of value.

DIPLOPODA (MILLIPEDES)

These arthropods are cylindrical, wormlike creatures, mahogany to dark brown or black in color, bearing two pairs of jointed legs per segment and ranging in length from 20 to 300 mm. In some parts of the world, particularly Australia and New Guinea, the repellent secretions expelled from the sides of their bodies contain a toxin of quinone derivatives and a variety of complex substances such as iodine and hydrocyanic acid, which the animal makes use of to produce hydrogen cyanide. Some species can spray these defensive secretions, and eye injuries, though rare in the United States, are not uncommon.

The lesions produced by millipedes are generally known as "burn" injuries and consist of a burning or prickling sensation and development of a yellowish or brown-purple lesion; subsequently a blister containing serosanguinous fluid forms, which may rupture. Eye contact can cause acute conjunctivitis, periorbital edema, keratosis, and much pain; such an injury must be treated immediately. Skin treatment consists of washing, washing, and washing the area thoroughly with soap and water and applying the cream as previously mentioned.


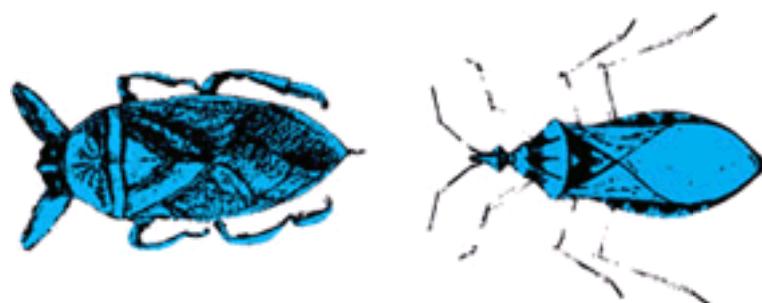
INSECTA

Lepidoptera (Caterpillars, Moths, and Butterflies)

The urticating hairs, or setae, of caterpillars are effective defensive weapons that protect some species from predators. The setae are attached to unicellular poison glands at the base of each hair. Both the larvae and the adults are capable of stinging, either by direct contact with the setae or indirectly when the creature becomes irritated. It appears that contraction of the caterpillar's abdominal muscles is sufficient to release the barbs from their sockets, allowing them to become airborne. Some caterpillars have a disagreeable smell or taste and are avoided by birds and other animals. The toxin found in the venom glands of some caterpillars may be derived from their ingestion of noxious plants, which are then metabolized. Earlier studies showed that the toxic material contained aristolochic acids, cardenolides, and histamine among other substances. In recent studies, fibrinolytic activity has been found at 16 and 18 kDa (isoelectric point of 8.5); coagulation defects such as prolonged prothrombin and partial thromboplastin times have been detected, and decreases in fibrinogen and plasminogen have been noted. It is thought that the hemorrhagic syndrome cannot be classified as being either totally fibrinolytic or a syndrome such as disseminated intravascular coagulopathy; it is also held that the venom has urkinase activity (Kawamoto and Kumada, 1984).

In some parts of the world the stings of several species of Lepidoptera give rise to a bleeding diasthesis, often severe and sometimes fatal. In the United States, envenomation by members of the family Saturniidae, the buck moths, the grapeleaf skeletonizer (family Zygaenidae), the puss moth (family Megalopygie), and the browntailed moth (*Euproctis* species) generally gives rise to little more than immediate localized itching and pain, usually described as burning, followed in some cases by urticaria, edema, and occasionally fever. In the more severe cases abroad—often due to *Megalopygidae, Dioptidae, Automeris, and Hermileucinae* species—there is localized pain as well as papules (sometimes hemorrhagic) and hematomas; on occasion there may also be headache, nausea, vomiting, hematuria, lymphadenitis, and lymphadenopathy. Cerebral edema, hemorrhage (intracranial hypertension), and mental changes have been noted for foreign species.

Treatment consists of placing cellophane tape over the affected area, removing it, and doing this again (to take out the setae); washing the area with warm soap and water and repeating this; and finally applying the cream previously mentioned.

Formicidae (Ants)


The stinging properties of the ants need no introduction. Most species sink their powerful mandibles into the flesh, providing leverage, and then drive their stings into the victim. Most ants have stings, but those that lack them can spray a defensive secretion from the tip of the gaster, which is often placed in the wound of the bite. Ants of the different species vary considerably in length, ranging from less than 1.5 mm to over 35 mm. In the United States, the clinically important stinging ants are the harvesting ants (*Pagonomyrmex*), fire ants (*Solenopsis*), and little fire ants (*Ochetomyrmex*). The harvester ants are large red, dark brown, or black ranging in size from 6 to 10 mm and having fringes of long hairs on the posterior of their heads. They are vicious stingers, and their venom is said to have strong cholinergic properties.

The venoms of the ants vary considerably. The venoms of the Ponerinae and Ecitoninae are proteinaceous in character, as is that of the Pseudomyrmex. The Myrmecinae venoms are a mixture of amines, enzymes and proteinaceous materials, histamine, hyaluronidase, and phospholipase A. Formicinae ant venom contains about 60% formic acid. Fire ants are unique in that while they are poor in polypeptides and proteins, they are rich in alkaloids, some 95%, and these appear to be the cause of pruritic pustules and necrosis (Blum 1989). The sting of the fire ant gives rise to a painful burning sensation, after which a wheal and localized erythema develop, leading in a few hours to a clear vesicle. Within 12 to 24 h, the fluid becomes purulent and the lesion turns into a pustule. It may break down or become a crust or fibrotic nodule. In multiple stingings there may be nausea, vomiting, vertigo, increased perspiration, respiratory difficulties, cyanosis, coma, and even death. Cross exposure to the venom of other species of ants is possible. Treatment of ant stings is dependent upon their number, whether an allergic reaction is involved, and whether there are possible complications.

Apidae (Bees)

In this family we include the bumble bees, honey bees, carpenter bees, wasps, hornets, and yellow jackets. The commonest stinging bee is *Apis mellifera,* but with the introduction and rapid spread of the Africanized bee, *Apis mellifer adansoni*, in the United States, the incidence of Hymenoptera poisonings is increasing. In 1996 there were at least 58 deaths and more than 1000 incidents of Africanized bee stings in Mexico and the United States. The venom of the Africanized bee is not remarkably different from that of the European bee, *A. m. mellifer.* The former bee is smaller and gives less venom, but its agressiveness is such that attacks of 50 to 500 bees are not unusual. The overwhelming dose of apamine, which is thought to be lethal factor, results in the serious or even fatal poisoning by this arthropod. In addition to apamine, the venom contains biologically active melittin synergized by phospholipase A $_2$, hyaluronidase, histamine, dopamine, and a mast cell–degranulating peptide, among other components. It is said that 50 stings can be serious and lead to respiratory dysfunction, intravascular hemolysis, hypertension, myocardial damage, hepatic changes, shock, and renal failure. With 100 or more stings, death can occur. A novel Fab-based antivenom for massive bee attacks has been reported but has not undergone clinical trial at the time of this writing. It could be of value in those cases where the patient survives the initial onslaught of the poisoning and before serious sequelae develop.

Heteroptera (True Bugs)

The clinically most important of the true bugs are the Reduviidae (the reduviids): the kissing bug, assassin bug, wheel bug, or cone-nose bug of the genus *Triatoma.* Generally, they are parasites of rodents and common in the nests of wood rat or in wood piles. These are elongated bugs with freely movable, cone-shaped heads and straight beaks. The most commonly involved species appear to be *Triatoma protracta, T. rubida, T. magista, Reduvius personatus,* and *Arilus cristatus.* Most are good fliers. During their nocturnal dispersal flights they are attracted to porch or artificial light. Once there, they do not seek to escape until dawn. Indeed, at the author's ranch in Portal, Arizona, more than 100 reduviids have been captured in a single night using bright artificial light. The average length of these bugs was 19 mm.

The venom of these bugs appears to have apyrase activity and to lack 5-nucleotidase, inorganic pyrophosphatase, phosphatase, and adenylate kinase activities, but it is fairly rich in protease properties. It inhibits collagen-induced platelet aggregation. It is said to be a protein of 16 to 19 kDa.

The bites of *Triatoma* species are definitely painful and give rise to erythema, pruritus, increased temperature in the bitten part, localized swelling, and—in those allergic to the saliva—systemic reactions such as nausea and vomiting and angioedema. With some bites the wound area will slough, leaving a depression. Treatment consists of cleansing the area and applying the cream previously described.

The water bugs are water-dwelling true bugs of which there are at least three families: Naucordiae, Belostomatidae, and Notonectidae that are capable of biting and evenomating humans. They are found in lakes, ponds, marshes, quiet fresh water, and swimming pools. The most common biter in the United States is *Lethocerus americanus,* a Belostomatidae, ranging in length from 12 to 70 mm, but some water bugs may reach 150 mm. The dorsal side is usually tan or brown, but it may be brightly colored, while the ventral side is brown. They are very strong insects and can immobilize snails, tadpoles, salamanders, and even small fish and water snakes. They are sometimes known as "toe biters" or "electric light bugs." In some parts of the world they are eaten in stews, but that is not likely to happen in the United States.

The venomousness of the water bugs has been attributed to their saliva, which is said to contain digestive enzymes, neurotoxic components, and hemolytic fractions. ApoLp-III has been isolated from the hemolymph of *Lathocerus medius.* It has a M(r) of 19,000, and an amino acid composition high in methionine. If molested, water bugs will bite, and some species can envenomate in or out of the water. Their bites give rise to immediate pain, some localized swelling, and—in one case seen by the author—induration and the formation of a small papule. Treatment consists of cleansing the areas and applying the cream previously noted.

There are some arthropods that are "poisonous" as opposed to "venomous"; that is, they have no mechanism for delivering their toxin and the poison must come through their being crushed or eaten. These would include, among others, the darkling beetles or stink bugs (*Eleodes*), and the blister beetles (*Epicauta*), for which cantharidin is known.

REPTILES

Lizards

The Gila monster (*Heloderma suspectum*) and the beaded lizards (*Heloderma horridum*) are divided into five subspecies. These large, corpulent, relatively slow-moving, and largely nocturnal reptiles have few enemies other than humans. They are far less dangerous than is generally believed. Their venom is transferred from venom glands in the lower jaw through ducts that discharge their contents near the base of the larger teeth of the lower jaw. The venom is then drawn up along grooves in the teeth by capillary action. The venom of this lizard has serotonin, amine oxidase, phospholipase A, and proteolytic as well as hyaluronidase activities but lacks phosphomonoesterase and phosphodiesterase, acetylcholinesterase, nucleotidase, ATP-ase, deoxyribonuclease, ribonuclease, amino acid oxidase, and fibrinogenocoagulase activities. The high hyaluronidase content seems to be consistent with the tissue edema seen in many clinical cases, and the low proteolytic activity is also consistent with the minimal tissue breakdown seen in clinical cases. The injection of large doses of Heloderma venom produces a fall in systemic arterial pressure with a decrease in circulating blood volume, tachycardia, and respiratory distress; in lethal doses, there is a loss of ventricular contractility (Russell and Bogert, 1981). An excellent review on the biology of the Gila monster has been published by Brown and Carmony (1991).

More recently the venom has been shown to contain a 25,376-kDa protein, helothermine, containing 223 amino acids and four pairs of disulfide bonds. Its mode of action appears to involve Ca^{2+} inhibitor from the sarcoplasmic reticulum (Morrissette et al., 1995). Its action on cerebellar granule cells has been described (Nobile et al., 1996). A fraction causing hemorrhage in internal organs and the eye, a glycoprotein of 210 amino acid residues with plasma kallikrein-like properties, has also been described (Dalla and Tu, 1997). According to Horikawa et al. (1998), a 35–amino acid residue, helodermin, that produces hypotension is partially attributed to activation of glibenclamide-sensitive K+ channels. Other definitive works on *Heloderma* venom have been published by Uddman et al. (1999) and Pohl and Waňk (1998). Treatment of Heloderma bites tends to be empiric. An experimental antivenom was once produced at the University of Southern California, but as an IgG product it elicited a large number of sensitivity reactions and its production was halted.

Snakes

From the beginnings of the human record, few subjects have stimulated minds and imaginations more than the study of snakes and snake venoms. No animal has been more worshiped yet more cast out, more loved yet more despised, more collected yet more trampled on than the snake. The essence of the fascination for and fear of snakes lies in their venom. In times past, the consequences of bites by venomous snakes often were attributed to forces beyond nature, sometimes to vengeful deities that were thought to be embodied in the serpents. To early peoples, the effects of snakebite were so surprising and violent that snakes and their poisons were shrouded with myth and superstition.

Among the more than 3500 species of snakes, approximately 400 are considered sufficiently venomous to be dangerous to humans (Dowling et al., 1968; Minton and Minton, 1969; Harding and Welch, 1980; Russell, 1980b, 1983; Junghanss and Budio, 1996). Venomous species can be divided into the Elapidae—the cobras, kraits, mambas, and coral snakes; the Hydrophiidae—the true sea snakes; the Laticaudidae—the sea kraits; the Viperidae—the Old World vipers and adders and the New World Crotalidae (now a subfamily), the rattlesnakes, water moccasins, copperheads, fer-de-lances, and bushmasters and some Asian species; and certain Colubridae, of which clinically the most important are the boomslang and bird snake of Africa and the rednecked keelback of Asia. However, several other colubrids must be viewed with concern (Minton and Minton, 1969; Minton, 1976; Mebs, 1977). There are no poisonous snakes in New Zealand, Hawaii, Ireland, and many other islands. Some medically important venomous snakes and their general distribution are shown in Table 26-3.

Table 26-3 Some Medically Important Snakes of the World

Snake Venoms The venoms of snakes are complex mixtures, chiefly proteins, a number of which have enzymatic activities. In some species the most active component of the venom is a peptide or polypeptide. Proteins and peptides make up about 90 to 95 percent of the dry weight of the venom. In addition, snake venoms contain inorganic cations such as sodium, calcium, potassium, magnesium, and small amounts of metals: zinc, iron, cobalt, manganese, and nickel. The importance of the metals in snake venoms is not clear, although in the case of some elapid venoms zinc ions appear to be necessary for anticholinesterase activity, and it has been suggested that calcium may play a role in the activation of phospholipase A and the direct lytic factor. Some proteases appear to be metalloproteins. Some snake venoms also contain carbohydrates (glycoproteins), lipids, and biogenic amines, whereas others contain free amino acid (Russell, 1967, 1980b, 1983; Tu, 1977; Elliott, 1978; Lee, 1979; Habermehl, 1981). A recent contribution on snake toxins, using mass spectrometric immunoassay and bioactive probe techniques, has been published by Tubbs et al. (2000).

Enzymes The venoms of snakes contain at least 25 enzymes, although no single snake venom contains all of them. Enzymes are the proteins responsible for the catalysis of many specific biochemical reactions that occur in living matter. They are the agents on which cellular metabolism depends. Enzymes are universally accepted as proteins, although a few have crucial dependencies on certain nonprotein prosthetic groups, or cofactors. All living cells contain enzymes. Some of the more important snake venom enzymes are shown in Table 26-4.

Proteolytic enzymes	Phosphomonoesterase
Arginine ester hydrolase	Phosphodiesterase
Thrombinlike enzyme	Acetylcholinesterase
Collagenase	RNase
Hyaluronidase	DNase
Phospholipase $A_2(A)$	5'-Nucleotidase
Phospholipase B	NAD-nucleotidase
Phospholipase C	L-Amino acid oxidase
Lactate dehydrogenase

Table 26-4 Enzymes of Snake Venoms

Proteolytic enzymes catalyze the breakdown of tissue proteins and peptides. They are known as proteolytic enzymes, peptide hydrolases, proteases, endopeptidases, peptidases, and proteinases. There may be several proteolytic enzymes in a single venom. The proteolytic enzymes have molecular weights between 20,000 and 95,000. Some are inactivated by edetic acid (EDTA) and certain reducing agents. The role of metal ions in catalysis was demonstrated many years ago by Wagner and Prescott (1966). Metals appear to be intrinsically involved in the activity of certain venom proteases and phospholipases.

The crotalid venoms examined so far appear to be rich in proteolytic enzyme activity. Viperid venoms have lesser amounts, whereas elapid and sea snake venoms have no proteolytic activity or very little. Venoms that are rich in proteinase activity are associated with marked tissue destruction.

Arginine ester hydrolase is one of a number of noncholinesterases found in snake venoms. The substrate specificities are directed to the hydrolysis of the ester or peptide linkage, to which an argine residue contributes the carboxyl group. This activity is found in many crotalid and viperid venoms and some sea snake venoms but is lacking in elapid venoms with the possible exception of *Ophiophagus hannah.* It was first demonstrated by Deutsch and Diniz (1955) in 15 snake venoms and subsequently has been identified in many others. Some crotalid venoms contain at least three chromatographically separable arginine ester hydrolases. The bradykinin-releasing and perhaps bradykinin-clotting activities of some crotalid venoms may be related to esterase activity.

Thrombin-like enzymes are found in significant amounts in the venoms of the Crotalidae and Viperidae, whereas those of Elapidae and Hydrophiidae contain little or none. The mechanism of fibrinogen clot formation by snake venom thrombin-like enzymes invokes the preferential release of fibrinopeptide A (or B); thrombin releases fibrinopeptides A and B. Paradoxically, the thrombin-like enzymes have been shown to act as defibrinating anticoagulants in vivo, whereas in vitro they clot plasma, citrated or heparinized plasma, or purified fibrinogen. Because of the obvious clinical potential of these enzymes as defibrinating agents, more attention has been directed toward the characterization and study of the thrombin-like enzymes than toward those of the other venom procoagulant or anticoagulant enzymes. The proteolytic action of thrombin and thrombin-like snake venom enzymes is shown in Table 26-5. This table also shows comparisons of ancrod (from *Calloselasma rhodostoma*), batroxobin (from *Bothrops moojen*i), crotalase (from *Crotalus adamanteus*), gabonase (from *Bitis gabonica*), and venzyme (from *Agkistrodon contortrix*); while Table 26-6 shows the molecular size of some thrombin-like enzymes.

Table 26-5 Proteolytic Action of Thrombin and Thrombin-like Snake Venom Enzymes

Table 26-6 Comparison of Snake Venom Thrombin-like Enzymes

Thrombin-like enzymes have been purified from the venoms of *Crotalus adamanteus* (crotalase) *Crotalus horridus horridus, Calloselasma (Agkistrodon) rhodostoma* (ancrod), *Agkistrodon contortrix contortrix, Deinagkistrodon (Agkistrodon) acutus, Bothrops atrox* (batroxobin), *Bothrops marajoensis, Bothrops moojeni, Trimeresurus gramineus, Trimeresurus okinavensis, and Bitis gabonica.* All these enzymes appear to be glycoproteins; with the exception of two, they appear to have molecular weights in the range of 29,000 to 35,000.

Thrombin-like enzymes have been used clinically and in animals for therapeutic and investigative studies. In experimentally induced venous thrombosis in dogs, treatment with ancrod before the formation of the thrombus prevented thrombosis and ensured vessel patency. However, ancrod had no thrombolytic effect when administered after thrombus formation. Trials of ancrod versus heparin and ancrod versus streptokinase in the treatment of deep venous thromboses of the lower leg have been conducted. Crotalase has been employed to evaluate the role of fibrin deposition in burns in animals (Bajwa and Markland, 1976). The role of fibrin deposition has been evaluated in tumor metastasis, in which fibrinogen is removed by treatment with ancrod or batroxobin. Ancrod also has been used to prevent the deposition of fibrin on prosthetic heart valves implanted in calves (Russell, 1980b, 1983). Ancrod and batroxobin have been used as defibrinogenating agents in clinical conditions of deep venous thrombosis, myocardial infarction, pulmonary embolus, central retinal vein occlusion, peripheral vascular disease, stroke, angina, glomerulonephritis, and renal transplant rejection (Markland, 1998).

Considerable study has been given to the hemostatic properties of venoms (Meier and Stocker, 1991; Ouayang and Huang, 1992; Hutton and Warrell, 1993; Marsh, 1994; Markland, 1998). The hemostatically active components are summarized in Table 26-7.

Table 26-7 Snake Venom Proteins Active on the Hemostatic System

Collagenase is a specific kind of proteinase that digests collagen. This activity has been demonstrated in the venoms of a number of species of crotalids and viperids. The venom of *Crotalus atrox* digests mesenteric collagen fibers but not other protein. EDTA inhibits the collagenolytic effect but not the argine esterase effect.

Hyaluronidase catalyzes the cleavage of internal glycoside bonds in certain acid mucopolysaccharides. This results in a decrease in the viscosity of connective tissues. The breakdown in the hyaluronic barrier allows other fractions of venom to penetrate the tissues. The enzyme is thought to be related to the extent of edema produced by the whole venom, but the degree to which it contributes to clinical swelling and edema is not known. The enzyme also has been referred to as the "spreading factor."

Phospholipase enzymes are widely distributed throughout the tissues of animals, plants, and bacteria. Some venoms are the richest sources of phospholipase A_2 (PLA_2) enzymes. PLA_2 catalyzes the Ca^{2+}-dependent hydrolysis of the 2-acyl ester bond, producing free fatty acids and lysophospholipid. Many PLA_2s have been sequenced. They have approximately 120 amino acids and 14 Cys residues forming seven disulfide bonds. The enzymes are widely distributed in the venoms of elapids, vipers, crotalids, atractaspids, sea snakes, and several colubrids so far studied. Although the sequences of these enzymes are homologous and their enzymatic active sites are identical, they differ widely in their pharmacologic properties. For example, taipoxin, a PLA_2 enzyme from the venom of the Australian elapid *Oxyuranus scutellatus,* has an intravenous LD_{50} in mice of 2 μg/kg, whereas the neutral PLA_2 from *Naja nigricollis* has an LD_{50} of 10,200 μg/kg, even though *N. nigricollis* PLA_2 is enzymatically more active.

Recent studies have shown that PLA_2 enzymes can exert their pharmacologic effects by different mechanisms: hydrolysis of membrane phospholipids, liberation of pharmacologically active products, and effects independent of enzymatic action. Similarly, snake venom PLA_2 enzymes can be separated into three major groupings depending on their pharmacologic activities: low-toxicity enzymes (LD_{50} > 1 mg/kg), high-toxicity enzymes (1 mg/kg > LD_{50} > 0.1 mg/kg), and presynaptically acting toxins (LD_{50} < 0.1 mg/kg). Interested readers are referred to reviews by Rosenberg (1978, 1979, 1990).

Phosphomonoesterase (phosphatase) is widely distributed in the venoms of all families of snakes except the colubrids. It has the properties of an orthophosphoric monoester phosphohydrolase. There are two nonspecific phosphomonoesterases, and they have optimal pH at 5.0 and 8.5. Many venoms contain both acid and

alkaline phosphatases, whereas others contain one or the other.

Phosphodiesterase has been found in the venoms of all families of poisonous snakes. It is an orthophosphoric diester phosphohydrolase that releases 5-mononucleotide from the polynucleotide chain and thus acts as an exonucleotidase, attacking DNA and RNA. More recently, it has been found that it also attacks derivatives of arabinose.

Acetylcholinesterase was first demonstrated in cobra venom and is widely distributed throughout the elapid venoms. It is also found in sea snake venoms but is totally lacking in viperid and crotalid venoms. It catalyzes the hydrolysis of acetylcholine to choline and acetic acid. The role of the enzyme in snake venoms is not clear.

RNase is present in some snake venoms in small amounts as the endopolynucleotidase RNase. It appears to have specificity toward pyrimidine-containing pyrimidyladenyl bonds in DNA. The optimum pH is 7 to 9 when ribosomal RNA is used as the substrate. This enzyme in *Naja oxiana* venom has a molecular weight of 15,900.

DNase acts on DNA and gives predominantly tri- or higher oligonucleotides that terminate in 3' monoesterified phosphate. *Crotalus adamanteus* venom contains two DNases, with optimum pH at 5 and 9.

5'-Nucleotidase is a common constituent of all snake venoms; in most instances it is the most active phosphatase in snake venoms. It specifically hydrolyzes phosphate monoesters, which link with a 5' position of DNA and RNA. It is found in greater amounts in crotalid and viperid venoms than in elapid venoms. The molecular weight as determined from amino acid composition and gel filtration with *Naja naja atra* venom has been estimated at 10,000. The enzyme from *N. naja* venom is enhanced by Mg^{2+}, is inhibited by Zn^{2+}, is inactivated at 75°C at pH 7.0 or 8.4, and has an isoelectric point of about 8.6. That from *Agkistrodon halys blomhoffi* shows a pH optimum of 6.8 to 6.9, with activity being enhanced by Mg^{2+} and Mn^{2+} and inhibited by Zn^{2+}. The enzyme has a low order of lethality, and its pharmacologic role in the venom is not understood (Russell, 1980b, 1983).

Nicotinamide adenine dinucleotide (NAD) nucleotidase has been found in a number of snake venoms. This enzymes catalyzes the hydrolysis of the nicotinamide N-ribosidic linkage of NAD, yielding nicotinamide and adenosine diphosphate riboside. Its optimum pH is 6.5 to 8.5; it is heat-labile, losing activity at 60°C. Its toxicologic contribution to snake venoms is not understood.

L-Amino acid oxidase has been found in all snake venoms examined so far. It gives a yellow color to the venom. This enzyme catalyzes the oxidation of L-a-amino and a-hydroxy acids. This activity results from a group of homologous enzymes with molecular weights ranging from 85,000 to 150,000. It has a high content of acidic amino acids. We found that the mouse intravenous LD_{50} of the enzyme from *Crotalus adamanteus* venom was 9.13 mg/kg body weight, approximately 4 times less than the lethal value of the crude venom, and that this enzyme had no effect on nerve, muscle, or neuromuscular transmission (Russell, 1980b, 1983).

Lactate dehydrogenase catalyzes the equilibrium between lactic acid and pyruvic acid. It is found in almost all animal tissues. It is a tetramer of 140,000 kDa and consists of two subunits of about 35,000 kDa.

Polypeptides Snake venom polypeptides are low-molecular-weight proteins that do not have enzymatic activity. During the past 30 years, a number of peptides of snake venoms have been characterized. In 1965, the first paper on the amino acid composition of a snake venom peptide was published (Yang, 1965), and at the First International Symposium on Animal Toxins in 1966, Tamiya presented a paper on the chromatography, crystallization, electrophoresis, ultracentrifugation, and amino acid composition of the venom of the sea snake *Laticauda semifasciata.* Most of the lethal activity of the poison was recovered as two toxins, erabutoxin a and b, using carboxymethylcellulose chromatography; 30 percent of the proteins were erabutoxins. The homogeneity of the crystalline toxins was demonstrated by rechromatography, disk electrophoresis, and ultracentrifugation (Tamiya et al., 1967). At the same meeting, Su and colleagues (1967) reported the isolation of a cobra "neurotoxin." The toxin was separated by repeated fractionation with ammonium sulfate. Since 1966, more than 80 polypeptides with pharmacologic activity have been isolated from snake venoms. Interested readers will find definitive reviews on these peptides in the works of Tu (1977), Elliott (1978), Rosenberg (1978), Lee (1979), Eaker and Wadstrom (1980), and Gopala-krishnakone and Tan (1992). More recently, erabutoxin a (Ea), a short-chain curamimetic, has been crystallized in monomeric and dimeric forms (Nastopoulos et al., 1998). Erabutoxin b (Eb) is said to be relatively ineffective at the mammalian neuromuscular junction (Vincent et al., 1998). Another curamimetic, a long-chain polypeptide, is alpha-cobratoxin, while a novel "neurotoxin" from *N. naja atra,* having 61 amino acid residues and 8 cystine residues, has been isolated by Chang et al. (1997).

In 1938, Slotta and Fraenkel-Conrat isolated a crystalline protein from the venom of the tropical rattlesnake *Crotalus durissus terrificus.* The protein exhibited most of the toxic properties of the crude venom and was named crotoxin. In addition to the toxic nonenzymatic protein portion, it was found to contain the enzymes hyaluronidase and phospholipase and possibly several others. It did not appear to have proteolytic or coagulant properties or 5'-nucleotidase activity, but it had neurotoxic, indirect hemolytic, and smooth muscle–stimulating properties. After removal of phospholipase A, crotoxin was further separated into a general toxic principle known as crotactin, which was found to have a greater lethal index than that of crotoxin, and a second component that may have been crotamine. The word *crotoxin* has been retained in one form or another in the literature as an identification for 17 different separations of the venom of *C. durissus terrificus* over the past 50 years. This has resulted in considerable confusion and disputes on research techniques, which could be more easily resolved on the basis of a frank statement about the method of isolation. For a thorough review of crotoxin, see Haberman and Breithaupt (1978).

At present, crotoxin is considered a neurotoxic and cytolytic PLA_2 of 30 kDa consisting of two dissimilar subunits: (1) an acidic, nontoxic component (crotapotin) without enzymatic activity and (2) a basic, weakly toxic PLA_2 component. Crotoxin accounts for about 50 percent of the total protein of the venom. The full activity of the complex requires the two components. The principal pharmacologic property appears to be the presynaptic interference with acetycholine release, and secondarily the densensitization of the acelycholine receptor (Haberman and Briethaupt, 1978, Bon et al., 1989, Fortes-Dias et al., 1999). A rabbit-raised antivenom neutralizes the lethal properties of the venom more than an equine preparation (Oshima-Franco et al., 1999). Mojave toxin, from the venom of the rattlesnake *Crotalus scutulatus scutulatus,* is similar to crotoxin. It contains 123 amino acid residues and has an estimated molecular weight of 14 kDa.

Toxicology It is not within the scope of this chapter to discuss all the pharmacologic activities of snake venoms. Interested readers are referred to Russell (1967), 1983, Mebs (1978), to the journal *Toxicon,* and to articles, in the compendia of the *International Society on Toxinology* for a more thorough consideration of the specific toxicologic effects of these poisons and their components. Since these earlier studies, more than 520 papers have been published on the toxinologic and biochemical properties of snake venoms. Some remarks, however, may be made about the venoms of the North American crotalids, particularly the rattlesnakes. The LD_{50}s of some North American snake venoms are shown in Table 26-8.

VENOM	INTRAVENOUS	INTRAPERITONEAL	SUBCUTANEOUS
Crotalus viridis helleri	1.29	1.61	3.65
Crotalus adamanteus	1.88	1.91	13.75
Crotalus atrox	2.18	3.71	17.75
Crotalus scutulatus	0.21	0.23	0.31
Agkistrodon piscivorus	4.17	5.11	25.10
Agkistrodon contortrix	10.92	16.51	26.00
Sistrurus miliarus	2.91	6.86	25.00

NOTE: All determinations were made at 25-g lethal dose of the same group. All mice were counted within a 14-h period and were observed for 30 h.

SOURCE: Russell, 1983, with permission.

Table 26-8 LD$_{50}$ by Different Routes of Injection

In general, the venoms of rattlesnakes and other New World crotalids produce alterations in the resistances (and often the integrity) of blood vessels, changes in blood cells and blood coagulation mechanisms, direct or indirect changes in cardiac and pulmonary dynamics, and—with crotalids like *C. durrissus terrificus* and *C. scutulatus*—serious alterations in the nervous system and changes in respiration. In humans, the course of the poisoning is determined by the kind and amount of

venom injected; the site where it is deposited; the general health, size, and age of the patient; the kind of treatment; and those pharmacodynamic principles noted earlier in this chapter. Clinical experience indicates that death in humans may occur within less than 1 h or after several days, with most deaths occurring between 18 and 32 h. Hypotension or shock is the major therapeutic problem in North American crotalid bites. In some cases the hypotension is associated with acute blood loss secondary to bleeding and/or hemolysis, but in most patients shock is associated with a decrease in circulating fluid volume, with varying degrees of blood cell loss. It is not surprising, therefore, to find that numerous studies have been directed at determining the mechanisms responsible for snake venom poisoning, hypotension, and shock. These studies have been reviewed elsewhere (Russell, 1983).

Experimentally, it has been found that an intravenous bolus injection of a *Crotalus* venom causes an immediate fall in blood pressure and varying degrees of shock, associated with initial hemoconcentration followed by a decrease in hematocrit values. There is increased blood volume in the lungs, an increase in pulmonary artery pressure with a concomitant decrease in pulmonary artery flow, and a relatively stable heart stroke volume (Russell et al., 1962).

Carlson and colleagues (1975) observed that when *Crotalus* venom is given intravenously and slowly over a 30-min period, there is hypovolemia secondary to an increase in capillary permeability to protein and red blood cells. The laboratory findings showed initial hemoconcentration, lactacidemia, and lipoproteinemia. In cats the same findings are seen, followed by a fall in hematocrit and in some cases hemolysis related to the dose of venom. During this period the cat may be in shock or at a near-shock level, depending on the amount of venom injected or perfused. Respirations become labored, and if the period is prolonged, the animal becomes oliguric, rales develop, and the animal dies.

There appears to be no doubt that the shock or hypotension is caused by a decrease in circulating blood volume secondary to an increase in capillary permeability, which leads to the loss of fluid, protein, and to some extent erythrocytes. The severity of the hypotension is dose-related, and restoration of circulating fluid volume can be achieved with intravenous fluids. In patients with hypovolemic shock due to venom, steroids are of no value, but the use of isoproterenol hydrochloride may be indicated. Antivenom in itself may not reverse a deep shock state, but a combination of parenteral fluids or plasma expanders, isoproterenol hydrochloride, and antivenom is definitely of value. Evidence to the present time indicates that the fraction of the venom that most probably is responsible for the circulatory failure is a peptide. The properties of this peptide have been presented elsewhere (Russell, 1996).

Snakebite Treatment The treatment of bites by venomous snakes is now so highly specialized that almost every envenomation requires specific recommendations. However, three general principles for every bite should be kept in mind: (1) snake venom poisoning is a medical emergency requiring immediate attention and the exercise of considerable judgment; (2) the venom is a complex mixture of substances of which the proteins contribute the major deleterious properties, and the only adequate antidote is the use of specific or polyspecific antivenom; (3) not every bite by a venomous snake ends in an envenomation. Venom may not be injected. In almost 1000 cases of crotalid bites, 24 percent did not end in a poisoning. The incidence with the bites of cobras and perhaps other elapids is probably higher. In the United States, 14 percent of crotalid bites are so trivial that antivenom is not recommended. It would be difficult to detail specific treatments for the almost 400 snakes implicated in snake venom poisoning. Perhaps several recent works will suffice. For the United States, Russell (1980, 1983, 1996, 1998), Dart and Russell (1992), and Heard et al. (1999); for Europe, Persson and Karlson-Stiber (1996) and Sorkine et al. (1996); for Africa, Visser and Chapman (1978) and Chippaux et al. (1996); for Central America, Russell (1997); for Australia, Sutherland (1983) and White (1996); for the carpet viper, Warrell and Arnett (1976); for Russell's viper, Warrell (1989); and in general (worldwide), Dowling et al. (1968), Russell (1983), Warrell (1996), and Junghanss and Bodio (1996).

ANTIVENOM

Because of their protein composition, many toxins produce an antibody response; this response is essential in producing antisera. An antivenom consists of venom-specific antisera or antibodies concentrated from immune serum to the venom. Antisera contain neutralizing antibodies: one antigen (monospecific) or several antigens (polyspecific). Animals immunized with venom develop a variety of antibodies to the many antigens in the venom. The serum is harvested, partially or fully purified, and further processed before being administered to the patient. The antibodies bind to the venom molecules, rendering them ineffective. Antivenoms have been produced against most medically important snake, spider, scorpion, and marine toxins.

Antivenoms are available in several forms: intact IgG antibodies or fragments of IgG such as $F(ab)_2$ and Fab. They are prepared through $(NH_4)_2SO_4$ or Na_2SO_4 precipitation, pepsin or papain digestion, and other procedures, among which the elimination of the Fc, or complement-binding and complement-sensitizing fraction, is one of the most important. The molecular weight of the intact IgG is about 150,000, whereas that of Fab is approximately 50,000.

The molecular size of IgG prevents its renal excretion and produces a volume of distribution much smaller than that of Fab. The elimination half-life of IgG in the blood is approximately 50 h. Its ultimate fate is not known, but most IgG is probably taken up by the reticuloendothelial system and degraded with the antigen attached. Fab fragments have an elimination half-life of about 17 h, and are small enough to permit renal excretion.

Since all antivenom products are produced through the immunization of animals, this increases the possiblity of hypersensitivity. Type I (immediate) hypersensitivity reactions are caused by antigen cross-linking of endogenous IgE bound to mast cells and basophils. Binding of antigen by a mast cell may cause the release of histamine and other mediators, producing an anaphylactic reaction. Once initiated, anaphylaxis may continue despite discontinuation of antivenin administration. An additional concern is an *anaphylactoid* reaction. This is a term for a syndrome resembling an anaphylactic reaction; its etiology is unknown but it appears to be associated with aggregated protein in the antiserum. Protein aggregates may activate the complement cascade, producing an anaphylactic-like syndrome. An important difference between anaphylactic and anaphylactoid reactions is that anaphylactoid reactions are dose-dependent and may be halted by removing the antigen. Type III hypersensitivity (serum sickness) may develop several days after antivenom administration. In these cases, antigen-antibody complexes are deposited in different areas of the body, often producing inflammatory responses in the skin, joints, kidneys, and other tissues. Fortunately, these reactions are rarely serious. The risks of anaphylaxis should always be considered when one is deciding whether to administer antivenom.

It has been said, principally by nonclinical researchers, that antivenoms have little effect on the local tissue changes produced by snake venoms. Perhaps this opinion now needs to be reevaluated on the basis of new knowledge and experience. The supposition is based on the early clinical experience, where antivenom doses were obviously too low to effectively neutralize *all* the deleterious activities of a venom. For instance, in 1950 the dose of Antivenom [Crotalidae] Polyvalent for a minimal crotalid envenomation was 1 to 3 vials, for a moderate envenomation 3 to 5 vials, and for a severe envenomation, 5 to 8 vials. By 1970, these doses had been revised upward (Russell, 1980), and at the present time the average dose of this antivenom in the United States is 11.3 vials, with the average dose at the author's medical center being 17 and as many as 50 vials having been given. Also, hospital time has been reduced from 5 to 8 days to 2 to 3 days, and patients leave the hospital with little or no local tissue destruction.

It has become evident that the ability of an effective antivenom to alleviate or neutralize the deleterious properties of a venom should be dependent on its ability to neutralize the effects of the *whole* venom, and that up until the not too distant past, antivenoms were judged solely on the basis of their ability to neutralize the lethal effect of a venom. I suggest that the best solution at this time is just to use more antivenom. Apparently, the ability of the antigen(s) to produce the antibody(ies) necessary to neutralize the cytolytic effect is either too weak or too small in quantity to stimulate the neutralization necessary to alleviate the cytolytic effects of the venom to the level of other antigen/antibody reactions.

In the United States a new Fab antivenom, CroFab, has been developed by Therapeutic Antibodies (now Protheric). It is an ovine antiserum. One of its advantages over the IgG product is that the former reaches its maximum protein level in the blood in 20 to 25 min, while the IgG product requires 40 to 50 min to reach the same level. Experiences with the efficacy and safety of the CroFab antivenom are found in Dart et al. (1997) and Seifert et al. (1997). It has become obvious that the use of this product may require periodic administration rather than single-bolus doses of the antivenom (Boyer et al., 1999).

TOXIC EFFECTS OF PLANTS

Stata Norton

INTRODUCTION

In the course of evolution, plants have been attacked by pathogens (viruses, bacteria, and fungi) and eaten by animals from insects to elephants. In response, plants have developed various elegant defenses, including synthesis of chemicals that inhibit the actions of pathogens and rapidly acting chemicals designed to deter attack by inducing negative effects on the gastrointestinal, cardiac, or nervous systems of plant predators. The quickest way for a plant to protect itself from being eaten is to produce chemicals that are irritating on contact. Nausea and gastric irritation occurring in close conjunction with ingestion are also effective deterrents.

Of the many species of plants that contain toxic chemicals, only a few can be described here. Selection has been based on three considerations: frequency with which contact occurs, importance and seriousness of toxic effect, and scientifically interesting nature of the action of the chemical.

It is important to note that toxic effects of the same species of plant may vary with differences in production of the toxic chemical by plants. The reasons for variability in concentration of toxic chemicals are several:

1. Different portions of the plant (root, stem, leaves, seeds) often contain different concentrations of a chemical. For example, paclitaxel (Taxol), an antineoplastic drug from species of *Taxus* (yew), is present in various parts of *Taxus cuspidata.* The needles, bark, wood, and mature cones contain, in that order, decreasing concentrations of paclitaxel (Fett-Netto and DiCosmo, 1992).
2. The age of the plant contributes to variability. Young plants may contain more or less of some constituents than mature plants. For example, in spring pokeweed (*Phytolacca americana*), sprouts and young leaves are safer to eat than mature leaves. The saponin produced in pokeweed as it develops contributes to the toxicity of the mature plant (Blackwell, 1990).
3. Climate and soil influence the synthesis of some chemicals. For example, lichens produce carotenoids in direct relation to the amount of sunlight, with the advantage to the plant that carotenoids protect from excessive ultraviolet light (Czeczuga, 1988).
4. Genetic differences within a species may alter the ability of individual plants to synthesize a chemical. Synthesis of related toxic chemicals often is found in taxonomically related species as a characteristic of a genus and sometimes as a familial characteristic. For example, species of *Ranunculus* (buttercup) produce an acrid juice that releases the irritating chemical anemonin. Some other genera of the same family (Ranunculaceae) also release anemonin.

TOXIC EFFECT BY ORGAN

Skin

Allergic Dermatitis Most people are familiar with dermatitis caused by some plants, such as poison ivy. Equally familiar is the allergenic response of many individuals in the form of "hay fever" or summer rhinitis.

Philodendron (family Araceae, arum family) and *Rhus* (Ana-cardiaceae, cashew family) are not closely related plants, but species of both genera cause contact dermatitis as an allergic reaction. *Philodendron scandens* is a common houseplant, while *Rhus radicans* (poison ivy) is native to North America. In addition to poison ivy, the toxicodendron group of plants contains *Rhus diversiloba* (poison oak) and *Rhus vernix* (poison sumac). The active ingredients in *P. scandens* are resorcinols, especially 5-*n*heptadecatrienyl resorcinol (Knight, 1991). In *R. radicans,* the allergenic component is a mixture of catechols called urushiol. The most active compound in urushiol is 3-*n*-pentadecadienyl catechol, representing approximately 60 percent of urushiol (Johnson et al., 1972). As in allergies in general, there is no response to the initial exposure; even with repeated exposure, individuals show marked variation in severity of response. The allergens in urushiol will sensitize about 70 percent of persons exposed, making the response to poison ivy and related plants the most common form of allergic contact dermatitis in the United States. Urushiol is fat-soluble, penetrates the stratum corneum, and binds to Langerhans cells in the epidermis. These haptenated cells then migrate to lymph nodes, where T cells are activated; they then return to the skin, where they are involved in the dermatitis (Kalish and Johnson, 1990). Contact dermatitis also develops with repeated exposures to the sap of mango fruit, because the skin of the fruit contains oleoresins that cross-react with allergens of poison ivy (Tucker and Swan, 1998).

Flower growers and other individuals who handle bulbs and cut flowers of daffodils, hyacinths, and tulips sometimes develop dermatitis from contact with the sap. These conditions occur frequently enough to have achieved common names: "hyacinth itch," "daffodil itch," and "tulip fingers." The rashes are due to irritation from alkaloids (masonin, lycorin, and several related alkaloids) or to needle-like crystals of calcium oxalate in the bulbs (Gude et al., 1998). Most of these alkaloids do not act as allergens, but one, tulipalin-A, which causes "tulip fingers" from sorting and peeling tulip bulbs, has allergenic properties. Tulipalin-A, alpha-methylene-gamma-butyrolactone, is present in some cultivars in a concentration as high as 2 percent. A safe threshold for this allergen is considered to be a concentration of 0.01 percent (Hausen et al., 1983). The advantage to the plant of the tulipalins is not their allergenic properties but that they are strong antifungal agents (Christensen and Kristiansen, 1999).

The allergens of plants tend to be located in the outer cell layers of plant organs. In allergic contact dermatitis to chrysanthemums (*Dendranthema* species), the allergens are sesquiterpene lactones present in small hairs (trichomes) on the stems, undersides of leaves, and in flowering heads (McGovern and Barkley, 1999).

An immunoglobulin-mediated hypersensitivity, called the *latex-fruit syndrome,* results in cross-sensitivity in some individuals to latex in rubber gloves and fruit. The major allergen in natural rubber latex from the rubber tree, *Hevea brasiliensis,* is prohevein, a chitin-binding polypeptide found in several plants. Hevein, a 43–amino acid N-terminal fragment of prohevein, is the major binding component (Alenius et al., 1996). Individuals sensitive to latex rubber may be sensitized to several fruits containing a chitinase with a hevein-like domain, including banana, kiwi, tomato, and avocado (Blanco et al., 1999).

Pollen from several genera in the family Asteraceae (for example, mugwort, *Artemisia vulgaris* in Europe, and ragweed, *Ambrosia artemisiifolia* in North America) contains allergens causing summer rhinitis. Immunoglobulin antibodies produced by sensitized individuals cross-react with mugwort and ragweed pollen. The cross-reactive allergen has been identified as a highly conserved 14-kDa protein, profilin, found as well in birch pollen (Hirschwehr et al., 1998).

Allergy to grass pollen is worldwide in occurrence and causes serious morbidity and economic cost. Individuals with grass pollen allergy react to pollen from a number

of species. *Poa* and *Festuca* species are major contributors to the allergic response (Lovborg et al., 1999).

Contact Dermatitis One of the most common exposures to toxic substances in plants reported to poison-control centers in the United States is from the houseplant *Dieffenbachia* (dumb cane, arum family). Children and workers in plant nurseries are the usual patients. *Dieffenbachia* does not cause allergic dermatitis, but when leaves or stems are broken, the juice is immediately irritating to mucous membranes. Children may chew the leaves of the plant and workers in greenhouses cut the plant in the course of their work. Contact of the eye or tongue to the juice results in pain and rapid development of edema and inflammation, which may take days or weeks to subside. The toxicity is due to a combination of factors. The leaves contain irritating calcium oxalate crystals coated with a trypsin-like inflammatory protein. Release of a histamine-like or serotonin-like chemical may be involved in the immediate pain (Pamies et al., 1992). The needle-like crystals of calcium oxalate, called raphides, are located in ampule-shaped ejector cells throughout the surface of the leaf. Slight pressure on these cells causes expulsion of the raphides (McIntire et al., 1990).

Acute dermatitis is caused by contact with the trichomes of species of *Urtica* (nettles). Even gentle contact with the hairs causes pain and erythema from penetration of the skin by the trichomes. In the stinging nettles, *Urtica urens* and *Urtica dioica* (family Urticaceae), the trichomes covering the leaves and stems consist of fine tubes with bulbs at the end that break off in the skin and release fluid containing histamine, acetylcholine, and serotonin, causing the acute response (Oliver et al., 1991). Exposure to *Urtica ferox* (poisonous tree nettle), a plant widespread in New Zealand, has caused death in humans and animals. A defense against ingestion by animals, similar to that of nettles, has been developed by *Mucuna pruriens* (cowhage), a legume, with pods covered with barbed trichomes that cause pain, itching, erythema, and vesication. The trichomes of *M. pruriens* contain mucinain, a proteinase responsible for the pruritus (Southcott and Haegi, 1992).

Several species of *Ranunculus* (buttercup) cause contact dermatitis. These plants contain ranunculin, which releases the toxic principle protoanemonin, also present in *Anemone,* another genus of the buttercup family. Protoanemonin is readily converted to anemonin, which has marked irritant properties. Ingestion of plants containing protoanemonin may result in severe irritation of the gastrointestinal tract (Kelch et al., 1992).

The genus *Euphorbia* (Euphorbiaceae, spurge family) contains hundreds of species dispersed over temperate and tropical regions. Characteristically, the stems and leaves exude milky latex when damaged. The latex contains diterpene esters irritating to the skin. *Euphorbia marginata* (snow-on-the-mountain) is a common plant in the United States, growing wild from Minnesota to Texas and cultivated for its attractive foliage. Individuals using the plant in flower arrangements may come in contact with the latex and develop skin irritation (Urushibata and Kase, 1991). Serious eye irritation has been reported (Frohn et al., 1993). The latex of *Euphorbia pulcherrima,* poinsettia, cultivars of which are common house plants, may cause contact dermatitis (Massmanian, 1998), but the large number of exposures to poinsettia reported to poison-control centers result in minor irritation (Krenzelok et al., 1996). A major ester found in *Euphorbia resinifera* and several other species of *Euphorbia* is resiniferatoxin. It acts at the vanilloid receptor of the primary sensory neurons that mediate pain perception and neurogenic inflammation. Resiniferatoxin is a potent analog of capsaicin but desensitizes with less stimulation of the receptor than capsaicin. This property is being used to desensitize sensory neurons to mitigate neuropathic pain (Appendino and Scallazi, 1997).

Photosensitivity Not all cases of dermatitis from plants are due to skin contact. Poisoning of livestock from *Hypericum perforatum* (St. John's wort) has been reported in the United States, New Zealand, Australia, North Africa, Iraq, and Europe. The toxic principle is hypericin (hexahydroxydimethylnaphthodianthrone), which is present throughout the plant. Sheep are the most commonly affected animals, ingesting the plant in pasturage. The effect in sheep is development of edematous lesions of the skin, especially in areas not well covered with hair, including the ears, nose, and eyes. Hypericin causes photosensitization, and lesions appear after exposure to sunlight (Sako et al., 1993). In human consumption of St. John's wort, photosensitivity is a rare event (Ernst et al., 1998).

Gastrointestinal System

Direct Irritant Effects The most common outcome of ingestion of a toxic plant is gastrointestinal disturbance (nausea, vomiting, and diarrhea) from irritation of the mucous membranes. Many different kinds of chemicals are responsible for this. Some have found a place in medicine as mild purgatives, such as cascara sagrada ("sacred bark"). Cascara is obtained from the bark of *Rhamnus purshiana* (California buckthorn). The active ingredient is emodin.

Tung nut (*Aleurites fordi*) is grown widely in the world, including the southwestern United States, Taiwan, mainland China, Japan, and India. The seeds, from which commercially useful oil is expressed, are the most toxic part. Ingestion of the ripe nuts causes abdominal pain, vomiting, and diarrhea. Outbreaks of poisoning are most common in children (Lin et al., 1996).

Buffalo bean or buffalo pea (*Thermopsis rhombifolia*) is a legume growing wild in the western United States. Loss of life of livestock has been reported from consumption of the mature plant with seeds. Children develop nausea, vomiting, dizziness, and abdominal pain from eating the beans (McGrath-Hill and Vicas, 1997). The active toxic substances are quinolizidine alkaloids.

Aesculus hippocastanum (horse chestnut) and *Aesculus glabra* (Ohio buckeye) are common trees with attractive panicles of flowers in the spring. Nuts of both trees contain a glucoside called esculin. When eaten by humans, the main effect is gastroenteritis, which may be severe if several nuts are consumed. Esculin is poorly absorbed from the gastrointestinal tract of humans, and its systemic effects are limited. In cattle the glucoside may be hydrolyzed in the rumen, releasing the aglycone to cause systemic effects. Cattle develop signs of nervous system stimulation—a stiff-legged gait and, in severe poisoning, tonic seizures with opisthotonus (Casteel et al., 1992). While the most common poisoning of cattle occurs from ingestion of nuts, they may also be poisoned in pasture in spring by eating new leaves and buds.

Antimitotic Effects *Podophyllum peltatum* (May apple) contains the toxic purgative podophyllotoxin, especially in foliage and roots. In low doses, mild purgation predominates. Overdose results in nausea and severe paroxysmal vomiting (Frasca et al., 1997). Podophyllotoxin inhibits mitosis by binding to microtubules, and this property has made the toxin of interest in the treatment of cancer (Schacter, 1996).

Colchicine is best known in western medicine for its antimitotic effect, which is particularly useful in attacks of gout. Colchicine is the major alkaloid in the bulbs of *Colchicum autumnale* (autumn crocus, lily family), native to Asia Minor. Severe gastroenteritis (nausea, vomiting, diarrhea, and dehydration) follows ingestion of the bulbs. Systemic effects may develop, including confusion, delirium, hematuria, neuropathy, and renal failure. Bone marrow aplasia results from block of mitosis in bone marrow. The antimitotic action is caused by block of the formation of microtubules and subsequent failure of the mitotic spindle. Additional toxic effects may be due to lectins in the plant. Several plants, including *Colchicum autumnale,* contain lectins that are potent inducers of a gelatinase by mononuclear white blood cells. It has been suggested that the acute toxicity of many plant lectins may be partially mediated by induction of gelatinase from leukocytes (Dubois et al., 1998). High circulating levels of gelatinase have been shown to be present in circulatory shock.

In southern Europe, hay for cattle may contain the wild autumn crocus and deaths occur if contamination is heavy. In other countries similar poisoning has been found after human ingestion of tubers of *Gloriosa superba* (glory lily), an ornamental lily that contains colchicine. The plant grows wild in Sir Lanka, and poisoning by *Gloriosa* tubers has been reported as the most common plant poisoning in that country. Poisoning has also been reported in India (Mendis, 1989).

Lectin Toxicity *Wisteria floribunda* (family Leguminosae) is a common ornamental climbing vine or small tree with lilac-colored flowers from which pods containing several seeds develop in the fall. The plant is of interest as a research tool because the seeds contain a lectin with affinity for *N*-acetylglucosamine on mammalian neurons. The lectins of legumes are a well-studied family of plant proteins with a wide repertoire of binding to specific cell-surface carbohydrates. Wisteria species also contain saponins (Nohara et al., 1996). The seeds of wisteria cause severe gastroenteritis when ingested. A few seeds can result in headache, nausea, and diarrhea within hours, followed by dizziness, confusion, and hematemesis (Rondeau, 1993).

Ricinus communis (castor bean) is a member of the family Euphorbiaceae, which contains several genera that produce toxic chemicals. The castor bean is an ornamental plant introduced from India and grown in temperate regions as an annual. The seeds are large and attractively mottled. If the seeds are eaten, children and adults experience no marked symptoms of poisoning for several days. In this interval there is some loss of appetite, with nausea, vomiting, and diarrhea developing gradually. After that, gastroenteritis becomes severe, with persistent vomiting, bloody diarrhea, dehydration, and icterus in fatal cases. Death occurs in 6 to 8 days. The fatal dose for a child is 5 to 6 seeds; it is about 20 seeds for an adult. Postmortem examination shows foci of necrosis in the liver, spleen, lymph glands, intestine, and stomach. Fatality is low in individuals who eat the seeds—less than 10 percent when a "fatal" dose is consumed—because the toxic protein is largely destroyed in the intestine. Death from castor beans is caused by two lectins in the beans: ricin I and ricin II. The more toxic is ricin II. Ricin II consists of two chains of amino acids. The A chain (molecular weight 30,000) inactivates the 60s ribosomal subunit of cells by catalytic depurination of a single adenosine residue within the 28s rRNA (Bantel et al., 1999) and blocks protein synthesis. The A chain is endocytosed into the cell cytosol after the B chain (molecular weight 33,000) binds to a terminal galactose residue on the cell membrane. The two chains are linked by disulfide bonds. Similar toxic lectins are found in the seeds of *Abrus precatorius* (jequirity bean), attractive scarlet and black beans that are sometimes made into necklaces. Abrin-a, one of four isoabrins from the plant, has the highest

inhibitory effect on protein synthesis and consists of an A chain of 250 amino acids and a B chain of 267 amino acids (Tahirov et al., 1994). The LD$_{50}$ of abrin injected in mice is less than 0.1 µg/kg, making abrin one of the most toxic substances known.

Ricin-type lectins with both A and B chains are potentially deadly if they pass, even in small quantities, through the gastrointestinal tract. Plants that produce only A chains offer much less risk when ingested. Young shoots of pokeweed (*Phytolacca americana*) are sometimes used in the spring as a salad green. Mature leaves and berries may cause gastrointestinal irritation with nausea and diarrhea. The plant produces three isozymes of single-chain lectins (PAP, PAPII, and PAP-S; molecular weights about 30,000) that can inhibit protein synthesis in cells by inactivating rRNA. Single-chain, ribosome-inhibiting proteins do not enter intact cells readily, but if the cell membrane has been breached by a virus, they may enter the cell (Monzingo et al., 1993). Lectins that bind strongly to the cells lining the small intestine and are endocytosed by them may be "nutritionally toxic" if they are consumed over a long period. Experimentally, reduction in weight gain has been the major finding from the presence of high quantities of some lectins in the diet. A correlation between strength of binding to the brush border of the jejunum and effectiveness as an antinutrient has been reported (Pusztai et al., 1993).

Lung

In addition to the well-recognized involvement of the lung and airway tissues in allergic asthma in some individuals sensitized to plant allergens, the lung is directly affected by some plant chemicals.

Cough Reflex It has been found that workers who handle two peppers, *Capsicum annum* (cayenne pepper) and *Capsicum frutescens* (chili pepper), have a significantly increased incidence of cough during the day. The major irritant ingredients in *Capsicum* are capsaicin (trans-8-methyl-*N*-vanillyl-6-nonenamide) and dihydrocapsaicin (Surh et al., 1998). Capsaicin-sensitive nerves in the airway are involved in the irritation and cough (Blanc et al., 1991). Sensory endings of C fibers are part of the cough reflex, and the principal neurotransmitter for these fibers, the neuropeptide substance P, is depleted by capsaicin. Capsaicin activates a subtype of the vanilloid receptor found in the airway, spinal cord, dorsal root ganglion, bladder, urethra, and colon. Capsaicin can be irritating to the skin, and individuals handling the peppers may experience irritation and vesication.

Cell Death In the laboratory, rats are highly susceptible to monocrotaline from seeds of *Crotalaria spectabilis* (showy rattlebox, legume family) and develop a condition resembling pulmonary hypertension. In the rat, monocrotaline is converted in the liver into an active pyrrolic metabolite responsible for the cardiopulmonary lesions (Schultze et al., 1991). Apoptosis of arterial endothelial cells may be involved early in the onset of pulmonary hypertension (Thomas et al., 1998). In many other species, hepatitis is the primary toxicity.

Cardiovascular System

Cardioactive Glycosides Several disparate families of plants contain species with cardioactive glycosides, the best known of which is *Digitalis purpurea* (foxglove, Scrophulariaceae family). In the lily family, squill (*Scilla maritima*) contains scillaren, and lily of the valley (*Convallaria majalis*) contains convallatoxin in the bulbs. Both glycosides have actions resembling digitalis. Milkweeds (*Asclepias* species, Asclepiadaceae family) are noted for the glycosides in the plants, which are consumed by monarch butterfly caterpillars during their development. The glycosides are retained into the adult stage and help protect the butterflies from predators. The cardiac glycoside [6'-0-(E-4-hydroxycinnamoyl) desglucouzarin] in *Asclepias asperula,* like digitalis, inhibits Na$^+$,K$^+$-ATPase (Abbott et al., 1998). Two plants in the Apocynaceae family contain cardiac glycosides. *Nereum oleander* (bay laurel) is native to the Mediterranean area but is grown ornamentally in many regions. The major glycosides, oleandrin and nerium, may be present in concentrations as high as 0.5 mg/g plant material. Animals and humans have been poisoned by eating the leaves or seeds. The effect is identical to that of digitalis toxicity: nausea, vomiting, and cardiac arrhythmias (Clark et al., 1991). A related plant, *Thevetia peruviana* (yellow oleander), is a common ornamental in the United States. Human poisoning has also been reported in Australia, Melanesia, Thailand, and India. The seeds are the major source of the cardiac glycosides, the most active of which is thevetin A. The fatal dose to an adult is 8 to 10 seeds (Prabhasankar et al., 1993).

Action on Cardiac Nerves *Veratrum viride* (American hellebore, lily family), native to eastern North America, produces several toxic alkaloids that are distributed in all parts of the plant. European hellebore (*Veratrum album*) and *Veratrum californicum* in western North America have similar alkaloids. *V. album* was part of the "vegetable materia medica" for centuries, employed to "slow and soften the pulse." These species of *Veratrum* contain a mixture of alkaloids, including protoveratrine, veratramine, and jervine. After ingestion, the alkaloids cause nausea, emesis, hypotension, bradycardia, and sometimes muscle spasm. The primary effect of the veratrum alkaloids on the heart is to cause a repetitive response to a single stimulus resulting from prolongation of the sodium current (Jaffe et al., 1990). Several species of *Zigadenus,* including *Zigadenus nuttalli* (death camas), contain *Veratrum*-like alkaloids. The plants grow throughout North America and the white bulbs may be mistaken for wild onions. Cattle are also poisoned in pastures where the plants are common. All parts of the plant are toxic (Heilpern, 1995).

Aconitum species have been used in western and eastern medicine for centuries. The European plant, *Aconitum napellus* (monkshood, Ranunculaceae family), is a perennial grown in gardens for its ornamental blue flowers. The roots of *Aconitum kusnezoffi* (chuanwu) and *Aconitum carmichael* (caowu) are in the Chinese materia medica. Poisoning may occur from intentional or accidental ingestion, and the concentration of the alkaloids—aconitine, mesaconitine, and hypoaconitine—varies depending on species, place of origin, time of harvest, and processing procedure (Chan et al., 1994). In addition to cardiac arrhythmias and hypotension, the alkaloids cause gastrointestinal upset and neurologic symptoms, especially numbness of the mouth and paresthesia in the extremities. The alkaloids cause a prolonged sodium current in cardiac muscle with slowed repolarization (Peper and Trautwein, 1967). The neurologic effects are due to a similar action on voltage-sensitive sodium currents in nerve fibers (Murai et al., 1990).

In Greece almost 2500 years ago, Xenophon described a serious condition called "mad honey poisoning" that developed in his soldiers after they had consumed honey. It consists of marked bradycardia, hypotension, oral paresthesias, weakness, and gastrointestinal upset, resembling aconitine poisoning. In severe poisoning there is respiratory depression and loss of consciousness. The condition is caused by eating honey contaminated with grayanotoxins. Some of the action of grayanotoxins is central. Grayanotoxin I (acetylandromedol) slows both the opening and closing of sodium channels in nerves (Narahashi, 1986). Honey poisoning has been reported in Turkey, Japan, Nepal, Brazil, Europe, and some parts of North America. Grayanotoxins are produced exclusively by several genera of Ericaceae (heath family). They have been isolated from *Rhododendron ponticum* (Onat et al., 1991) and *Kalmia angustifolia* (Burke and Doskotch, 1990). The toxin gets into honey from nectar collected by bees from the flowers. The grayanotoxins are present throughout the plants, including leaves, flowers, pollen, and nectar. Livestock have been poisoned by eating leaves of the plants. Toxicity has been reported in goats and sheep eating leaves of *Rhododendron macrophyllum* (Casteel and Wagstaff, 1989).

Vasoactive Chemicals Mistletoe is a parasitic plant on trees and has over the centuries been considered either holy or demonic. The poisonous qualities of mistletoe were recognized by John Gerarde in his herbal in 1597. He described a case of poisoning from mistletoe berries in which the tongue was inflamed and swollen, the mind distraught, and strength of heart and wits enfeebled. The mistletoe that appears in shops at Christmastime in the United States is *Phoradendron tomentosum,* a member of the same family as European mistletoe (*Viscum album,* Loranthaceae family). The American mistletoe contains phoratoxin, a polypeptide with a molecular weight of about 13,000. Experimentally, phoratoxin produces effects in animals that resemble the effects of viscotoxins: hypotension, bradycardia, negative inotropic effects on heart muscle, and vasoconstriction of the vessels of skin and skeletal muscle. Phoratoxin is only one-fifth as active as the viscotoxins (Rosell and Samuelsson, 1988). Viscotoxins are basic polypeptides (molecular weight of about 5000). Serious poisoning from the plants is rare and includes gastrointestinal distress and hypotension.

Vasoconstriction is a primary toxic effect of some plant chemicals. Of the various fungi that produce toxic principles, some are parasitic or symbiotic on grasses used as food by humans and livestock. *Claviceps purpurea* (ergot) is a fungus parasitic on grains of rye. This fungus has caused outbreaks of unusual poisonings in several European countries since the Middle Ages. The condition was called "St. Anthony's fire" from the blackened appearance of the limbs of some sufferers. The main toxic effect of ergot alkaloids is vasoconstriction, primarily in the extremities, followed by gangrene. Abortion in pregnant women is also common after ingestion of contaminated rye flour. Ergot alkaloids are derivatives of lysergic acid. Some of the alkaloids have been used in therapeutics, especially ergotamine and ergonovine.

Another fungus, *Acremonium coenophialum,* grows symbiotically on the forage grass tall fescue (*Festuca arundinacea*) and produces some ergot alkaloids and other lysergic acid derivatives. The fungus causes "fescue toxicosis" in cattle grazing on infected plants (Hill et al., 1994). The condition in cattle includes decreased weight gain, decreased reproductive performance, and peripheral vasoconstriction. In the southwestern United States, *Stirpa robusta* (sleepy grass) also is infected with an *Acremonium* fungus. Horses grazing in areas where the infected perennial grass grows become somnolent, presumably as a result of ingesting lysergic acid amide, ergonovine, and related alkaloids produced by the fungus (Petroski et al., 1992).

Caulophyllum thalictroides (blue cohosh or papoose root, Berberidaceae family) contains a vasoactive glycoside and methylcytisine, causing coronary artery

vasoconstriction and uterine stimulation. Toxic effects on the fetal myocardium from maternal ingestion have been reported (Jones and Lawson, 1998).

Liver

Hepatocyte Damage In 1884 cases of "hepatitis" in cattle in Iowa were found to be caused by ingestion of species of *Senecio* (ragwort or groundsel, aster family). *Senecio* is a large genus of plants with worldwide distribution. Species containing significant concentrations of pyrrolizidine alkaloids are responsible for liver damage in the form of hepatic venoocclusive disease. Species of three other genera, *Crotalaria, Heliotropium,* and *Symphytum,* also contain pyrrolizidine alkaloids. *Heliotropium* and *Symphytum* are in the borage family. Different animal species show marked differences in susceptibility to pyrrolizidine alkaloids. Susceptible species are rats, cattle, horses, and chickens; resistant species are guinea pigs, rabbits, gerbils, hamsters, sheep, and Japanese quail. Different susceptibilities are related in general to the rate of hepatic pyrrole formation, although other sources of differences must be present (Huan et al., 1998). Damage to hepatocytes has been proposed to be due to the formation of pyrrole metabolites from the alkaloids by liver microsomes, with cross-linking of DNA strands by the metabolites (Carballo et al., 1992). Human deaths from pyrrolizidine alkaloids have been reported in several countries, including South Africa, Jamaica, and Barbados. In Afghanistan there was an epidemic of hepatic venoocclusive disease from consumption of a wheat crop contaminated with seeds of a species of *Heliotropium* (Tandon et al., 1978). The clinical signs associated with the liver damage resemble those of cirrhosis and some hepatic tumors and may be mistaken for those conditions (McDermott and Ridker, 1990). The clinical condition has been described as a form of the Budd-Chiari syndrome, with portal hypertension and obliteration of small hepatic veins (Ridker et al., 1985). Human consumption also occurs from *Symphytum* and *Senecio* species in some herbal preparations, such as "comfrey tea" or "groundsel tea." Hepatitis in cattle grazing on these plants, most commonly *Senecio,* has been reported in Africa and Asia as well as in the United States. Cows and horses are seriously affected. The condition is progressive, and death occurs after weeks or months of grazing on contaminated pastures. The major toxic alkaloid in *Senecio vulgaris* (common groundsel) is retrorsine; it is jacobine in *Senecio jacobaea* ("stinking willie").

Inhibition of RNA Polymerase Many of the nonedible mushrooms may cause gastrointestinal distress, but most are not life-threatening. Most deaths from mushroom poisoning worldwide are due to liver damage following consumption of *Amanita phalloides,* appropriately called "death cap." *Amanita ocreata* (death angel) is equally dangerous. *A. phalloides* contains two types of toxic chemicals: phalloidin and amatoxins. Phalloidin is a cyclic heptapeptide that may be responsible for some of the diarrhea that develops 10 to 12 h after ingestion of *A. phalloides.* Phalloidin combines with actin in muscle cells to interfere with muscle function but is not readily absorbed from the gastrointestinal tract (Cappell and Hassan, 1992). The amatoxins are bicyclic peptides (molecular weight 900) and are absorbed. The most toxic, alpha-amanitin, has a strong affinity for hepatocytes and binds to RNA polymerase II, thus inhibiting protein synthesis (Jaeger et al., 1993). Serious clinical signs develop slowly, beginning about the third day after ingestion. Treatment in severe cases may require liver transplant; there is no other specific treatment. Administration of silymarin, the active principle of the thistle *Silybum marianum,* in the form of its soluble succinate has been used. Several hypotheses have been proposed for the therapeutic action of silymarin, including free radical scavenging and stimulation of ribosomal RNA polymerase (Flora et al., 1998). Renal lesions are found in cases of severe amanita poisoning, with damage most prominent in proximal tubules. In addition to the amanitas, several species of *Lepiota* (parasol mushrooms) produce amatoxins, notably *Lepiota helveola* and *Lepiota bruneo-incarnata.*

Block of Sphingolipid Biosynthesis Fumonisins are toxins produced by the fungus *Fusarium,* primarily by *Fusarium moniliforme* and *Fusarium proliferatum* growing on corn. Ingestion by horses of corn contaminated with *Fusarium* mold causes "moldy corn poisoning," or equine leukoencephalomalacia. The signs in affected horses are lethargy, ataxia, convulsions, and death (Norred, 1993). There are several target organs, but the liver is a primary target in every species; in horses, it is liver and brain; in pigs, liver and lung; in rats, liver and kidney; in chickens, liver (Riley et al., 1994). In humans, an association with esophageal cancer has been suggested (Yoshizawa et al., 1994). Chemically fumonisins are diesters of propane-1,2,3-tricarboxylic acid and a pentahydroxyicosane containing a primary amino acid (Gurung et al., 1999). The structure of fumonisins is similar to that of sphingosine, and their toxicity has been proposed to be related to the blocking of enzymes in sphingolipid biosynthesis (Norred, 1993).

Lantadene Toxicity *Lantana camara* (Verbenaceae family) has been described as one of the 10 most noxious weeds in the world. It is an attractive flowering shrub, native to Jamaica and commonly cultivated in greenhouses. *L. camara* thrives outdoors in hot, dry climates. An unusual property of the plant is that it inhibits the growth of neighboring plants. In India, livestock poisoning from *L. camara* is a serious problem. Cattle grazing on the plant develop cholestasis and hyperbilirubinemia. The leaves are toxic to some nonruminants, including rabbits and guinea pigs. Several triterpenoids have been isolated from the plant. One that has been shown to induce hepatotoxicity is lantadene A (22-beta-angeloyloxy-3-oxo-olean-12-en-28-oic acid) (Sharma et al., 1991).

Kidney and Bladder

Carcinogenic Chemicals Bracken fern (*Pteridium aquilinum*) grows worldwide and, in the United States, primarily east of the Rocky Mountains. It has been described as one of the five most common plants on the planet and is found locally in heavy concentrations. Bracken fern is the only higher plant known to cause cancer in animals under natural conditions of feeding. The commonest bladder tumors in cattle are epithelial and mesenchymal neoplasms (Kim and Lee, 1998). The major carcinogen is reported to be ptaquiloside, a norsesquiterpene glucoside present in high concentrations in bracken, especially in crosiers and young unfolding fronds. Ptaquiloside alkylates adenines and guanines of DNA (Shakin et al., 1999). It has been proposed that human consumption of bracken fern leads to an increased incidence of esophageal and stomach cancers, based on geographic association of consumption of the fern and cancer incidence.

Kidney Tubular Degeneration Species of *Xanthium* (cocklebur, aster family) are annual plants found in several countries. Toxicosis in livestock is most common in spring and early summer due to ingestion of seedlings and young plants. Pigs, sheep, cattle, horses, and fowl can be affected in pastures where two- and four-leaf seedlings are present. The clinical signs are depression and dyspnea. Pathologic findings include tubular degeneration and necrosis in the kidney and centrilobular necrosis in the liver (del Carmen Mendez et al., 1998).

Most deaths from mushroom poisoning are due to fulminant hepatic failure from *Amanita*-type mushrooms. However, acute renal failure is the cause of death in poisoning from *Cortinarius* species. *Cortinarius* is a large genus of woodland fungi, found especially in northern conifer forests. Species vary widely in habit and in edibility. In one series of poisonings from *Cortinarius orellanus* and related species involving 135 cases in which the mushrooms were eaten, deaths secondary to acute renal failure occurred in almost 15 percent of the cases. Renal biopsy showed acute degenerative tubular lesions with inflammatory interstitial fibrosis (Bouget et al., 1990).

Blood

Anticoagulants Fungal infections in sweet clover (*Melilotus alba*) silage and hay have caused serious toxicity and death in cattle in the northern plains of the United States and Canada and, more recently, in California (Puschner et al., 1998). Deaths are from hemorrhages caused by dicumarol, a fungal metabolite. Dicumarol [3,3'-methylene-bis(4-hydroxycoumarin)] is an effective anticoagulant, causing prothrombin deficiency, and has been used therapeutically for this purpose.

Cyanogenic Chemicals Cyanogens are constituents of several different kinds of plants. One that is present in the kernels of apples, cherries, peaches, and related genera in the rose family is amygdalin, found in the highest amounts in the seeds of the bitter almond *Prunus amygdalus,* var. *amara.* Amygdalin is not present in the seeds of the sweet almond, the nut used for food. The amount of cyanogen in peach (*Prunus persica*) kernels is enough to cause poisoning in small children if several kernels are eaten. The small seeds of apples are unlikely to present a problem. In the stomach, amygdalin releases hydrocyanic acid, which combines with ferric ion in cytochrome oxidase or methemoglobin. The result of ingestion of several bitter almond seeds is classic cyanide poisoning with death as in asphyxia.

Cassava is a staple food starch from *Manihot esculenta* (Euphorbiaceae family), which is grown extensively in some parts of Africa as a major food source. The untreated root contains linamarin, a cyanogenic glucoside. During processing of the root for human consumption, the cyanogen is removed. However, local processing may be inadequate. Chronic ingestion of linamarin in cassava has been proposed as the cause of epidemics of konzo, a form of tropical myelopathy with sudden onset of spastic paralysis (Tylleskar et al., 1992). Degeneration of the corticospinal motor pathway in affected individuals may be caused by production of thiocyanate from linamarin and stimulation of neuronal glutamate receptors by thiocyanate (Spencer, 1999). Another plant containing linamarin is flax, *Linum usitatissumum,* the seed of which is the source of linseed oil. In some European countries, as a domestic remedy, linseeds are soaked overnight and the extract is used as a laxative, exposing these individuals to cyanide from the linamarin (Rosling, 1993).

Central and Autonomic Nervous Systems

Excessive stimulation of neurons results in toxic signs varying with the specific receptors involved. Permanent damage to the nervous system is a serious consequence of excessive neuronal stimulation.

Epileptiform Seizures The parsley family of plants (Apiaceae or Umbelliferae) contains some of the most edible (for example, carrots) and some of the most poisonous plants in the northern hemisphere. The fleshy tubers of *Cicuta maculata* (water hemlock) may be mistaken for other edible wild tubers. A single tuber may cause fatal poisoning, characterized by tonic-clonic convulsions. The toxic principle, cicutoxin (a C_{17}-polyacetylene), has been shown to be a potent blocker of potassium channels of T lymphocytes (Strauss et al., 1996). A similar action on potassium channels of neurons could account for the central nervous system effects.

Several members of the mint family (Labiatae) are noted for their pleasant essential oils, such as pennyroyal (*Hedeoma*), sage (*Salvia*), and hyssop (*Hyssopus*). These oils contain monoterpenes. For example, sage contains thujone, camphor, and cineole. In high doses, taken orally, well above amounts used for flavoring, these monoterpenes can cause tonic-clonic convulsions (Burkhard et al., 1999).

Excitatory Amino Acids Widely divergent species of plants produce amino acids that mimic the action of glutamate on the central nervous system. Most fast excitatory transmission in the mammalian brain is mediated by inotropic receptors for the amino acid glutamate on specialized neurons. Three types of glutamate receptors are named after three different agonists: AMPA (alpha-amino-3-hydroxyl-5-methyl-4-isoxazolepropionate), NMDA (*N*-methyl-D-aspartate), and kainate [kainic acid, 2-carboxy-4-(1-methyleney1)-3-pyrrolidine acetic acid] receptors. The excitatory amino acids (EAAs) from plants act on one or more of these glutamate receptor subtypes. The consequence of ingestion of EAAs is excessive stimulation, which may result in death of neurons. Kainic acid is present in the marine red alga *Digenia simplex.* Under some climatic conditions, the algae reproduce rapidly, causing a "red tide." Filter-feeding mussels eat the algae and humans may be poisoned by eating the mussels. A similar problem exists with the green alga *Chondria aranta,* growing in northern oceans. The alga produces domoic acid, a tricarboxylic amino acid, as does the marine diatom *Nitzschia pungens.* In 1987 there was a serious outbreak of poisoning in Canada in individuals eating mussels containing domoic acid. The acute symptoms were gastrointestinal distress, headache, hemiparesis, confusion, and seizures. Prolonged effects were severe memory deficits and sensorimotor neuronopathy (Teitelbaum et al., 1990). The action of domoic acid is to release glutamate by activating presynaptic kainate- or AMPA-type receptors (Scallet and Ye, 1997).

The fungus *Amanita muscaria* (fly agaric) got its name from its poisonous actions on flies. Poisoning from this woodland mushroom and from *Amanita pantherina* (panther agaric, common in western United States) is due to the content of the EAA, ibotenic acid, and possibly to its derivative, muscimol. The effects are somewhat variable: central nervous system depression, ataxia, hysteria, and hallucinations. Myoclonic twitching and seizures sometimes develop (Benjamin, 1992). The content of ibotenic acid varies with the time of year—more has been reported in spring than in fall.

EAAs are also found in flowering plants. The pea family (Leguminosae) contains several species that produce EAAs in the seeds. Willardiine [1-(2-amino-2-carboxyethyl) pyrimidine-2,4-dione] has been isolated from *Acacia willardiana, Acacia lemmoni, Acacia millefolia,* and *Mimosa asperata* (Gmelin, 1961). Willardiine acts as an agonist on the AMPA and kainate receptors (Jane et al., 1997). Other important EAAs are present in species of *Lathyrus. Lathyrus sylvestris* (flat pea) is a perennial indigenous to Europe and central Asia and naturalized in Canada and the northern United States. The plant is eaten by livestock in these areas. An acute neurologic condition in sheep begins with weakness and progresses to tremors and prostration, sometimes with clonic movements and seizures (Rasmussen et al., 1993). The seeds contain DABA (2,4-diaminobutyric acid) and lower quantities of BOAA (beta- *N*-oxalylamino-L-alanine). Both DABA and BOAA are excitatory neurotoxins acting on the AMPA-type receptor. Seeds of *Lethyrus sativus* (chickling pea) contain more BOAA than DABA, and the seeds of this plant are used as food by humans in parts of Africa. Lathyrism is a condition developing from consumption of large quantities of *L. sativus* seeds over periods of months or longer. Affected individuals have corticospinal motor neuron degeneration with severe spastic muscle weakness and atrophy but little sensory involvement (Spencer et al., 1986).

Mannosidase Inhibitors Swainsonine is an indolizidine alkaloid found in *Swainsonia canescens,* an Australian plant, and in *Astragalus lentiginosus* (spotted locoweed) and *Oxytropis sericea* (locoweed) in the western United States. Cattle consume these weeds in pasture. The common name comes from the most obvious consequence of ingestion of the locoweeds: abberrant behavior with hyperexcitability and locomotor difficulty. In animals dying from locoweed poisoning there is cytoplasmic foamy vacuolation of cerebellar neurons. The toxic ingredient, swainsonine, causes marked inhibition of liver lysosomal and cytosomal alpha-mannosidase and Golgi mannosidase II. Inhibition of the Golgi enzyme results in abnormal brain glycoproteins and accumulation of mannose-rich oligosaccharides (Tulsiani et al., 1988). The pathology is not limited to the nervous system, and the effects of swainsonine poisoning are found in several tissues. A major effect in animals grazing at high altitudes is congestive heart failure. The condition has been called "high mountain disease" (James et al., 1991).

Motor Neuron Demyelination Paralysis develops from some toxins without primary excitation of neurons. *Karwinskia humboldtiana,* family Rhamnaceae, is a shrub of the southwestern United States, Mexico, and Central America. Common names are buckthorn, coyotillo, and tullidora. Anthracenones are found in the seeds, varying with growth; green fruit may be more toxic than ripe fruit (Bermudez et al., 1986). Both human and livestock poisonings occur, occasionally in epidemic proportions. The clinical syndrome that develops after a latency of several days is ascending flaccid paralysis, beginning with demyelination of large motor neurons in the lower legs and, in fatal cases, leading to bulbar paralysis (Martinez et al., 1998). Sensory fibers are largely spared. In addition to neurotoxicity, the anthracenones in *Karwinskia,* especially peroxisomicine A_2 [3,39-dimethy1-3,39,8,89,9,99- hexa-hydroxy-3,30,4,49-tetrahydro-(7,10-bianthracene)-1,19-2H,29H-dione], cause atelectasis and emphysema in lungs and massive liver necrosis. Inhibition of catalase in peroxisomes has been proposed as a mechanism for the cellular toxicity (Martinez et al., 1997).

Parasympathetic Stimulation Several plant alkaloids affect the autonomic nervous system, mimicking or blocking the transmitter acetylcholine at autonomic ganglia (nicotinic receptors) or the peripheral endings of the parasympathetic system (muscarinic receptors). The postsynaptic receptors at terminations of the parasympathetic nerve fibers are called "muscarinic" after the selective stimulation of these receptors by muscarine, which was first extracted from the mushroom *Amanita muscaria.* However, this mushroom contains only trace amounts of muscarine, and poisoning is due to its content of ibotenic acid. Some mushrooms of the genera *Inocybe, Clitocybe,* and *Omphalatus* contain significant amounts of muscarine, and consumption of toxic species causes diarrhea, sweating, salivation, and lacrimation, all referable to stimulation of parasympathetic receptors (de Haro et al., 1999).

Parasympathetic Block The belladonna alkaloids (l-hyoscyamine, atropine or *d,r*-hyoscyamine, and scopolamine), present in several genera of plants of the family Solanaceae, are best known for their block of muscarinic receptors. The plants are widely distributed and have had a place in the materia medica of many cultures. *Datura stramonium* (jimsonweed) is native to India and contains primarily scopolamine; *Hyoscyamus niger* (henbane) is native to Europe and contains mostly l-hyoscyamine; *Atropa belladonna* (deadly nightshade), also native to Europe, contains atropine; *Duboisia myoporoides* (pituri) in Australia contains l-hyoscyamine. Of the two active alkaloids, l-hyoscyamine and scopolamine, the latter has greater action on the central nervous system, while l-hyoscyamine acts primarily to block muscarinic receptors of the parasympathetic nervous system. The effects of modest doses of l-hyoscyamine or atropine are referable to muscarinic block: tachycardia, dry mouth, dilated pupils, and decreased gastrointestinal motility. Large doses of either or of scopolamine affect the central nervous system: confusion, bizarre behavior, hallucinations, and subsequent amnesia. Deaths are rare, although recovery may take several days. *Datura* (*Brugmansia*) *suaveolens* (angel's trumpet) is used as an ornamental houseplant and contains significant quantities of atropine and scopolamine (Smith et al., 1991). Seeds of the weed *Datura ferox* contain belladonna alkaloids and are contaminants of animal feed in some parts of Europe. In areas where seeds for human consumption are not carefully sorted before milling and where *Datura stramonium* and *Datura metei* are common weeds, millet, wheat, rye, corn and beans sometimes are contaminated with the seeds. The amount needed to poison an adult is about 20 seeds. Symptoms from eating bread made from contaminated flour are typical of poisoning from belladonna alkaloids (van Meurs et al., 1992). An unusual source of belladonna poisoning has been reported from eating wasp honey. Some wasps (*Polistes* species) store enough honey to attract humans to steal their honey. Atropine-like poisoning has been reported from consuming the honey when the wasps have gathered nectar from *Datura inoxia* (Ramirez et al., 1999).

The seeds of *Solanum dulcamara* (woody nightshade, bittersweet) are brilliant orange-red and are gathered for flower arrangements in the fall. The seeds contain solanine, a glycoalkaloid, responsible for the acute toxicity from ingested seeds, including tachycardia, dilated pupils, and hot, dry skin, as in atropine poisoning (Ceha et al., 1997).

Skeletal Muscle and Neuromuscular Junction

Neuromuscular Junction Block Block of the neuromuscular junction of skeletal muscle may result from either block of postsynaptic acetylcholine (nicotinic) receptors by an antagonist or by an agonist causing excessive stimulation of the receptor followed by prolonged depolarization. Nicotine, for which the receptor is named, stimulates autonomic ganglia as well as the neuromuscular junction. An isomer of nicotine, anabasine ($C_{10}H_{14}N_2$), present in *Nicotiana glauca* (tree tobacco), produces prolonged depolarization of the junction. Consumption of the leaves of the plant has caused severe, generalized muscle weakness and respiratory compromise, following flexor muscle spasm and gastrointestinal irritation (Mellick et al., 1999). Curare, the South American arrow poison, is a potent neuromuscular blocking agent for skeletal muscle and kills by stopping respiration. Paralysis is due to block of acetylcholine at the postsynaptic junction. Curare is obtained from tropical species of *Strychnos* and *Chondrodendron.* However, not all plants producing chemicals that block acetylcholine are of tropical origin. In warm weather,

blooms of blue-green algae are not uncommon in farm ponds in temperate regions, particularly ponds enriched with fertilizer. Under these conditions, one species of alga, *Anabaena flos-aquae,* produces a neurotoxin, anatoxin A, which depolarizes and blocks acetylcholine receptors, both nicotinic and muscarinic, causing death in animals that drink the pond water. The lethal effects develop rapidly, with death in minutes to hours from respiratory arrest (Short and Edwards, 1990). Anatoxin A is 2-acetyl-9-azabicyclo [4.2.1] non-2-ene (Hyde and Carmichael, 1991).

Methyllycaconitine is a norditerpenoid present in *Delphinium barbeyi* (tall larkspur) and some related species. The plant contaminates western pastures in the United States and causes death of livestock. Poisoned cattle show muscle tremors, ataxia, and prostration and die from respiratory failure. The alkaloid has a high affinity for the acetylcholine receptor and causes death by blocking the action of acetylcholine at the neuromuscular junction, much as curare does (Dobelis et al., 1999). Physostigmine has been used successfully as an antagonist in some cases of methyllycaconitine poisoning (Pfister et al., 1994). Methyllycaconitine is being used experimentally as a selective probe for discriminating different acetylcholine-binding sites in the brain (Davies et al., 1999).

Skeletal Muscle Damage Direct damage to skeletal muscle fibers has been demonstrated in some plant poisonings. Species of *Thermopsis* (family Leguminosae) grow commonly in the foothills of the Rocky Mountains. Mature seeds of these plants form attractive pods, as in many legumes. Seeds of the poisonous species of *Thermopsis* contain quinolizidine alkaloids, principally anagyrine and thermopsine. Human poisoning from eating the seeds is rare, but cases have been reported in young children (Spoerke et al., 1988). The symptoms in children are abdominal cramps, nausea, vomiting, and headache lasting up to 24 h. Serious poisoning has occurred in livestock grazing on *Thermopsis montana* (false lupine). The animals develop locomotor depression with prolonged recumbency. Microscopic areas of necrosis in skeletal muscle are found on autopsy (Keeler and Baker, 1990).

Among the common contaminants of animal feeds are seeds of *Cassia obtusifolia* (sicklepod, family Leguminosae). Consumption of the seeds of *C. obtusifolia* causes illness in cattle, swine, and chickens. The toxic effect is a degenerative myopathy of cardiac and skeletal muscle. It has been shown that extracts of *C. obtusifolia* inhibit NADH-oxidoreductase activity in bovine and porcine heart mitochondria in vitro (Lewis and Shibamoto, 1989), possibly related to the anthraquinone content of the seeds.

Bone

Soft Tissue Calcification In 1967, Worker and Carrillo proposed that a decrease of bone calcification and wasting in cattle grazing along the eastern coastal plains of South America was due to the consumption of *Solanum malacoxylon* (nightshade family, Solanaceae). They recognized the association of the presence of the plant in the fields with the condition. The disease, known in Argentina as *enteque seco,* is characterized by calcification of the entire vascular system, especially the heart and aorta. Lungs, joint cartilage, and kidney are also affected in the worst cases. Sheep and cows are both affected by ingestion of the plant. The general picture resembles vitamin D intoxication. A water-soluble vitamin D–like substance, a glycoside of 1,25-dihydroxycholecalciferol, has been isolated from the plant (Skliar et al., 1992).

Cestrum diurnum (day-blooming jasmine) causes hypercalcemia and extensive soft tissue calcification in grazing animals in Florida, resembling the action of *S. malacoxylon.* A dihydroxyvitamin D_3 glycoside in the leaves is the toxic agent (Durand et al., 1999). *Cestrum laevigatum* causes a similar deposition of calcium in chickens (Mello and Habermehl, 1992). The plant is occasionally a contaminant of hay in Europe. However, ingestion of the dried plant by cattle results primarily in liver damage (van der Lugt et al., 1991).

Reproductive System and Teratogenesis

Embryo loss and teratogenesis in herbivores caused by ingestion of some plants are serious factors in livestock production worldwide. The types of plants and the abortifacient or teratogenic chemicals they contain are diverse.

Teratogens *Veratrum californicum* is native to the mountains of North America where sheep are grazed. An incidence of terato-genesis as high as 25 percent has been reported in pregnant sheep in these areas, along with an incidence of early embryonic death as high as 75 percent (Keeler, 1990). The teratogenic manifestations are dependent on the developmental stage at the time of ingestion, as with many teratogens. Malformations in the offspring involve cyclopia, exencephaly, and microphthalmia. During the fourth and fifth weeks of gestation, limb defects are common; on gestational days 31 to 33, the result of ingestion is stenosis of the trachea (Omnell et al., 1990). The alkaloids in *Veratrum* that are responsible for the defects are jervine, 11-deoxojervine, and 3-*O*-glucosyl-11-deoxojervine. Although there is species difference in sensitivity, birth defects occur in cows and goats grazing on *Veratrum californicum* and can be produced experimentally in chickens, rabbits, rats, and mice (Omnell et al., 1990), hamsters (Gaffield and Keeler, 1993), and rainbow trout embryos (Crawford and Kocan, 1993). The *Veratrum* alkaloids are teratogenic by blocking cholesterol synthesis and thus the response of fetal target tissue to a gene locus (sonic hedgehog locus, Shh). The Shh locus has a role in developmental patterning of head and brain, and block of cholesterol synthesis has been shown experimentally to result in loss of midline facial structures (Cooper et al., 1998).

A cluster of fetal malformations characterized by deforma-tion of limbs and spinal cord is found after ingestion of several related alkaloids from different species of plants during a sensi-tive gestational period. This syndrome has been found in cattle grazing on *Lupinus caudatus* and *Lupinus formosus* (lupines), *Nicotiana glauca* (tree tobacco), and *Conium maculatum* (poison hemlock), known historically as the plant that Socrates drank when condemned to death by the Athenians. The fatal actions of the poison in that instance are described by Plato in the *Phaedo* dialogue. The active alkaloids in these plants have been identified as anagyrine (*L. caudatus*), ammodendrine (*L. formosus*), anabasine (*N. glauca*), and coniine (*C. maculatum*). It has been proposed that these alkaloids depress fetal movements during susceptible gestational periods and in this way cause malformations (Lopez et al., 1999). Not all species are equally affected by coniine. Notably, rats and hamsters do not show teratogenesis in response to coniine but goat and chick embryos are susceptible (Forsyth et al., 1996).

Abortifacients The active alkaloid in the legumes *Astragalus* and *Oxytropus* is swainsonine. In addition to actions on the nervous system, swainsonine frequently causes abortions when locoweeds are ingested by pregnant livestock (Bunch et al., 1992). Two genera of tropical legumes, *Leucaena* and *Mimosa,* contain a toxic amino acid, mimosine [beta-*N*-(3-hydroxy-4-pyridone)-alpha-aminoproprionic acid]. Mimosine is found in large amounts in foliage and seeds of *L. leucocephala, L. glauca* and *M. pudica.* In cattle the amino acid causes incoordinated gait, goiter and reproductive disturbances including infertility and fetal death (Kulp et al., 1996). Mimosine arrests the cell cycle after cells enter S phase (Hughes and Cook, 1996).

Lectins that are ribosome-inactivating proteins may have many biological effects when ingested, including antifertility, abortifacient, and embryotoxic actions. A lectin from bitter melon seeds (*Momordica charantia,* family Cucurbitaceae) has been shown to have such effects. The lectins are alpha- and beta-momorcharins, single-chain glycoproteins with molecular weights of about 29,000. The momorcharins are known to induce midterm abortion in humans (Wang and Ng, 1998).

SUMMARY

A great number of toxic chemicals have been produced by plants for their own protection from the environment and from predators, including pathogenic organisms. The list of these defensive chemicals is steadily growing in the scientific literature and not all the chemicals are deleterious to humans. Throughout history a select number have been incorporated into therapy against disease and to combat morbidity, often with considerable success. Morphine from the latex of the opium poppy is an ancient historical example. If fungi are included with plants (as they are in this chapter), defensive chemicals of plants are responsible for some of our more recent successful therapies, such as antibiotics of the penicillin type and new treatments for cancer. On balance, in spite of the long list of potentially dangerous agents, it is fair to conclude that toxic chemicals from plants have proved more useful than harmful to humans. Finally, there is simply the pleasure of scientific inquiry into the successful adaptations of plants to their complex and often hostile environments.

AIR POLLUTION*

Daniel L. Costa

AIR POLLUTION IN PERSPECTIVE

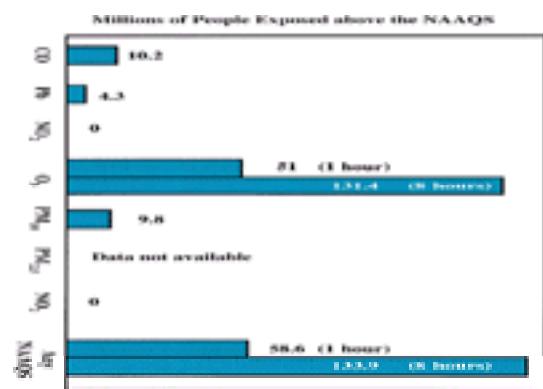
The last fifty years have brought remarkable changes in the way we view our environment. In the early 1950s, our industrial prosperity was often depicted as an expanse of factories with smokestacks belching opaque black clouds into the surrounding air. The growing environmental activism in the latter decades of the century—stemming from aesthetic and, more importantly, health concerns—forced regulatory legislation that has now made such scenes rare in most technologically advanced nations. Today, every urban community is in search of "clean industries." Yet ironically, we endure increasingly congested thoroughfares of automobiles commuting to these industries as we fuel a photochemical cauldron of oxidant air pollution—i.e., smog. Moreover, areas once considered "pristine" are today tarnished by the influx of polluted air masses that drift and disperse across hundreds of miles. Clearly, air pollution remains a reality of our twenty-first-century lifestyle, and while great strides have been made to reduce emissions from both stationary and mobile sources, unsatisfactory air quality now plagues much broader geographic areas. As a result, millions of people in the United States live in areas that are not in compliance with current National Ambient Air Quality Standards (NAAQS) (Fig. 28-1).


Figure 28-1. Number of people (millions) living in U.S. counties not in compliance with current 1998 NAAQS. (Adapted with permission from National Air Quality & Emission Trends Report, 1998.)

Most peoples of the western world today face fewer episodes of extreme air pollution; instead, they experience prolonged periods of relatively low-level exposure to complex mixtures of photochemically transformed stationary and mobile emissions. We know most about the health effects of individual pollutants, and we use this knowledge to drive controls where single pollutants dominate the situation. However, much less is understood about the realities of present-day patterns of diurnal and prolonged exposure and how mixtures of pollutants can affect human health. This chapter is intended to inform the reader as to the state of our knowledge of air pollution, with the goal of providing the reader with a fundamental knowledge and appreciation of the nature of the problem, its complexity, and the uncertainties in need of investigation.

A Brief History of Air Pollution

For most of history, air pollution has been a problem of microenvironments and domestic congestion. The smoky fires of early cave and hut dwellers choked the air inside their homes. When it was eventually vented outdoors, it combined with that of the neighbors to settle around the village in the damp cold night. With urbanization and the concomitant decrease in forest wood as a source of fuel, the need for heat and energy led to the burning and ambient release of sulfurous, sooty smoke from cheap coal. City dwellers had to endure the bad air, while those with wealth had country homes to which they could escape from time to time. The poor quality of urban air is well documented historically. Seneca, the Roman philosopher, in A.D. 61 wrote: "As soon as I had gotten out of the *heavy air* of Rome, and from the *stink* of the chimneys thereof, which being stirred, poured forth whatever *pestilential vapors and soot* they had enclosed in them, I felt an *alteration to my disposition*" (emphasis added: Miller and Miller, 1993).

Efforts to regulate air pollution, on the other hand, evolved more slowly. Beginning in the thirteenth century, community-based outcries received some recognition by governing officials, one example being the banning of domestic burning of "sea coal" in London by Edward I. Enforcement, however, was not effective and people largely resigned themselves to polluted air as part of urban life. By the seventeenth century, England, in the middle of several decades some refer to as "the little ice age," experienced further reductions in wood harvests, thus increasing reliance on sea coal for domestic heating. Despite Percival Pott's discovery that soot was related to the occurrence of scrotal cancer in chimney sweeps, the health community offered only a simple recommendation: "Fly the city, shun its turbid air; breathe not the chaos of eternal smoke . . . " (Brimblecombe, 1999)—advice hardly advanced from that of Seneca 1600 years earlier. In the late eighteenth century, the industrial revolution, which was powered by the burning of mined coal, added a second dimension to urban air pollution. These emissions were more acidic and hung in the air longer than the fluffy soot of the cheaper sea coal burned in home heaters. Continued soiling of buildings and damage to nearby crops brought community boards to address sanitary reforms to cut the worse of the pollution peaks and episodes, but any gains were soon offset by growth. By the end of the nineteenth century and into the early twentieth century, power plants were being built to provide energy for factories and eventually to light homes. Steel mills and other industries proliferated along riverbanks and lakeshores, oil refineries rose in port cities and near oilfields, and smelters roasted and refined metals in areas near large mineral deposits.

By 1925, air pollution was common to all industrialized nations, but people became less tolerant of the nuisance of acidic-soot corrosion of all exposed surfaces and the general discomfort that came with smoky air. Public surveys were initiated—as in Salt Lake City in 1926, New York City in 1937, and Leicester, Great Britain, in 1939—to bring political attention to the problem and promote the implementation of controls (Miller and Miller, 1993). However, it was not until the great air pollution

disasters in the Meuse Valley, Belgium, in 1930; Donora, Pennsylvania, in 1948; and the great London fog of 1952 that air pollution was indicted primarily as a health issue. In the United States, California was already leading the way with passage of the Air Pollution Control Act of 1947 to regulate the discharge of opaque smokes. Visibility problems in Pittsburgh during the 1940s had also prompted efforts to control smoke from local industries, but it was the initiative of President Truman that provided the federal impetus to deal with air pollution. This early effort culminated in congressional passage of a series of acts starting with the Air Pollution Control Act of 1955.

The prosperity and suburban sprawl of the late 1950s provided the third and perhaps most chemically complex dimension of air pollution. The term *smog,* though originally coined to describe the mixture of smoke and fog that hung over large cities such as London, was curiously adopted for the eye-irritating photochemical reaction products of auto exhaust that blanketed cities such as Los Angeles. Early federal legislation addressing stationary sources was soon expanded to include automobile-derived pollutants (the Clean Air Act of 1963, amended in 1967, and the Motor Vehicle Air Pollution Control Act of 1965). The landmark Clean Air Act (CAA) of 1970 evolved from the early legislation, and despite being only an amendment, it was revolutionary. It recognized the problem of air pollution as a national issue and set forth a plan to control it. The Act established the U.S. Environmental Protection Agency (USEPA) and charged it with the responsibility to protect the public from the hazards of polluted outdoor air. Seven "criteria" air pollutants [ozone (O_3), sulfur dioxide (SO_2), particulate matter (PM), nitrogen dioxide (NO_2), carbon monoxide (CO), lead (Pb), and total hydrocarbons—the last now dropped from the list, leaving six criteria pollutants] were specified as significant health hazards in need of *individual* National Ambient Air Quality Standards (NAAQS). These NAAQS were mandated for review every 5 years as to the adequacy of the existent standard to protect human health (Table 28-1). For each of the criteria pollutants, there was to be developed a Criteria Document, which would provide a detailed summary of the available database on that pollutant and then would be integrated into a staff paper for use by the EPA Administrator to set the NAAQS. With regard to the Primary NAAQS, only health criteria could be used, including a safety factor for the most susceptible groups. Secondary consideration was given to agricultural and structural welfare; economic impacts were not to be involved in standard setting itself—only in the implementation procedures. Other hazardous air pollutants (HAPs), of which there were eight listed at the time, were to undergo health assessments to establish emission controls. The CAA of 1970 was by far the most far-reaching legislation to date.

Table 28-1 U.S. National (Primary) Ambient Air Quality Standards*

The accidental release of 30 tons of methyl isocyanate vapor into the air of the shanty village of Bhopal, India, on December 3, 1984, killed an estimated 3000 people within hours of the release, with another 200,000 injured and/or permanently impaired. The tragedy shocked the world, and raised the issue of HAPs in the United States to a new level of concern. While such a disaster has never struck the United States, accidental industrial releases or spills of toxic chemicals are surprisingly common, with 4375 cases recorded between 1980 and 1987, inflicting 11,341 injuries and 309 deaths (Waxman, 1994). The HAPs, which had been the stepsister of the criteria pollutants for more than a decade after the passage of the CAA, have since garnered more public and policy attention. There is concern not only for accidental releases of fugitive or secondary chemicals—such as phosgene, benzene, butadiene, and dioxin, into the air of populated industrial centers—but also for potential chronic health effects, with cancer often being the focus of attention. The slow progress of regulatory decisions on HAPs (only eight between 1970 and 1990) led to a mandated acceleration of the process under the CAA amendment of 1990. Section 112(b) currently lists 188 chemicals or classes of chemicals for which special standards and risk assessments are required. The chemicals listed are those of greatest concern on the basis of toxicity (including cancer) and estimated release volumes. These emissions are mandated for control to the maximal achievable control technology (MACT), and any residual health risk after MACT is to be considered in a separate quantitative risk assessment. The database for this process utilizes existing knowledge or, if necessary, mandates further research by the emitter. While many of these chemicals are now better controlled than in the past, most residual risk estimates are yet to be completed.

Emissions from motor vehicles are addressed primarily under the CAA Title II, Emission Standards for Mobile Sources. The reduction of emissions from mobile sources is complex and involves both fuel and engine/vehicle reengineering. Despite continued refinements in combustion engineering through the use of computerized ignition and timing, fuel properties have drawn recent attention for improvement. For example, to reduce wintertime CO, several oxygenates (including ethers and alcohols) have be formulated into fuels both to reduce cold-start emissions and enhance overall combustion. Perhaps the most prominent of the ethers is MTBE (methyl tertiary butyl ether), which became a controversial additive in the early 1990s, arising in part from odor and reports of asthma-like reactions by some individuals during auto refueling at service stations. Today, the controversy has taken an unexpected twist; MTBE has now been removed from fuel, not because health concerns associated with airborne exposure but rather due to leakage from service-station storage tanks into groundwater. Ironically, this prescribed remedy for an air problem has evolved into a new problem: groundwater contamination. This example illustrates the broad complexity of pollution control, measures that transcend engineering. Meanwhile, the introduction of another fuel additive, methylcyclopentadienyl manganese tricarbonyl (MMT)—to boost octane ratings of fuel and improve engine performance and combustion—is being carefully reviewed under Title II because of concerns regarding the potential introduction of manganese into the environment, reminiscent of use lead in fuels from the 1930s to 1970s, when lead fuel additives were banned.

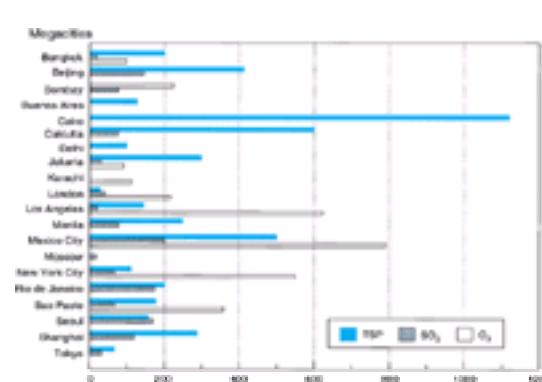
Internationally, the magnitude and control of air pollution sources vary considerably, especially among developing nations, which often forgo concerns for health and welfare because of cost and the desire to achieve prosperity. Fig. 28-2 illustrates the variation among international megacities in regard to three major urban pollutants: total suspended particulate (TSP) matter, sulfur oxides (SO_x), and O_3. The recent political upheaval in eastern Europe has revealed the consequences of decades of uncontrolled industrial air pollution. While vast improvements are now becoming evident in this area, as industries are being modernized and emissions controlled, many Asian, African, and South American cities have virtually unchecked air pollution. Some nations as well as the World Health Organization (WHO) have adopted air quality standards as a rational basis for guiding control measures, but the lack of binding regulations and/or economic fortune has impeded significant controls and improvements (Lipfert, 1994). In addition to local socioeconomic and political concerns, emissions of air pollutants will, in all probability, spawn problems of "international pollution" as we enter the twenty-first century, when the impact of long-range transport of polluted air masses from one country to another fully matures as a global issue (Reuther, 2000). This was the subject of some controversy between Canada and the United States in the late 1980s and into the 1990s as a result of the air mass transport of acid sulfates from industrial centers of the midwestern United States to southern Ontario. However, reduction in SO_2 emissions has somewhat relieved the tension over the last several years (Fig. 28-3).


Figure 28-2. Comparison of ambient levels of 1-h maximum ozone, annual average of total suspended particulate matter, and sulfur dioxide in selected cities from around the world to illustrate the variation in these levels from country to country with respect to the United States. (Reproduced with
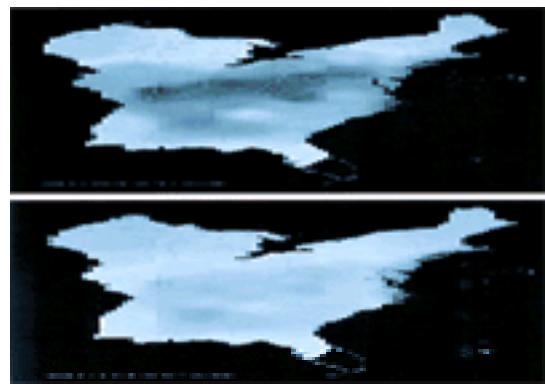

Figure 28-3. Reduction in ambient sulfate concentrations between 1990–1991 and 1997–1998 in the rural U.S. Midwest from CASTNet monitoring data.

The acid sulfates are dispersed by prevailing winds toward the eastern United States and southeastern Canada, contributing to the acid rain deposition (see Fig. 28-9). (Adapted with permission from National Air Quality & Emission Trends Report, 1998.)

Figure 28-9. Areas in 1988 where precipitation in the East fell below pH 5: acid rain.

The acidity of the air in the east is thought to result from air mass transport of fine sulfated particulate matter from the industrial centers of the Midwest. (Reproduced with permission from National Air Pollutant Emission Trends Report, 1998.)

ASSESSING RISKS ASSOCIATED WITH AIR POLLUTION

"Risk Assessment" has become a formalized process, originally described in the landmark 1983 National Research Council Report, whereby evidence regarding toxicity, exposure, and dose-dependency are systematically organized to estimate the degree of risk to a population. The health database for any air pollutant comprises data from animal toxicology, controlled human studies, and epidemiology. But, because each of these research approaches has inherent strengths and limitations, an appropriate assessment of an air pollutant requires the careful integration and interpretation of data from all three methodologies. Thus, one should be aware of the attributes of each (Table 28-2).

Table 28-2 Strengths and Weaknesses of Disciplinary Approaches for Obtaining Health Information

Epidemiologic studies reveal associations between exposure to a pollutant or pollutants and the health effect or effects in the *community* or *population* of interest. Because data are garnered directly under real exposure conditions and involve large numbers of humans, the data are of direct utility to the regulatory community assessing the impact of that pollution. Moreover, with proper design and analysis, studies can explore either acute or long-term exposures and theoretically can examine trends in mortality and morbidity, accounting irreversible effects as well as responses in population subsets (i.e., sensitive groups). Why, then, is this approach to the study of air pollution not the exclusive choice of regulators in decision making? The problem here is that it is often difficult to control independent and personal variables in the human population because of genetic diversity among individuals and lifestyle differences, their mobility over time, and the lack of adequate exposure data—especially on a personal basis. Also, it is difficult to segregate a single pollutant from copollutants and the influence of meteorologic confounders. Thus, at best, only associations can be drawn between the broad-based exposure data and effects, with these effects typically of a gross nature—mortality, hospitalizations, etc. Rarely is a causal relationship discernible even in the presence of strong statistical significance. However, recent advances in exposure estimation and study design and analysis (e.g., time series) have allowed epidemiologists to examine relationships with greater confidence and specificity. These models limit the impact of covariates and longer time-based influences and thus allow epidemiologists to tease out effects of short-term pollution not accessible formerly (Schwartz, 1991). Similarly, newer approaches that employ field studies—sometimes called *panel studies*—incorporate time-series design and regression analyses of more focused exposure data (ideally personal) and targeted clinical endpoints in the exposed population under study. The endpoints often derive from empiric human and animal studies. These novel approaches are clearly evident in the most recent studies of particulate matter air pollution (see below).

Studies that involve controlled human exposures have been used extensively to evaluate the criteria air pollutants regulated by the USEPA. Because most people are exposed to these pollutants in their daily lives, human volunteers can be ethically exposed to them (with the exception of Pb, which has cumulative and irreversible effects). Exposures are conducted in a controlled environment, are generally of short or limited repeat durations, and all responses must be reversible. Clearly, data of this type are very valuable in assessing potential human risk, since they are derived from the species of concern and are rooted in our well-established clinical knowledge and experience. Additionally, suspected "susceptible or sensitive" individuals representing potential high-risk groups can be studied to better understand the breadth of response in the exposed public. However, clinical studies have practical limitations. Ethical issues are involved in every aspect of a clinical test; potentially irreversible effects and carcinogenicity are also always of concern, along with the definition of an acceptable level of hyperresponsiveness in a so-called sensitive individual who may be subjected to testing. Likewise for any test subject, there are obvious restrictions on the invasiveness of biological procedures, though

sophistication in medical technology has made accessible a large array of molecular biomarkers from peripheral blood and nasal, bronchial, and alveolar lavage fluids as well biopsied cells from airway segments (Devlin et al., 1991; Salvi et al., 1999). Finally, the cost, the limited numbers of subjects that usually can be evaluated, and the inability to address chronic exposure issues are also constraints on human testing. Where partnership with animal toxicology studies has been established, studies in laboratory animal species can sometimes open the door for at least limited direct human exposure study. Analogously, in vitro studies in both human and animal cell and tissue systems allow the elucidation of mechanisms of toxicity and identify basic biological responses that serve the extrapolation of animal data to humans as well as supporting the feasibility and ethical limitations of human study even with toxic air pollutants (see below).

Animal toxicology is frequently used to predict or corroborate suspected effects in humans. In the absence of human data, animal toxicology constitutes the essential first step of risk assessment: *hazard identification*. The importance of animal toxicology in elucidating pathogenic mechanisms should not be overlooked, however, as knowledge of the basic in vivo biological processes involved in toxic injury or disease is critical to extrapolating databases across species and to estimating uncertainties. Knowledge of the toxic mechanism(s) provides the underpinnings to the "plausibility" of the findings when extrapolated to humans and, under carefully defined and highly controlled circumstances, may allow *quantitative* estimates of risk. Animal toxicology studies have been used to investigate all of the criteria air pollutants and many of the HAPs as well. The strength of this discipline is that it can involve methods that are not practical in human studies, including a diversity of exposure concentrations and durations, and the inclusion of a wide array of invasive biological procedures. The minimization of uncontrolled variables (e.g., genetic and environmental) may be the greatest strength of the animal bioassay. On the other hand, the clear limitation of this approach lies in the extrapolation of the findings from animals to the day-to-day human life scenario. Ideally, a test animal is selected with knowledge that it responds in a manner similar to that of the human (*homology*). *Qualitative* extrapolation of homologous effects is not unusual with most toxic inhalants, but *quantitative* extrapolation is frequently clouded by uncertainties of the relative *sensitivity* of the animal or specific target tissue compared with that of the human. Uncertainties about the target tissue dose also loom large, as it constitutes the first obstacle to quantitative extrapolation (see below). With respect to the target tissue dose, however, most animal toxicologists make every effort to keep exposure concentrations at 5- to 10-fold that of the anticipated human exposure until appropriate dosimetric data can be ascertained. The higher doses are typically needed to achieve a group response among a limited pool of animals (maybe 6 to 10) to represent a large population effect, where perhaps only a few of hundreds or thousands may be responsive; although it must be appreciated that mechanisms may differ at different dose levels. Despite these limitations, animal studies have provided the largest database on a wide range of air toxicants and have proven utility in predicting human adverse responses to chemicals.

Health scientists must appreciate the strengths and weaknesses of these approaches if an appropriate estimation of toxic risk or potential hazard is to be reached. However, other scientific disciplines also are integral to the full assessment of the impact of air pollution on society. Chemical and engineering methodologies are used together to detect and control pollutants in the atmosphere and develop empiric test systems to gather information used to evaluate individual toxicity and/or physicochemical interactions. Their use in determining local and personal exposure for panel and prospective epidemiologic studies is most important. Other disciplines, such as meteorology and atmospheric chemistry, relate to the real world by yielding information on the dispersion of pollutants from their sources and the conditions leading to the stagnation of air masses and the accumulation of pollutants. Recreating these environments to the extent possible, using surrogate atmospheres, is critical to understanding toxic risks and creating models to estimate human risk. Last, data derived from studies in plants are now being appreciated more than ever. Not only are commercial and native vegetation affected by pollution but plants themselves are being appreciated as sensitive "sentinels," warning us of the impact of pollution. When these elements are considered collectively, the economist can inform regulators and the public at large of the cumulative impact and adversity of pollution on our standard of living (Maddison and Pierce, 1999).

Animal-to-Human Extrapolation: Issues and Mitigating Factors

Extrapolation is the process of relating empiric study findings to real-world scenarios. The utility and value of animal toxicology is most dependent on this process. Thus, the selection of an animal species as a toxicologic model should involve more than considerations of cost and convenience. Whenever possible, effects that are homologous between the study species and humans should guide selection of the test species. For example, if irritant responses to an upper airway irritant (e.g., SO$_2$ or formaldehyde) are of interest, the guinea pig, with its labile and reactive bronchoconstrictive reflex, should be selected over the rat, which is not particularly responsive to sensory irritants. By contrast, certain strains of rats exhibit a clear neutrophilic response to deep lung irritants, such as O$_3$, that resembles the human response. Other innate differences in sensitivity among species may relate to differences in lung structure, specific regionally based cell metabolism or polymorphisms, or overall defenses (e.g., antioxidants) (Paige and Plopper, 1999; Slade et al., 1985). When such nuances are unclear or unknown, the replication of responses in multiple species builds confidence in the finding as being the product of conserved mechanisms across species and therefore its relevance to the human. However, new transgenic and knockout strains of mice (and in some cases rats), specially engineered to address hypotheses focused on genetically linked traits, have given toxicologists a new instrument for the study of air pollutants.

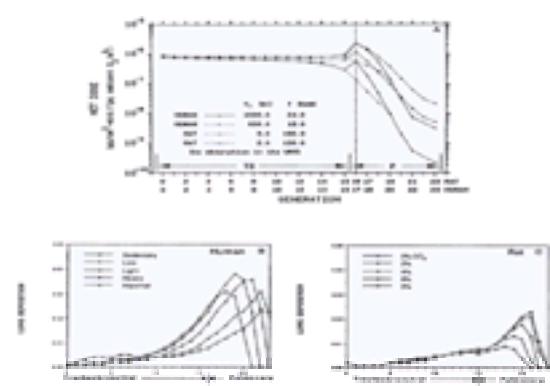
An essential part of extrapolating responses from species to species is an accurate assessment of the relative dosimetry of the pollutant along the respiratory tract. Significant advances in studies of the distribution of gaseous and particulate pollutants have been made through the use of empiric and mathematical models, the latter of which incorporate parameters of respiratory anatomy and physiology, aerodynamics, and physical chemistry into predictions of deposition and retention. Empiric models combined with theoretical models aid in relating animal toxicity data to humans and help refine the study of injury mechanisms with better estimates of the target dose. Figure 28-4A and Figure 28-4B illustrates the application of such an approach to the reactive gas ozone and insoluble 0.6-μm spherical particles, respectively, as each is distributed along the respiratory tract of humans and rats. Anatomic differences between the species clearly affect the deposition of both gases and particles, but the qualitative and to a large extent quantitative similarities in deposition profiles are noteworthy. This is not surprising if one argues teleologically that the lungs of each species evolved with similar functional demands (i.e., O$_2$–CO$_2$ exchange, blood acid/base balance), mechanical impediments, and environmental stresses. One needs only a cursory review of the comparative lung physiology literature to appreciate the allometric consistency of the mammalian respiratory tract to meet the challenge of breathing air. This design coherency has provided the fundamental rationale for the use of animal models for the study of air pollutants.


Figure 28-4. Theoretical (normalized to the concentration in inspired air) uptake curves for the reactive gas ozone in a resting/exercising human and a rat (A). Likewise, the percent deposition in the airways of a 0.6 μm insoluble particle in the respiratory tracts of a resting/exercising human (B) and rat (C).

Here 8% inspired CO$_2$ in the rat augments ventilation up to threefold. Airway generation refers to that airway branch numbered from the trachea (0). [Panel A is from Overton and Miller, 1987, and panels B and C are from Martonen et al., 1992. Reproduced with permission.]

Susceptible subpopulations that may show exaggerated responsiveness to a pollutant deserve special mention. The existence of hyperresponsive individuals and groups is well accepted among those who study air pollution toxicology, but little is actually known about the host traits that make certain individuals responsive. This appreciation for sensitive populations is specifically noted in the CAA, where their protection is mandated in the promulgation of NAAQS. There are some definable subgroups that are assumed to be susceptible, including children, the elderly, and those with a preexisting disease (e.g., asthma, cardiovascular disease, lung disease). However, the assumption that these groups are indeed susceptible is based more on perceptions than on real data. In some cases susceptibility may reside in some innate responsiveness, while in other cases it may relate more to the loss of functional reserve or compensation, perhaps altering a response threshold. The reasons for paucity of data likely lie in the difficulty in ethically conducting studies in humans who are potentially at higher risk and recruiting such individuals on a volunteer basis. However, inroads into this issue have been made in recent years, in part because of more precise definitions of potential risk factors, allowing researchers to design studies that examine host attributes that need not be at life-threatening stages of impairment and the development of more appropriate animal models of disease or dysfunction. Hence, studies in both animals and human subjects are being devised specifically to investigate the roles of diet (e.g., antioxidant

content), exercise (as it relates to dosimetry), and age, gender, and race. In addition, studies in human subjects with mild asthma or heart-lung disease have been conducted to address the degree of sensitivity that these compromised groups exhibit. Analogously, animal models with imposed cardiopulmonary impairments are being used more and more to address the same basic questions.

Recent advances in molecular biology have provided tools to bioengineer mice (and occasionally rats) with virtually any trait that is under the control of identifiable genes. Transgenic strains can express desired traits derived from other animals or even humans, or knockout models can be made devoid of specific traits to isolate the impact of that trait on the animal's responsivity to a toxic challenge. These animal models add to the availability of natural mutants that have been inbred historically to purify a desired genotype to achieve a specific phenotype, ideally one that is analogous to that of the human (Ho, 1994: Glasser et al., 1994). Natural mutant and bioengineered transgenic and knockout rodent models provide unparalleled potential to examine specific genetic factors involved in response (i.e., susceptibility). Current technology can also target genes for specific expression in the lung (e.g., linked to surfactant protein C), and in some cases it can even provide a control gene with which an investigator can switch the gene of interest on or off using a pharmacologic or chemical prechallenge. Such advances allow the dissection of underlying mechanisms under very controlled scenarios and avoid the problems of having a gene be inappropriately active or inactive through all life stages (Gossen et al., 1996).

To date the emphasis of studies using these genetically modified animal models have been on mechanisms associated with disease pathogenesis (Recio, 1995; Suga et al., 2000). Among the most popular uses of knockout and transgenic mice has been in the study of inflammatory cytokines and associated products in asthma, as the expression of many of these mediators are thought to be under the control of single genes (e.g., Kakuyama et al., 1999, Kuhn et al., 2000). Clearly these genetically modified mice are ideally suited for the study of mechanism of action where a specific mediator-based hypothesis can be tested as it relates to an impaired function, pathology, or altered inflammatory pattern. When these models are derived to exhibit a desired pathology or disease due to a genetic defect—for example involving lung structure or growth (e.g., emphysema or fibrosis), such that by adulthood the animal exhibits the disease—the model may serve as a surrogate of the human condition (e.g., O'Donnell et al., 1999).

The use or genetically modified animal models in air pollution research has lagged behind that of basic science and toxicology in general. The reasons for this are unclear and may relate to the difficulties in incorporating such data into conventional risk-assessment paradigms. However, with recent interest in potentially susceptible groups, there has been a definitive upswing in the use of pharmacologically or naturally altered as well as bioengineered animals (Kodavanti et al., 1999) and an effort to more closely link mechanistic profiles to basic human biology. Ozone has frequently been the test pollutant in these new studies, since more is known about O_3 and its effects in humans than about any other air pollutant. Frequently, these studies address aspects of inflammation and antioxidant capacity relative to challenge by ozone and other oxidants (Johnston et al., 1999; Kleeberger et al., 2000). But with the current interest in particulate matter (PM) health effects, these and other models are being redirected; for example: strain differences and acid coated PM (Ohtsuka et al., 2000); hypertransferrinemic mice and metal-rich PM (Ghio et al., 2000); and metallothionein-null mice and mercury vapor (Yoshida et al., 1999). The curious are directed to the rapidly evolving literature in this area of research.

Air Pollution: Sources and Personal Exposure

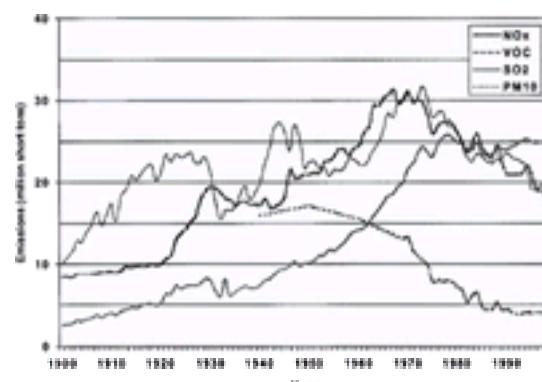
In terms of tons of anthropogenic material emitted annually in the United States (as of 1998), five major air pollutants account for 98 percent of pollution (Fig. 28-5): CO (52 percent), SO_x (14 percent), volatile organic compounds (VOCs; 14 percent), PM (4 percent), and NO_x (14 percent). The remainder consists of Pb, which is down >90 percent since 1983, when it was banned from gasoline, and a myriad of other compounds considered under the category of hazardous air pollutants. On a national basis, since 1996, PM and SO_x increased slightly and NO_x remained the same, while VOCs and CO decreased slightly. Obviously, for any specific locality, this emission picture can vary widely. In the vicinity of a smelter, for example, SO_x, metals, and/or PM dominate the pollutant profile; while a refinery air shed would be dominated by VOCs; and in suburban areas, where the automobile is the main source of pollution, CO, VOCs, and NO_x would prevail along with their primary photochemical product, O_3.


Figure 28-5. Emission trend for volatile organic compounds (VOC), nitrogen oxides (NO$_x$), sulfur dioxide (SO$_2$), and particulate matter (PM <10 μm) from 1900 (or when records began) to 1998.

Note that since the passage of the Clean Air Act of 1970, most emissions have decreased or, in the case of nitrogen oxides, have leveled off. (Reproduced with permission from National Air Pollutant Emission Trends Report, 1998 .)

Classically, air pollution has been distinguished on the basis of the chemical redox nature of its primary components. Dickens's eighteenth-century "London's particular," in which SO_2 and smoke from incomplete combustion of coal accumulated as a chilled, acidic fog, was termed "reducing-type" air pollution. This acidic mix would react with surfaces, corroding metal and eroding masonry, as is characteristic of reductive chemistry. Historically, this reducing-type atmosphere has been associated with smelting and related combustion-based industries (as along the Meuse River in 1930 and Donora, Pennsylvania, in 1948) as well as large, coal-based urban centers such as London (1952) and New York (1962). In contrast, Los Angeles has always had a characteristically "oxidant-type" pollution consisting of NO_x and many secondary photochemical oxidants, such as O_3, aldehydes, and electron-hungry hydrocarbon radicals. In photochemical air pollution, atmospheric reaction products of automobile exhaust and sunlight are trapped by regional topography or meteorologic inversion. This condition is today referred to colloquially as "smog" or "haze."

The classic types of air pollution were implicitly seasonal. Reducing air pollution occurred during winter periods of oil and coal combustion and meteorologic inversions, while the oxidant atmospheres occurred during the summertime, when sunlight is most intense and can catalyze reactions among the constituents of auto exhaust. While some regions of the United States may still experience a more reducing-type or oxidant-type atmosphere, today the distinction between these smogs is largely academic. Most modern industrial centers have undergone a considerable reduction in smoky, sulfurous emissions while experiencing a proliferation of automobiles that contribute tons of oxidant precursors into the air. Thus, major metropolitan areas, most notably those in the northeastern United States, have atmospheres with both reducing and oxidant air pollutants. Sulfates may predominate over nitrates in the air, in contrast to the southwestern United States, but no longer is the northeastern smog simply a sulfur-based problem. Nonetheless, Los Angeles (though challenged by Houston for the number-one spot in 1999) remains the prototypical center of photochemical air pollution in the United States. Outside the United States, however, many megacities remain plagued by the classic forms of air pollution. For example, uncontrolled industrial emissions surrounding cities like Beijing and the northern sectors of Mexico City are dominated by oil, coal, and industrial emissions, whereas southern Mexico City, Santiago, and Tokyo have substantially (but not so exclusively) automobile-derived oxidant smogs. The lack of policies and controls are responsible for the fact that the levels of air pollution in these cities greatly surpass those of any U.S. city. Clearly, air pollution remains a worldwide problem, where the estimate of people exposed to ozone at potentially harmful levels exceeds 480 million (Schwela, 1996).

Indoor versus Outdoor People in the United States (and in most industrialized nations) spend in excess of 80 percent of their time indoors at work, at school, and at home or between these places in an automobile (Robinson and Nelson, 1995). Generally, the time spent indoors is disproportionately higher for adults, who have relatively less time to participate in outdoor activities, especially during the day, when outdoor pollutants are usually at their highest levels. Children and outdoor workers, by contrast, are much more likely to encounter outdoor air pollution at its worst; in fact, because of the relatively high activity levels of these subgroups compared with inactive office workers, their lungs may incur a considerably larger dose of any given pollutant. Thus, while it is important to characterize and track

pollution levels in outdoor air, the most appropriate measure for exposure should involve a paradigm that addresses the total personal exposure of the individual or group of concern, and taken one step further, also dose to the lungs. However, defining typical paradigms of personal exposure can be exceedingly difficult, as personal monitoring is tedious, expensive, and complex given the many potential pollutants one may encounter and can involve a personal dynamic as individual as that person's lifestyle. Frequently, groups of people are monitored in order to develop models for the projection expected exposure values.

The indoor environment has only recently been widely appreciated as a major contributor to total personal exposure. The energy crisis of the 1970s spurred efforts to increase home and building insulation, reduce infiltration of outside air, and minimize energy consumption. At the same time, indoor sources of air contaminants have been on the rise from household products and furnishings, which—when combined with poorly ventilated heating systems and overall reductions in air-exchange rates—give rise to potentially unhealthy indoor air environments. As people began to notice patterns of odors, microbiologic growth, and even ill health, measures of indoor air became a significant part of environmental assessment. Personal exposure has, therefore, come to include the myriad of potential sources, both outdoors and indoors.

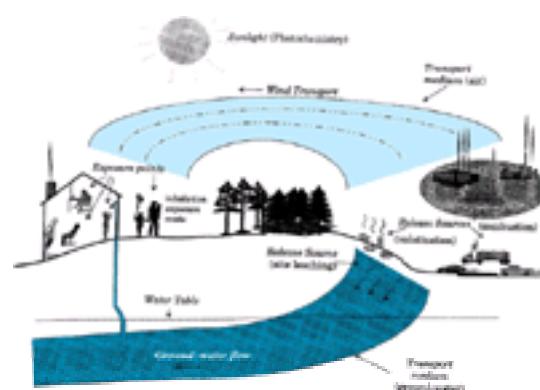
It is clear now that indoor air can be even more complex than outdoor air. Indeed, outdoor air permeates the indoor environment in spite of the reduced air exchange in most buildings. However, many variables determine how well components of the outdoor air infiltrate. The current evidence suggests that the average insulated home has about one air change per hour, resulting in indoor concentrations of pollutants that range from 30 to 80% of those outdoors. For nonreactive gases (e.g., CO), there could likely be nearly a 1:1 indoor/outdoor ratio in the absence of a "sink" for that gas; the ratio for fine particulate matter (<2.5 μm) could also be fairly high (~0.4 to 0.7), since these particles can easily penetrate through cracks and open spaces. In contrast, the indoor/outdoor ratio of O_3 would likely be low (<0.3) because of its reactivity. Obviously, household differences in the use of window ventilation and air conditioning would be important variables. Where there are independent sources of contamination indoors, the ratio of an indoor pollutant to that outdoors can even exceed 1 (e.g., NO_2). Unvented space heaters and poorly vented fireplaces and wood stoves or fresh paint and cleaning agents can be significant indoor sources. However, attention now is being directed toward the many and varied insidious sources of indoor contaminants: certain soils and construction masonry (radon), gas cooking appliances (NO_x), sidestream tobacco smoke (PM, CO, and a host of carcinogenic polyaromatics), and carpets, furnishings, dry-cleaned clothes, and household air fresheners (VOCs). Some of these chemicals can even interact with one another as has been found to occur with O_3 diffused indoors reacting with VOCs emitted from household cleaners. The complexity of these multiple sources underscores the importance of appreciating the total exposure scenario if we are to understand the nature of air pollution and its potential effects on humans (Fig. 28-6).


Figure 28-6. Illustration of contributors to the total personal exposure paradigm showing how these indoor and outdoor factors interact.

EPIDEMIOLOGIC EVIDENCE OF HEALTH EFFECTS

Outdoor Air Pollution

Acute and Episodic Exposures A number of air pollution incidents have been documented where concentrations of contaminants have risen to levels that are clearly hazardous to human health. When a single chemical has been accidentally released (e.g., methyl isocyanate in Bhopal, India), establishing the relationship between cause and ill effect is typically straightforward. However, most air pollution situations involve complex atmospheres, and establishing a specific cause other than the air pollution incident itself can be difficult. Three acute episodes of community air pollution are considered classic (Meuse Valley, Donora, and London). In each event, community inhabitants were clearly affected adversely; hospitalizations were concomitant with or were followed closely with an elevation in the mortality rate. Although no single contaminant could be fully blamed in any of these, the air pollution was the "reducing-type," in which acrid, coal-derived sulfurous gas and industrial particulate matter (including many metal sulfates) accumulated within a blanket of cool moist air. In each case, a meteorologic inversion (cold air capped above by a blanket of warm air, with little or no vertical air mixing) prevailed for 3 or 5 days, during which time the concentration of pollutants rose well above the normal levels for these already heavily polluted areas. No actual measurements of pollution were made in the Meuse Valley and Donora, but crude measurements of the London fog recorded daily averages of smoke and SO_2. These were estimated at 4.5 mg/m³ and 1.34 ppm, respectively, on the worst day. Brief (on the order of hours) peak concentrations probably reached even higher levels. During the Meuse Valley episode, 65 people died, while in Donora the number was 20. These deaths were considered "excess" deaths when compared with normal mortality rates for that time of year.

The famous "London smog" of 1952 is estimated to have resulted in 4000 excess deaths. Hospital admissions increased dramatically, mainly among the elderly and those with preexisting cardiac and/or respiratory disease. Even otherwise healthy pedestrians, their visibility limited to as little as 3 ft, covered their noses and mouths in an attempt to minimize their exposure to the "choking" air. Those with preexisting health problems were particularly affected and made up the majority of deaths. It is ironic that 16 years earlier, 3200 deaths had been predicted for London should it experience an episode like that of the Meuse Valley (Firkert, 1936). Although the London 1952 incident brought the issue of air pollution to the public consciousness, many additional episodes occurred later, with the 1956 and 1962 incidents being among the most notable. As recently as December 1991, London experienced a winter smog alert that exhibited black smoke at 148 μg/m³ and SO_2 at 72 ppb (four times and twice the seasonal average, respectively). The difference here was that the polluted atmosphere was far more the result of air contamination by automobile emissions than domestic burning of coal (Anderson, 1999), in keeping with the trends noted above. Mortality and hospital admissions were again affected, and again mostly among the elderly and cardiopulmonary-impaired (mortality: ↑14 percent cardiovascular and ↑22 percent respiratory; ↑43 percent for respiratory admissions). London has not been alone among industrialized cities significantly affected by air pollution episodes in the more recent past. New York; Steubenville, Ohio; Pittsburgh, Pennsylvania; Athens, Greece, and entire regions like those of the Netherlands and the Ruhr Valley of Germany have all had air pollution episodes of note between 1970 and 1990. Air pollution events continue to decrease over time in the modern world, both in their frequency and intensity. What episodes do arise are dwarfed in their impact by the classic smog episodes.

So much has the air improved in recent times that many have thought that the problem of sulfur-based industrial pollution was essentially resolved. However, in the late 1980s, there were revelations regarding acidic pollution of lakes and defoliation of forests (Calvert et al., 1985) as well as new studies showing increased emergency room visits among potentially susceptible populations—asthmatics (Bates and Sizto, 1987). A series of studies showed acute effects of ambient levels of pollution that occur during the summer (summer haze) in areas of central and northeastern North America. These peaks of pollution were typified by increases in O_3 and sulfates, characteristic of the new generation of pollution in most U.S. urban areas. The increase in sulfate consisted of both acidic and atmospherically neutralized forms of sulfuric acid and photochemically derived O_3; such hazes cover large regions and can be widely transported. In one southern Ontario–based study, there was a consistent association in the summer between hospital visits for acute respiratory problems, especially among asthmatic children, and daily levels of both O_3 and sulfate. Interestingly, the apparent combined temporal or sequential patterns of O_3 and sulfate were associated with the health effects, but neither constituent alone. Similar results have been reported for the upstate New York area as well (Thurston et al., 1992), but acidity as [H⁺], which is common in summer haze, was thought to play a more dominant role. However, studies of children at summer camps, where they are active and outdoors most of the day, had reported decrements in daily measured pulmonary function on days when both O_3 and acidity levels were elevated but still below those that would be predicted to have a measurable effect (Lippmann, 1989). Animal toxicology and clinical studies in adolescent asthmatics have lent further support to the belief that H⁺ can affect airway function, particularly in the presence of O_3. Studies in the South and Southwest similarly have found effects in young asthmatics, but these appear to relate more specifically to O_3, since sulfate is less prominent. This finding is in agreement with earlier data from the Los Angeles area showing a high degree of correlation between diminished performance among high school athletes and increased oxidant levels.

Of the many studies of air pollution over the last 10 to 15 years, none has had more impact on today's perspective of the risks associated with pollution than a series of studies using a relatively new analyses of contemporary or preexistent daily mortality and morbidity trends and regional air monitoring data. These studies showed significant and consistent associations between health impacts of ambient PM at levels thought to be safe. Prior to this period, measurable effects of PM and SO_2 were not easily detected below the 24-h mean for smoke and SO_2 levels of 250 $\mu g/m^3$ and 0.19 ppm, respectively. The new findings showed effects, evidenced by increases in mortality and morbidity rates at or below their contemporaneous NAAQS [50 $\mu g/m^3$, annual mean; 150 $\mu g/m^3$ daily maximum for PM of diameter <10 μm (PM_{10})]. The new studies made use of novel time-series analyses that are based on Poisson regression modeling to distinguish changes in daily death counts associated with short-term changes in PM air pollution. The studies initially found effects with TSP matter, which includes virtually all particles to about 35 μm in mass median aerodynamic diameter (MMAD—a median particle size normalizing the particle to unit density and spherical shape for aerodynamic comparison). These studies were followed with stronger associations with particles considered almost fully inhalable—PM_{10} (an MMAD at which PM is aerodynamically separated at an initial 50 percent efficiency at 10 μm and increasingly at smaller sizes). Most recently, even stronger associations have been found with an analogous but fully and deeply respirable particle—$PM_{2.5}$. As the PM gets smaller, it represents more anthropogenic sources of pollution. The statistical methodology applied in these studies had an advantage over conventional regression analyses in that it could detect short-term trends and minimized the effects of other pollutants and potential confounders with longer time constants (Schwartz, 1991; reviewed by Pope and Dockery, 1999).

In contrast to the three epidemiologic studies used to defend the 1987 PM_{10} NAAQS, there were more than thirty used for the 1997 revision of the standard and promulgation of a new $PM_{2.5}$ NAAQS [15 $\mu g/m^3$, annual mean; 65 $\mu g/m^3$ daily maximum for PM of diameter <2.5 μm ($PM_{2.5}$)]. These newer studies have shown a significant health impact of PM, linked to mass and not necessarily sulfate or any other constituent. Although effects are most apparent in individual groups already compromised by cardiopulmonary diseases, there is no one accepted mechanism to account for these findings (Schwartz, 1994; Costa, 2000). That the association is not somehow linked to the composition of the PM has drawn considerable attention from researchers who are trying to establish a "biologically plausible" link to some attribute of PM other than mass alone. The linkage to mass and not composition is somewhat counterintuitive to the toxicology community, especially in light of the fact that all PM is not constitutively identical. Nevertheless, the collective data show that for day-to-day fluctuations in the mass concentration of 10 $\mu g/m^3$ airborne PM, there occurs an increase of about 0.6 to 1 percent (excess) mortality. In addition to mortality, morbidity (in terms of hospital visits, inhaler use by asthmatics, and school absenteeism) also is associated with ambient PM levels; other factors such as temperature, humidity, O_3, SO_2, and other pollutants per se do not explain the observed effects. At this point the consistency of the phenomenon from one geographic site to another and over time is remarkable. Even revisiting the mortality data from the 1952 London incident demonstrates that PM was likely the pollutant of most prominence interms of the adverse health consequences back almost 50 years (Schwartz and Marcus, 1990).

The direction and design of population studies today, frequently referred to as panel or cohort studies, are largely person-based, where groups of people are studied (e.g., nursing home residents, schoolchildren) in their immediate environment using non- or minimally invasive clinical tools (e.g., pulmonary or cardiac function, symptoms, blood screenings, etc.) to correlate effects with ambient and/or personal environmental and air pollutant measures. These studies sacrifice the power of group numbers for more direct and individual data in an attempt to link biomarkers with exposure. These novel approaches have the promise of eventually offering clues as to causality, which is not possible with conventional epidemiology, and recent studies are showing increasingly more subtle changes in cardiopulmonary function with exposure to very modest air pollution.

Long-Term Exposures Epidemiologic studies of the chronic effects of air pollution are difficult to conduct because of the nature of the goal: outcomes associated with long-term exposures. The usual approach of retrospective, cross-sectional studies is frequently confounded with unknown variables and inadequate historical exposure data. A good example of the problem of confounding is cigarette smoking. Without extensive control of both active of passive smoking, the ability to discern the impact of air pollution or a disease outcome such as chronic bronchitis and emphysema would be greatly impaired because of the high background of disease attributable to smoking and the imprecision of most indices of smoking exposure in this type of study. In contrast, prospective studies have the advantage of more precise control of confounding variables, such as the tracking of urinary cotinine as an index of tobacco smoke exposure, but they can be very expensive and require substantial time and dedication on both the part of the investigators as well as the population under study. Depending on the study size and design, exposure aspects can also be problematic, but loss of subjects due to dropout is usually more troublesome.

Despite these deficiencies, there have been several epidemiology studies of both types conducted with the aim of determining long-term air pollution health effects. In general, these studies have suggested a positive association between urban pollution and progressive pulmonary impairment. On the one hand, cross-sectional studies in the Los Angeles Air Basin have found evidence of accelerated "aging-like" loss of lung function in people living for extended periods in regions of high oxidant pollution as compared with areas where sea air circulates and lowers the overall pollutant concentrations (Detels et al., 1991). Similarly, chronic exposure to SO_2 and PM in the Netherlands over a 12-year period was shown prospectively to gradually impair lung function (Van De Lende et al., 1981). And even rural areas in western Pennsylvania, which are swept by reducing-type pollutants transported from midwestern industrial centers, have been shown to have a higher incidence of respiratory symptoms as determined from a questionnaire-based design (Schenker et al., 1983). While the role of any specific pollutant in these studies is difficult to dissect, the message that air pollution contributes to deterioration of lung health seems clear.

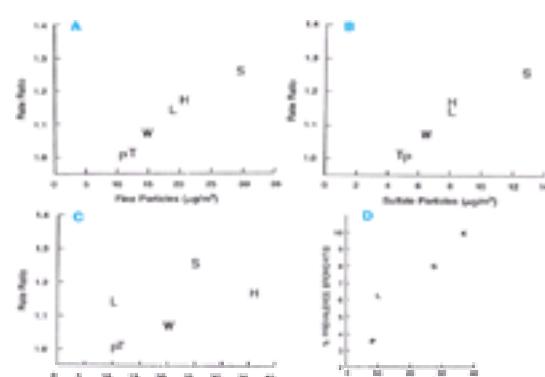
Among the most detailed prospective epidemiologic studies of the chronic health effects of current levels of air pollution has been the so-called Harvard Six Cities Study begun in the early 1970s. The cities were chosen to represent a range of air quality (based on SO_2 and PM). Initially, there was great dependence on routine regional air-monitoring data, but over time air analyses of microenvironments by the investigators themselves predominated. The initial design of these studies included the gathering of parental questionnaire data (including some 20,000 people) about the prevalence of respiratory problems in schoolchildren and has been continued over twenty years with tracking of similar data along with periodic assessments of pulmonary function. When compared across cities, [H+] (measured in four of the six cities) was correlated (Fig. 28-7A) better than was sulfate with the prevalence of bronchitis in children age 10 to 12 (Speizer, 1989). However, as the assessment program evolved, more detailed study revealed mortality associations with PM as noted above, and represented in Fig. 28-7B Fig. 28-7C and Fig. 28-7D, but the role of [H+] in this relationship with acute mortality was less convincing than that associated with the sulfate or fine (£2.5 μm) PM (sulfates co-associate with fine PM in the atmosphere) (Dockery et al., 1993). But more importantly with regard to long-term health, this study showed very significant effects of PM on the life spans of people living in Steubenville, Ohio—an area of industrial reducing-type pollution. Over a 15-year period, the average human life span was reduced by about 2 years due to PM exposure. Another cohort-based mortality study of the long-term effects from PM, especially that derived from combustion ($PM_{2.5}$ and sulfate), was conducted using the data from 151 cities (Pope et al., 1995). This study confirmed the impact of PM on mortality, showing a 15 to 17 percent increased risk over 7 years, about equivalent to the risk of smoking over that period. Hence, there is now growing concern for the potential chronic health impacts and heightened risk of premature death from lifelong air pollution exposure.


Figure 28-7. Data from the Harvard Six Cities Studies indicating the superior relationship of PM$_{1(}$ and sulfate to mortality rates (A–C) in contrast to acidity (D), which correlates better with the prevalence of bronchitis in children. [Reproduced with permission from Speizer, 1989 (D) and Dockery et al., 1993 (A–C).]

The role of air pollution in human lung cancer is also difficult to assess because the vast majority of respiratory cancers result from cigarette smoking. However, many compounds that occur as urban air pollutants are known to have carcinogenic potency. Several of these compounds are among the 188 HAPs listed in the CAA Amendment of 1990. However, most of the HAPs and even fewer (about 10 percent) of the more than 2800 compounds that have been identified in the air have been

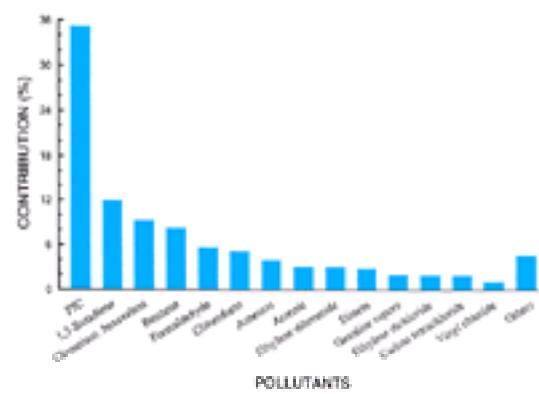
assayed for carcinogenic potency. Figure 28-8 gives estimates of the relative contributions of various chemicals to the lung cancer rate that is *not* associated with cigarette smoking, which, for outdoor air, is estimated to be about 2000 cases per year (Lewtas, 1993). This compares with about 2000 cases per year for passive environmental tobacco smoke and about 100,000 cases per year for smokers. Volatile organic compounds (VOCs) and nitrogen-containing and halogenated organics account for most of the compounds that have been studied with animal and genetic bioassays. Most of these compounds are derived from combustion sources ranging from tobacco to power plants to incinerators. Other potential carcinogens arise from mobile sources as products of incomplete combustion and their atmospheric transformation products as well as fugitive or accidental chemical releases. This contrasts with indoor air, where the sources are thought to derive largely from environmental tobacco smoke and radon, with some contribution from the off-gassed organics (e.g., adhesives, carpet polymers).


Figure 28-8. Relative contribution of individual airborne hazardous pollutants to lung cancer rates after removal of tobacco smoke cancer.

The total number of cancers from non-tobacco-smoke sources is estimated to be about 2000 per year. (Reproduced with permission from Lewtas, 1993.) PIC = products of incomplete combustion.

The cancer risk of any individual should be some function of the carcinogenic nature of the substance, the amount of material deposited, which is itself a function of the concentration in the ambient air and the cumulative volume inhaled, and of course the innate susceptibility of the individual (including genotypic traits and environmental factors such as diet, etc.). A significant body of data suggests that the majority of cancer risk from ambient air pollution lies within the particulate fraction. Among the many potent chemicals are the polycyclic organic chemicals, along with a group of less-volatile organics sometimes referred to as "semivolatiles" (including nitroaromatics). These persistent organics associate with the particulate matrix and thus could have a prolonged residence time at deposition sites within the respiratory tract. Genetic bioassays have revealed the potent mutagenicity, and presumably carcinogenicity, of various chemical fractions of ambient aerosols (Lewtas, 1993). Some of these compounds require metabolic transformation to activate their potency while others may be detoxified by their metabolism.

The cells lining the respiratory tract turn over relatively quickly, since they continuously interface with the ambient environment. Conceptually, their DNA would thus be frequently vulnerable to carcinogenic or oxidant-induced replication errors that, when fixed as mutations, could be tumorigenic. Copollutants, such as irritant gases that initiate inflammation, may promote carcinogenic activity by damaging cells and further enhancing their turnover. For example, there is experimental evidence that benzo(a)pyrene inhaled by rats whose respiratory tracts have been chronically irritated by SO_2 inhalation may result in bronchogenic carcinoma. Likewise, epidermoid carcinomas were produced in mice that inhaled ozonized gasoline, containing many reactive organic products, if these mice had been previously infected with influenza virus and had presumably developed inflammation. Many believe that the so-called rural-urban gradient of lung cancer, apparent even when corrected for cigarette smoking, is a product of these complex interactions. Thus, while the phenomenon of environmental lung cancer remains poorly understood, there is general sentiment for the early opinion expressed by Kotin and Falk in 1963: "Chemical, physical and biological data unite to form a constellation that strongly implicates the atmosphere as one dominant factor in the pathogenesis of lung cancer." At the time of this statement, however, the role of tobacco smoke was not widely appreciated.

Indoor Air Pollution

As outdoor air quality has improved over the last 20 to 30 years, there has been a growing awareness of the potential for indoor air pollution to elicit adverse health effects. The concerns about indoor air that at first brought skepticism have gained an element of respectability as various attributes of the indoor environment and its effect on health and well-being are being investigated. However, the issue remains controversial because many of the health problems associated with indoor air pollution generally involve nonspecific symptomatology and appear to involve a wide range of potential toxicants and sources (Molhave et al., 1986). The responses to indoor air pollution also appear to be affected by ambient comfort factors such as temperature and humidity. Two broadly defined illnesses that are largely unique to the indoor environment are discussed below (Brooks and Davis, 1992).

Sick-Building Syndromes This collection of ailments, defined by a set of persistent symptoms enduring at least 2 weeks (Table 28-3), occurs in at least 20 percent of those exposed and is typically of unknown specific etiology but is relieved sometime after an affected individual leaves the offending building (Hayes et al., 1995). Frequently but not always, this syndrome occurs in new, poorly ventilated, or recently refurbished office buildings. The suspected causes include combustion products, household chemicals, biological materials and vapors, and emissions from furnishings; they are exacerbated by the effect of poor ventilation on comfort factors. The perception of irritancy to the eyes, nose, and throat ranks among the predominant symptoms that can become intolerable with repeated exposures. Controlled clinical studies have shown concentration- and duration-dependent worsening of sensory discomfort after exposure to a complex mixture of 22 VOCs commonly found in the indoor environment (Molhave et al., 1986). The many factors contributing to such responses are poorly understood but include various host susceptibility factors such as personal stress and fatigue, diet and alcohol use, and other factors. Current biomarkers of response used in the laboratory include sensory irritancy to the eyes in volunteer test subjects and sometimes in animals as well. Animal studies using standard measures of sensory irritation or other corporal endpoints have had limited success in assessing sick-building syndromes (SBS) and related syndromes. The biggest problem generally lies in the VOC concentrations required to achieve responses in a limited pool of animals that relate to likely human exposures is too high to establish a plausible link to the human condition.

Eyes, nose, and throat irritation
Headaches
Fatigue
Reduced attention span
Irritability
Nasal congestion
Difficulty breathing
Nosebleeds
Dry skin
Nausea

source: Modified from Brooks and Davis, 1992, with permission.

Table 28-3 Symptoms Commonly Associated with the Sick-Building Syndromes

Building-Related Illnesses This group of illnesses, in contrast to the SBS, consists of well-documented conditions with defined diagnostic criteria and generally recognizable causes. These illnesses typically call for a conventional treatment regimen, since simply exiting the building where the illness was contracted does not readily reverse the symptoms. Several of the bicontaminant-related illnesses (e.g., legionnaires' disease, hypersensitivity pneumonitis, humidifier fever) fall into this group, as do allergies to animal dander, dust mites, and cockroaches. Some toxic inhalants might be classified in this group, such as carbon monoxide. In many cases, however, when the concentrations of CO, NO_2, and many VOCs result in less discernible or definable conditions, the responses may be mistaken for or considered to be SBS, thus complicating the assessment of the situation. It should be noted that many inhalants, such as NO_2 and trichloroethylene (a VOC common

to the indoor air arising from chlorinated water or dry-cleaned clothes), have been shown in animal toxicology studies to suppress immune defenses and allow opportunistic pathogens to proliferate in the lung. The involvement of immunologic suppression is a particularly controversial yet important attribute of indoor pollution because of its insidious nature and implications for all building-related illnesses. This is further complicated in that complex indoor environments comprising of chemicals and biologicals may also lead to in unexpected interactions that are virtually unstudied and thus are not appreciated in the assessment of indoor pollution.

POLLUTANTS OF OUTDOOR AMBIENT AIR

Classic Reducing-Type Air Pollution

The acute air pollution episodes of this century have made it clear that high concentrations of the reducing-type air pollution, characterized by SO_2 and smoke, are capable of producing disastrous human health effects. Empiric studies in human subjects and animals have long stressed the irritancy of SO_2 and its role in these incidents, while the full potential for interactions among the copollutants in the smoky, sulfurous mix has not been fully replicated in the laboratory. Nevertheless, the irritancy of most S-oxidation products in the atmosphere is well documented, and there are both empiric and theoretical reasons to suspect that such products act to amplify the irritancy of fossil fuel emission atmospheres via chemical transformations and related interactions.

Sulfur Dioxide *General toxicology* Sulfur dioxide is a water-soluble irritant gas. As such, it is absorbed predominantly in the upper airways and, as an irritant, can stimulate bronchoconstriction and mucus secretion in a number of species, including humans. As one of the earliest suspect air pollutants, it has been well studied over the years. Early studies with relatively high exposure concentrations of SO_2 showed airway cellular injury and subsequent proliferation of mucus-secreting goblet cells. This attribute of SO_2 has led to its use (>250 ppm) in the production of laboratory animal models of bronchitis and airway injury (Kodavanti et al., 1999). At much lower concentrations (<1 ppm), such as might be encountered in the polluted ambient air of industrialized areas, long-term residents experience a higher incidence of bronchitis. In fact, prior to the breakup of the Soviet block, many eastern European cities were renowned for widespread public affliction with bronchitis; now, 20 years later, the prevalence of bronchitis is greatly reduced (von Mutius et al., 1994). While other factors (diet, access to health care, other pollutants) may well have been involved in this reversal, reductions in ambient smoke and SO_2 are generally thought to be most important.

The concentrations of SO_2 likely to be encountered in the United States are lower still—on average, less than 0.1 ppm. Mandated use of cleaner (low-S) fossil fuels, emission control devices, and the use of tall emission stacks have largely been responsible for the reductions. However, on occasional down-drafting of smokestack plumes or meteorological inversions near point-sources result in low ppm levels of SO_2 that may pose a hazard to some individuals. A 2-min exposure to 0.4 to 1.0 ppm can elicit bronchoconstriction in exercising asthmatics within 5 to 10 min (Gong et al., 1995). However, it is the low-level, long-term effects, which erode pulmonary defenses, that continue to worry some regulators. Studies have shown that SO_2 is itself capable of impairing macrophage-dependent bacterial killing in murine models. Exposed mice have a greater frequency and severity of infection, which has been suggested to be linked to diminished ability to generate endogenous oxidants for bacterial killing. Analogously, rats exposed for 70 to 170 h to 0.1, 1.0, and 20 ppm exhibited reduced clearance of inert particles, while dogs exposed to 1 ppm for a year had slowed tracheal mucocilliary transport. The fact that the low-concentration exposures showed marked effects when extended over longer periods is consistent with the epidemiologic associations between SO_2 exposure and bronchitis. The evidence is not clear, however, as some studies show no overt pulmonary pathology. Guinea pigs and monkeys, for example, showed no effect on lung function or pathology after a year of continuous exposure to concentrations of 0.1 to 5 ppm (Alarie et al., 1970, 1972).

The penetration of SO_2 into the lungs is greater during mouth as opposed to nose breathing. An increase in the airflow rate further augments penetration of the gas into the deeper lung. As a result, persons exercising would inhale more SO_2 and, as noted with asthmatics, are likely to experience greater irritation. Once deposited along the airway, SO_2 dissolves into surface lining fluid as sulfite or bisulfite and is readily distributed throughout the body. It is thought that the sulfite interacts with sensory receptors in the airways to initiate local and centrally mediated bronchoconstriction. Labeled $^{35}SO_2$ studies indicate, however, that some residual S (presumably as protein reaction products) persists in the respiratory system for a week or more after exposure, and is slowly excreted in the urine (Yokoyama et al., 1971). In both rabbits and human subjects, sulfite that reaches the plasma has been shown to form *S*-sulfonate products of reaction with the disulfide bonds in plasma proteins (Gunnison and Palmes, 1974). The toxicologic significance of *S*-sulfonate proteins is unknown, but they might serve as markers of exposure.

Pulmonary Function Effects The basic pulmonary response to inhaled SO_2 is mild bronchoconstriction, which is reflected as a measurable increase in airflow resistance due to narrowing of the airways. Concentration-related increases in resistance have been observed in guinea pigs, dogs, and cats as well as humans. Exposure of isolated segments of the nose or airways of dogs and guinea pigs appeared to alter resistance in a manner consistent with receptor-mediated sensory stimulation. Airflow resistance increased more when the gas was introduced through a tracheal cannula than via the nose, since nasal scrubbing of the water-soluble gas was bypassed. Isolated nasal exposures increased nasal airflow resistance through the nose largely as a result of mucosal swelling, but the irritant effect appeared to signal to the more distal airways as well. Direct exposure of the trachea had a more dramatic effect on airflow resistance, but exposure of the intact nose and lungs together gave the most marked responses, consistent with the theory that a neural network involving receptor stimulation is involved in bronchoconstriction (Frank and Speizer, 1965; Nadel et al., 1965). Intravenous injection of atropine (a parasympathetic receptor blocker) or cooling of the cervical vagosympathetic nerves abolishes bronchoconstriction in the cat model; rewarming of the nerve reestablishes the response. The rapidity of the response and its reversal emphasize the parasympathetic tonal change in airway smooth muscle. Studies in human subjects have confirmed the predominance of parasympathetic mediation, but histamine from inflammatory cells may play a secondary role in the bronchoconstrictive responses of asthmatics (Sheppard et al., 1981).

Human subjects exposed to 1, 5, or 13 ppm SO_2 for just 10 min exhibit a rapid bronchoconstrictive response, with 1 to 3 ppm being a threshold for most if exercise is involved. Healthy individuals at rest seem to have a clear response at about 5 ppm, though there is considerable variation among individuals (Frank et al., 1962). Even 0.25 to 1 ppm for a few hours can induce bronchoconstriction in adult and adolescent subjects with clinically defined mild asthma (Sheppard et al., 1981; Koenig et al., 1981). Findings such as these (responses <0.5 ppm) have raised concerns about potential adverse effects in this sensitive subpopulation when it is exposed to peaks of SO_2 that are known to occur near point sources.

Chronic Effects Few long-term studies have been conducted with SO_2 at levels approaching those found in ambient air. Alarie and associates (1970) exposed guinea pigs to 0.13, 1.01, or 5.72 ppm SO_2 continuously for a year without adverse impact on lung mechanics. Similarly, monkeys exhibited no alteration in pulmonary function when exposed continuously for 78 weeks to 0.14, 0.64, and 1.28 ppm SO_2 (Alarie et al., 1972). Even in the presence of 0.1 mg/m^3 sulfuric acid, dogs exposed 16 h a day for 18 months to 0.5 ppm SO_2 showed no impairment in pulmonary function (Vaughan et al., 1969). Only higher levels of SO_2 for protracted periods of time [dogs to 5 ppm for 225 days (Lewis et al., 1969); rats to 350 ppm for 30 days (Reid, 1963)] have been shown to alter airway mucus secretion, goblet cell topography, or lung function, but these results are of little relevance to typical SO_2 levels in ambient air.

Sulfuric Acid and Related Sulfates

The conversion of SO_2 to sulfuric acid is favored in the environment. During oil combustion or the smelting of metal, sulfuric acid condenses downstream of the combustion processes with available metal ions and water vapor to form submicron sulfated fly ash. Sulfur dioxide continues to oxidize to sulfate in dispersing smokestack plumes in the presence of free soluble or partially coordinated transition metals such as iron, manganese, and vanadium within the ash particles. When coal is burned, the acid may adsorb to the surface or solubilize in ultrafine (<0.1 μm) metal oxide particles during emission. These sulfates on the surface of coal ash may constitute as much as 9 percent of the emitted sulfur—the rest is emitted as SO_2 gas. Photochemical environments in the lower troposphere can also promote acid sulfate formation via both metal-dependent and independent mechanisms, but studies have shown that most of the oxidation of SO_2 occurs within diluted plumes drifting in the atmosphere. Stack emissions may undergo long-range transport to areas distant from the emission source, allowing considerable time for sunlight-driven chemical reactions to occur. Although the fine-particle sulfates may exist as fine sulfuric acid (the primary source of free H^+), partially or fully neutralized forms (ammonium bisulfate and ammonium sulfate) predominate due to the abundance of natural atmospheric ammonia. As fine PM sulfates are transported long distances, they may contribute to regional summer haze and pose not only a health hazard to certain groups (e.g., asthmatics)–(Koenig et al., 1989), but may stress the general environment as acid rain (Calvert et al., 1985) (Fig. 28-9).

General Toxicology Sulfuric acid irritates respiratory tissues by virtue of its ability to protonate (H^+) receptor ligands and other biomolecules. This action can either directly damage membranes or activate sensory reflexes that initiate inflammation. Ammonia, which exists in free air at about 25 ppb and in much higher concentrations in the mammalian nasopharynx/oropharynx, is capable of neutralizing most of the irritant potential of acidic sulfates. The efficiency of this process is dependent on temperature, relative humidity, and air mixing and thus is a likely source of variability in biological responses. This is particularly true in animal studies involving standard whole-body exposure-chamber operation, in which excreta and bacteria may interact, giving rise to chamber ammonia concentrations up to 1100

ppb—more than enough to fully neutralize sulfuric acid up to several mg/m^3 (Higuchi and Davies, 1993). Similarly, endogenous ammonia such as that which exists in the mouth has been shown to inhibit responses up to 350 µg/m^3 sulfuric acid in exercising asthmatics (Utell et al., 1989). For this reason, most human test subjects rinse orally with citrus juice before a sulfuric acid study, so as to minimize this phenomenon.

Interestingly, there is considerable species variability in sensitivity to sulfuric acid, with guinea pigs being quite reactive to acid sulfates, in contrast to rats, which are highly resistant. The reasons for this difference are not fully understood but relate to receptor type and density in the airways and probably not on differences in neutralization by ammonia in the airway. The sensitivity of healthy humans appears to fall somewhere in between, with asthmatic humans being perhaps best modeled by the guinea pig. Overall, however, the collective data involving animals and humans are remarkably coherent, as reviewed in an article by Amdur (1989). To illustrate this point, Table 28-4 compares the acute toxicity of SO$_2$ and sulfuric acid in animals and human subjects, using indices detailed below, airway resistance, and bronchial clearance. To allow direct comparisons, the concentrations are presented as µmol/m^3 of the two compounds.

	µmol/		
	SO$_2$	H$_2$SO$_4$	REFERENCE
Guinea pigs 1 h:			
10% ↑ airway resistance	6	1	Amdur, 1974
Donkeys 30 min: ↓ altered bronchial clearance	6875	2	Spiegelman et al., 1968; Schlesinger et al., 1978
Normal subjects 7 min:			Lippmann and Altshuler, 1976
↓ altered bronchial clearance	520	1	Leikauf et al., 1981
Normal subjects 10 min:			
5% ↓ total volume	29	1.25	Amdur, 1954
Adolescent asthmatics 40 min: equal ↑ airway resistance	20	1	Koenig et al., 1989

Table 28-4 Comparative Toxicity of SO$_2$ and H$_2$SO$_4$ in Acute Studies

Pulmonary Function Effects Sulfuric acid produces an increase in flow resistance in guinea pigs due to reflex airway narrowing, or bronchoconstriction, which impedes the flow of air into and out of the lungs. This process can be thought of as a defensive measure to limit the inhalation of air containing noxious gases. The magnitude of the response is related to both acid concentration and particle size (Amdur, 1958; Amdur et al., 1978). Early studies indicated that as particle size was reduced from 7 µm to the submicron range, the concentration of sulfuric acid necessary to induce a response and the time to the onset of the response fell significantly. With large particles, even the sensitive guinea pig was able to withstand an exceedingly high (30 mg/m^3) challenge with little change in pulmonary resistance, in contrast to the <1 mg/m^3 challenge needed with the 0.3 µm particles (Amdur et al., 1978). Human asthmatics exposed to 2 mg/m^3 of acid fog (10 µm) for 1 h, a very high concentration for an asthmatic, experienced variable respiratory symptoms suggesting irritation, but no changes in spirometry were elicited (Hackney et al., 1989). The apparent reason for this PM size–based differential response is probably the scrubbing of large particles in the nose, while the small particles are able to penetrate deep into the lung, reaching receptors that stimulate bronchoconstriction and mucus secretion. The thicker mucus blanket of the nose may blunt (by dilution or neutralization by mucus buffers) much of the irritancy of the deposited acid, thus limiting its effects to mucous cell stimulation and a minor increase in nasal flow resistance. In contrast, the less shielded distal airway tissues, with their higher receptor density, would be expected to be more sensitive to the acid, as reflected by their responsiveness to the small particles reaching that area (Costa and Schlegel, 1998). This regional sensitivity and the longer residence time of a deposited particle relative to SO$_2$ gas probably were reflected in the relatively protracted recovery times observed in acid-exposed guinea pigs compared with animals exposed to SO$_2$ alone. Alternatively, the particles of ZnO used in this study provided soluble Zn^{+2} when combined with acid.

Asthmatics appear to be somewhat more sensitive to the bronchoconstrictive effects of sulfuric acid than are healthy individuals, but published studies have been inconsistent (Koenig et al., 1989; Utell et al., 1984). Asthma generally is characterized by hyperresponsive airways, so their tendency to constrict at low acid concentrations would be expected, just as asthmatic airways are sensitive to nonspecific airway smooth muscle agonists (e.g., carbachol, histamine, exercise) (Hanley et al., 1992). The variability may well relate to differences in the degree of impairment or underlying inflammation in the subjects, but this hypothesis remains to be confirmed. Airway hyperreactivity has been observed as an acute response in guinea pigs 2 h after a 1-h exposure to 200 µg/m^3 sulfuric acid and appears to be associated with pulmonary inflammation. Likewise in rabbits, increased airway reactivity was associated with arachidonate metabolites, products of epithelial cells as well as inflammatory cells. The general correlation between airway responsiveness and inflammation that appears to be important in grading asthma severity and risk of negative clinical outcomes may also be predictive of responses to environmental stimuli.

Effects on Mucociliary Clearance and Macrophage Function Sulfuric acid alters the clearance of particles from the lung and thus can interfere with a major defense mechanism. Effects on clearance of insoluble, radioactively labeled ferric oxide particles have been observed after as little as a single 1-h exposure in donkeys, rabbits, and human subjects. The impact on mucus clearance appears to vary directly with the acidity ([H$^+$]) of the acid sulfate, with sulfuric acid having the greatest effect and ammonium sulfate the smallest (Schlesinger, 1984). Curiously, there appears to be a biphasic response to the acid that has been observed in all animal species studies to date as well as in human subjects. In general, brief, single exposures of <250 µg/m^3 accelerate clearance, while high concentrations of >1000 µg/m^3 clearly depress clearance. Over several days, there also appears to be a cumulative (concentration times duration) dose-related depression of clearance. Longer-term exposure of rabbits to low-level acid ultimately slows clearance in apparent concert with hyperplasia of airway mucosecretory cells (Gearhart and Schlesinger, 1989). Acidification of mucus by H$^+$ (i.e., a fall in pH), even if localized, is hypothesized to have potential effects on mucus rheology and viscosity (Holma, 1989) as well as on mucus secretion and ciliary function. These effects are not unreasonable in light of the drop in macrophage intracellular pH reported in some acid studies (Qu et al., 1993).

Sulfate effects on bronchial clearance in both rabbits and humans and airway resistance in guinea pigs and in asthmatics (though sensitivities in these subjects can be quite variable) appear coherent relative to the irritant potency of sulfates: sulfuric acid > ammonium bisulfate > ammonium sulfate. Acidity appears to be the primary driving factor on most respiratory effects attributable to the acid sulfates even at the level of pulmonary macrophages. Lavaged rabbit macrophage phagocytosis was affected more after a single exposure to 500 µg/m^3 sulfuric acid than after 2000 µg/m^3 ammonium bisulfate (Schlesinger et al., 1990). However, there is some evidence at the level of cellular activation and arachidonate metabolism suggesting that the anionic component of the aerosol also plays some role. Although the consensus is that acidity is the active toxicant and is the primary metric to associate with population health effects, it remains unclear whether the bioactive form of [H$^+$] is more appropriately assayed as free ion concentration (as pH) or as total available ion concentration (titratable H$^+$).

Chronic Effects As might be expected, sulfuric acid induces qualitatively similar effects along the airways as are found with SO$_2$ at much higher concentrations. As a fine aerosol, sulfuric acid deposits deeper along the respiratory tract, and its high specific acidity imparts greater injury effect on various cells (e.g., phagocytes and epithelial cells). Thus, a primary concern with regard to chronic inhalation of acidic aerosols is its potential to cause bronchitis, since this has been a problem in occupational settings in which employees are exposed to sulfuric acid mists (e.g., battery plants). Early studies in the donkey that later were expanded in a rabbit model have provided fundamental data on this issue. The profound depression of clearance found in donkeys exposed repeatedly (100 µg/m^3 1 h per day for 6 months) promoted the hypothesis that a similar response (i.e., chronic bronchitis) can occur in humans. This argument was strengthened by the similar bronchitogenic responses of the two species when chronically exposed to cigarette smoke.

Many studies conducted with sulfuric acid in the rabbit are in general agreement with the early findings in the donkey (Schlesinger et al., 1979; Schlesinger 1984). These studies have expanded our knowledge of the biological response and its exposure-based relationship. The initial stimulation of clearance with subsequent depression has been shown to occur over 12 months with as little as 2 h per day at 125 µg/m^3 sulfuric acid (Schlesinger et al., 1992). Related studies also have demonstrated that the airways of exposed animals become progressively more sensitive to challenge with acetylcholine, showed a progressive decrease in diameter, and experienced an increase in the number of secretory cells, especially in the smaller airways (Gearhart and Schlesinger, 1989).

Unlike other irritants, such as O$_3$ (see below), sulfuric acid does not appear to stimulate a classic neutrophilic inflammation after exposure. Rather, eicosanoid homeostasis appears to be disturbed resulting in macrophage dysfunction and altered host defense, perhaps in part mediated by a decrease in intracellular pH. Long-term disease attributable to connective tissue disturbances induced by sulfuric acid seems to be of lesser concern than is the impact on mucociliary function and the potential effect on ventilation and arterial oxygenation (Alarie et al., 1972, 1975). Therefore, it seems reasonable to postulate that chronic daily exposure of humans to sulfuric acid at levels of about 100 µg/m^3 may lead to impaired clearance and mild chronic bronchitis. As this is less than an order of magnitude above

haze levels of sulfuric acid, the possibility that chronic irritancy may elicit bronchitic-like disease in susceptible individuals (perhaps over a lifetime or in children because of dose differences) appears to be reasonable.

Particulate Matter

Particulate matter in the atmosphere is a mélange of organic, inorganic, and biological materials whose compositional matrix can vary significantly depending on local point sources. The contribution to any regional PM matrix from long-range transport of emissions or transformation products can also be substantial, particularly for fine (<2.5-μm) particles. There is now a large epidemiologic database contending that PM elicits both short- and long-term health effects at current ambient levels (near the NAAQS). According to the epidemiology, these effects appear to be less affected by gross particle composition (e.g., inorganic versus organic) and nominal size (e.g., TSP, PM_{10}, $PM_{2.5}$) than by basic gravimetric measures of ambient exposure. Many have argued that this relationship contradicts the basic tenets of conventional air pollution toxicology, which is rooted in the concept of chemical-specific toxicity. A number of hypotheses that draw upon various physical and chemical attributes of PM have been offered in search of a "biologically plausible" explanation for the reported epidemiologic observations. Prominently included among these hypotheses are PM-associated metals, organics, acidity, size distribution (focusing on the unique bioactivity of ultrafine PM), PM oxidant activity or reactivity, and potentially toxic or allergenic biologicals. However, at present, there is simply not enough basic understanding of the respective roles of PM composition and size to defend one hypothesis overwhelmingly over another, nor is there reason to unseat the PM mass-based correlation with health outcomes. Although the animal and human toxicologic database is growing rapidly with regard to the issue of causation, much remains to learned before new regulatory indices can be adopted.

From research directed initially toward potential occupational hazards, it is known that several metals and silicates that make up at least part of the inorganic phase of PM can be cytotoxic to lung cells, and that organic constituents theoretically can induce toxicity either directly or via metabolism to genotoxic agents. Also, studies focusing on very small, ultrafine (<0.1 μm) particles suggest that though these particles are low in mass, they are high in number and thus provide substantial particle surface to biological surface interaction. Less is known about the role of biologically derived materials such as endotoxin and bioallergen fragments that may elicit rudimentary inflammatory responses, but the involvement of these substances in agricultural and indoor exposures is very real. Finally, in the early days of air pollution toxicology, there was considerable interest in PM–copollutant interactions, but our knowledge in this area beyond the data derived largely from one laboratory (Amdur et al., 1986) is very limited.

Metals There have been many standard acute and subchronic rodent inhalation studies with specific metal compounds, often oxides or sulfates. These relate most appropriately to occupational exposures. The systemic toxicities of metal compounds are presented in detail elsewhere in this text; the effects of many metals delivered by inhalation may differ from their impact when administered systemically. Since virtually any metal can be found at some concentration in ambient PM and many have toxic or prooxidant potential, their role in PM toxicity has garnered considerable interest (Costa and Dreher, 1999). The most common are metals released during oil and coal combustion (e.g., transition and heavy metals), metals derived from the earth's crust as dust (e.g., iron, sodium, and magnesium), and metals used functionally in fuels, such the antiknock gasoline metal lead (much reduced since its ban in 1983) or metals released from engine wear. Metals derived from anthropogenic combustion sources tend to enrich the fine fraction (<2.5 μm) of PM, while coarse (2.5- to 10-μm) PM is made up of metal compounds of crustal origin (e.g., Fe_2O_3, SiO_2).

Metal compounds can be separated physicochemically: those that are essentially water-insoluble (e.g., metal oxides and hydroxides such as those that might be released from high-temperature combustion sources or derived from the geocrustal matrix) and those that are soluble or mostly soluble in water (often chlorides or sulfates such as those that might form under acidic conditions in a smoke plume or leach from acid-hydrated silicate particles in the atmosphere). Solubility appears to play a role in the toxicity of many inhaled metals by enhancing metal bioavailability (e.g., nickel from nickel chloride versus nickel oxide), but insolubility can also be a critical factor in determining toxicity by increasing pulmonary residence time within the lung (e.g., insoluble cadmium oxide versus soluble cadmium chloride). Moreover, some metals, either in their soluble forms or when coordinated on the surface of silicate or bioorganic materials, can promote electron transfer to induce the formation of reactive oxidants (Ghio et al., 1992). Thus, caution is warranted in assessing inhaled metals, as both their chemical and physical attributes and not simply their total mass govern their effects in the lung. It is likely that a number of mechanisms are involved in the action of inhaled PM-associated metals.

Gas-Particle Interactions The coexistence of pollutant gases and particles in the atmosphere raises the concern that these phases may interact chemically or physiologically to yield unpredictable outcomes. Many studies have shown that these generic interactions are feasible as mechanisms for altering the toxicity of either the particle or the gas. The guinea pig bronchoconstriction model used for many years by Amdur and associates has clearly shown that SO_2 can interact with metal salts to potentiate particle irritancy. The mechanism(s) behind this interaction involve the solubility of SO_2 in a liquefied aerosol as well as the ability of the metal to catalyze the oxidation of the dissolved gas to sulfate. In the case of sodium chloride aerosol, potentiation appeared to be governed primarily by the solubility of SO_2 in that salt droplet and its enhanced respiratory penetration, while metal salts such as manganese, iron, and vanadium functioned through the formation of the stronger irritant sulfate (Amdur and Underhill, 1968). The degree of response to the mixture was dictated by the aerosol itself, indicating that it was indeed the proximate irritant. Studies in humans have been less revealing about such interactions, perhaps in part as a result of differences in study design and methodology.

Metal smelting or the combustion of coal can emit sulfuric acid that is physically associated with ultrafine metal oxide particles. Analogous particles can be furnace-generated in the laboratory and diluted in cool clean air to expose animals (Amdur et al., 1986). These ultrafine particles are distributed widely and deeply in the lung and enhance the irritant potency beyond that predicted on the basis of the sulfuric acid concentration alone. Exposure of guinea pigs to 30 to 60 μg/m^3 sulfuric acid combined with ultrafine zinc oxide produced dose-dependent decreases in DL_{CO}, total lung capacity, and vital capacity and increases in cells, protein, and a variety of enzymes in lavage fluid that were not completely resolved 96 h after exposure (Amdur, 1989). Other studies of combustion products of different coals emphasized again the role of surface associated acidic *S*-compounds. Illinois No. 6 coal, which has a layer of sulfuric acid sorbed on the surface of the ultrafine ash, produced more effects in the guinea pig model than the more alkaline Montana lignite, which has sorbed neutralized sulfate, even though the absolute amount of sulfate was greater in the Montana lignite (Chen et al., 1990). While the exact physicochemical interaction between SO_2 and zinc oxide to bring about enhanced effects is arguably a combination of surface and solubility mechanisms, similar studies using inert carbon black appear consistent with its role as carrier for reactive gases such as ozone and various aldehydes to enhance delivery of toxic materials to the deep lung (Jakab, 1992). The result was enhanced infectivity when the test animals were subsequently exposed to pathologic bacteria. Thus, the combination of the inert or chemically active particles with a toxic gas appears able to enhance the impact of the gas alone, either by altering dose distribution or the formation of a more toxic product.

Another potential interaction may result from the ability of gaseous pollutants to influence the clearance of particles from the lung or alter the metabolism or cellular interactions with lung-deposited particles. The early studies by Laskin at New York University in the 1960s, showing an intriguing interaction of SO_2 and benzo(*a*)pyrene to promote carcinogencity, were noted earlier; however, this result may well have been due to impaired clearance as well as the promoting activity of inflammation. Similarly, rats exposed to an urban 8-h daily profile of ozone for 6 weeks, followed by a 5-h exposure to asbestos, were found to retain three times as many fibers as did the controls 30 days later. In this case, the fibers were deposited in the distal airways and penetrated more deeply into the intercellular areas, where they seemed inaccessible to phagocytic removal (Pinkerton et al., 1989). These studies, together with those focusing on irritancy and infectivity, raise the prospect that realistic exposure scenarios of gaseous and particulate pollutants can interact through either chemical or physiologic mechanisms to enhance either immediate or associated long-term risks of complex polluted atmospheres.

Ultrafine Carbonaceous Matter Carbonaceous material often forms the core of fine PM. The organic materials, which can be of a semivolatile or nonvolatile nature, are more often dispersed within the structure of PM, forming layers or sheaths. Estimates of the carbonaceous content vary considerably but are nominally considered to be about 30 to 60 percent of the total mass of fine PM. The sources of organic carbon are varied and include the combustion products of natural smoke (e.g., forest fires) and engine exhaust as well as stationary sources (fugitive fly ash). Elemental carbon is at the core of most diesel PM, though many complex organics can be associated with its surface. It has been estimated that diesel contributes about 7 percent of the fine urban PM emissions, which, when expressed as an annual U.S. average, are about 2 μg/m^3 (USEPA, 1993). Because of the higher use of diesel fuel in Europe and along U.S. freeways, the diesel content of ambient PM has been estimated to be as high as 30 percent.

As an air pollutant, the carbonaceous core of PM has been considered largely inert except in experimental "overload" conditions associated with long-term, high-exposure concentrations in rodent bioassays (addressed below). The potential of PM to act as a carrier of certain irritant gases was noted earlier. Recently, however, carbon in the ultrafine mode (<0.1 μm) has been suggested to be more toxic than the same substance in the larger fine-mode range (2.5 μm), perhaps due to differences in surface reactivity or tissue penetration (Oberdorster et al., 1994; Donaldson et al., 1998). Ultrafine PM possesses extremely high surface area while contributing almost negligible mass to $PM_{2.5}$. This is relevant to the diesel issue, since diesel PM is made up of aggregated ultrafine carbon with small amounts of various combustion-derived complex polycyclic and nitroaromatic compounds and only a trace of metals. However, whole diesel exhaust also contains significant amounts of NO_x, CO, and SO_x as well as formaldehyde, acrolein, and other aldehyde compounds, which are known to be irritants. Recent studies of diluted exhaust in

humans reveals that the diesel exhaust mix is inflammogenic and to a degree cytotoxic to airway cells (Salvi et al., 1999). Animal and in vitro cell studies with diesel particles themselves, however, have not shown much acute toxicity. But further studies of the same isolated diesel PM reacted in vitro with ozone before testing in a biological system indicate significant enhancement of the inherently low toxicity of diesel PM (Madden et al., 2000). This underscores the potential importance of interactions among air pollutants as the critical factor in air pollution toxicity.

Chronic Effects and Cancer Chronic exposure studies have been conducted with a number of particles ranging from titanium dioxide and carbon to diesel exhaust and coal fly ash aerosol. Of these substances, diesel exhaust has been the most extensively studied (reviewed by Cohen and Nikula, 1999). The diesel particle is of interest because it can constitute a significant portion of an urban particulate load in some cities (especially in Europe). The primary concern with diesel has been the suspicion that it can induce lung cancer and thus is classified as a Class B carcinogen. However, despite evidence from over forty occupational studies (primarily railway yard, truck, and bus workers) implicating diesel exhaust as a mild carcinogen, confounding elements undermine virtually every study. If one looks to empiric studies, potential carcinogenicity is suggested by several chronic exposure studies in animals and in vitro data indicating mutagenicity in *Salmonella* bacteria and enhanced sister chromatid exchange rates in Chinese hamster ovary cells. (These genotoxic effects have been linked to the nitroarenes associated with the diesel PM.) However, animal studies have not resolved the question of carcinogenic health risk from diesel. The in vivo chronic bioassay studies in rats show a pattern of tumorigenesis that appears to be an effect of the bulk loading of particulate material in the lungs. At high concentrations of diesel PM (3.5 and 7 mg/m^3), normal mucociliary clearance in rats is gradually overwhelmed, resulting in a progressive buildup of particles in the lungs. By 12 months (and increasingly upon approaching 18 to 24 months), clearance essentially ceases and there is evidence of ongoing inflammation, oxidant generation, epithelial hyperplasia, and fibrogenic activity around agglomerates of particles and phagocytic cells in the distal areas of the lung. These patchy sites of injury are associated with the eventual development of adenosarcomas and squamous cell carcinomas in the rats involved in these studies. At lower concentrations, where the particle buildup does not occur, tumors do not develop.

The phenomenon of overwhelming mucociliary clearance of inert particles deposited in the rodent lung has been termed "overload" and is a common finding at the highest exposure concentrations of chronic bioassays involving PM exposures. While this phenomenon could not occur in humans exposed to PM in the ambient environment, it is a subject worthy of consideration in a discussion of PM health effects, as it relates to the interpretation of toxicologic data. Several, poorly soluble particles have induced lung tumors in chronic rat bioassays only under the circumstance of overload; tumors have not developed under similar conditions in mice and hamsters. Among these particles are titanium dioxide, carbon black, toner dust, talc, and diesel PM; the potential for tumors is especially marked when the particles are in the ultrafine mode. In the rat, the time course and pattern of accumulation, chronic inflammation, epithelial hyperplasia, and tumorigenesis are essentially the same for all of the particles. In contrast, the degree of active inflammation in the mouse and hamster under similar overload conditions appears much less and thus is thought to be an important distinction among the species that relates to their sensitivities. Classic in vivo genotoxicity seems largely absent. Not surprisingly, the interpretation of cancer data under these conditions remains controversial. The closest analogy in humans would be coal miners who do not appear to have an enhanced risk of lung cancer except when smoking is not involved.

The issue, then, is whether rat bioassay cancer data under conditions of overload are relevant to risk assessment. A recent review by an expert panel (ILSI, 2000) concluded that rats, while apparently unique in this response, may represent a sensitive subgroup, and that tumorigenesis data from the rat bioassay under conditions of overload cannot be summarily dismissed as not relevant to the consideration of cancer risk in humans. However, the data should be interpreted and weighed in the context of lower concentrations and the tumor incidence and pathology found therein.

Photochemical Air Pollution

Photochemical air pollution arises from a series of complex reactions in the troposphere close to the earth's surface and comprises a mixture of ozone, nitric oxides, aldehydes, peroxyacetyl nitrates, and a myriad of reactive hydrocarbon radicals. If SO_2 is present, sulfuric acid PM may also be formed; likewise, the complex chemistry can generate organic PM, nitric acid vapor, and condensate. From the point of view of the toxicology of photochemical air pollutants, the gaseous hydrocarbon component is no longer listed collectively as a Criteria pollutant, although individual compounds may fall into the category of HAPs (most often associated with cancer). In general, the concentrations of the hydrocarbon precursors in ambient air generally do not reach levels high enough to produce acute toxicity. Their importance stems largely from their roles in the chain of photochemical reactions that leads to the formation of oxidant smog or haze.

The oxidant of most toxicologic importance in the so-called photochemical "soup" is O_3. It is important to appreciate that atmospheric O_3 is not summarily undesirable. About 10 km above the earth's surface there is sufficient short-wave ultraviolet (UV) light to directly split molecular O_2 to atomic $O^\cdot$, which can then recombine with O_2 to form O_3. This O_3 accumulates to several hundred ppm within a thin strip of the stratosphere and absorbs incoming short-wavelength UV radiation. The O_3 forms and decomposes and reforms to establish a "permanent" barrier to UV radiation, which lately has become a issue of concern, as this barrier is threatened by various anthropogenic emissions (Cl_2 gas and certain fluorocarbons) that enhance O_3 degradation. The consequence is excess infiltration of UV light to the earth's surface and the potential for excess skin cancer risk and immune suppression.

The issue is different in the troposphere, where accumulation of O_3 serves no known purpose and poses a threat to the respiratory tract. Near the earth's surface, NO_2 from combustion processes efficiently absorbs longer-wavelength UV light, from which a free O atom is cleaved, initiating the following simplified series of reactions:

$$NO_2 + hv \text{ (UV light)} \circledR O^\cdot + NO^\cdot \qquad (1)$$
$$O^\cdot + O_2 \circledR O_3 \qquad (2)$$
$$O_3 + NO^\cdot \circledR NO_2 \qquad (3)$$

This process is inherently cyclic, with NO_2 regenerated by the reaction of the $NO^\cdot$ and O_3. In the absence of unsaturated hydrocarbons, this series of reactions would approach a steady state with no excess or buildup of O_3. The hydrocarbons, especially olefins and substituted aromatics, are attacked by the free atomic $O^\cdot$, resulting in oxidized compounds and free radicals that react with $NO^\cdot$ to produce more NO_2. Thus, the balance of the reactions shown in Eqs. (28-1) to (28-3) is upset, leading to buildup of O_3. This reaction is particularly favored when the sun's intensity is greatest at midday, utilizing the NO_2 provided by morning traffic. Aldehydes are also major by-products of these reactions. Formaldehyde and acrolein account for about 50 percent and 5 percent, respectively, of the total aldehyde in urban atmospheres. Peroxyacetyl nitrate (CH_3COONO_2), often referred to as PAN, and its homologs also arise in urban air, most likely from the reaction of the peroxyacyl radicals with NO_2.

Short-Term Exposures to Smog

In the 1950s and 1960s, the complexity of photochemical air pollution challenged toxicologists to ascertain its potential to affect human health adversely. The toxicity of O_3 was shown to be very high even at low ppm concentrations. Concerns that the complex atmosphere was even more hazardous, a number of studies were undertaken with actual (outdoor-derived) or synthetic (photolyzed laboratory-prepared atmospheres) smog in an attempt to assess the potency of a more realistic pollution mix. When human subjects were exposed to actual photochemical air pollution (Los Angeles ambient air pumped into a laboratory exposure chamber), they experienced changes in lung function similar to those described in controlled clinical studies of O_3 alone (i.e., reduction in spirometric lung volumes; see below), thus supporting the view that this is the pollutant of primary concern. Acute animal studies using synthetic atmospheres (usually irradiated auto exhaust) provided evidence indicating deep lung damage, primarily within the small airway and proximal alveolar epithelium. In some of these studies, early evidence of edema appeared in the interstitium, particularly in older animals. Additionally, mice similarly exposed were found to be more susceptible to bacterial challenge and lung pneumonias. With time, after the termination of an acute exposure, end-airway lesions recovered and the susceptibility to infection waned, although some pathology in the distal lung persisted for more than 24 h.

While O_3 appeared to be the prime toxicant in many of these studies, there was some evidence that other copollutants were involved. When guinea pigs were exposed to irradiated auto exhaust, airway resistance increased quickly, in contrast to the pattern of O_3 alone, where less effect is seen on resistance than on breathing rate. This indicated that a more soluble irritant(s) probably was active, presumably reactive aldehydes. Thus, the array of effects of a complex atmosphere may be more diverse than would be predicted if it were assumed that O_3 alone was responsible.

Chronic Exposures to Smog

Studies in animals and human populations have attempted to link degenerative lung disease with chronic exposure to photochemical air pollution. Cross-sectional and

prospective field studies have suggested an accelerated loss of lung function in people living in areas of high pollution. However, as with many studies of this type, there are problems with confounding factors (meteorology, imprecise exposure assessment, and population variables). Recently, studies have been conducted in children living in Mexico City, which has oxidant and PM levels far in excess of any city in the United States. These studies have focused on the nasal epithelium as an exposure surrogate for pulmonary tissues, using biopsy and lavage methodologies to assess damage. Dramatic effects were found in exposed children, consisting of severe epithelial damage and metaplasia as well as permanent remodeling of the nasal epithelium. When children migrate into Mexico City from cleaner, nonurban regions were evaluated, even more severe damage was observed, suggesting that the remodeling in the permanent residents imparted some degree of incomplete adaptation. Since the children were of middle-class origin, these observations were not likely confounded by poor diet (Calderon-Garcidueñas et al., 1992). These dramatic nasal effects have raised concerns for the more fragile, deep lung tissues, where substantial deposition of oxidant air pollutants is thought to occur.

An extensive, now classic synthetic smog study in animals was undertaken at the Cincinnati EPA laboratory in the mid-1960s in an attempt to address the potential for long-term lung disease. Beagle dogs were exposed on a daily basis (16 h) for 68 months, followed by a clean-air recovery period of about 3 years (Lewis et al., 1974). A series of physiologic measurements were made on the dogs after the exposure, and after their 3-year recovery. They were then moved to the College of Veterinary Medicine at the University of California at Davis. The lungs of the dogs then underwent extensive morphologic examination to correlate with the physiology. Seven groups of 12 dogs each were studied. These were exposed to nonirradiated auto exhaust (group 1), irradiated auto exhaust (group 2), SO_2 plus sulfuric acid (group 3), the two types of exhaust plus the sulfur mixture (groups 4 and 5), and a high and a low level of NO_x (groups 6 and 7). The irradiated exhaust contained oxidant (measured as O_3) at about 0.2 ppm and NO_2 at about 0.9 ppm. The raw exhaust contained minimal concentrations of these materials and about 1.5 ppm NO. Both forms of exhaust also contained about 100 ppm CO. The controls did not show time-related lung function changes, but all the exposure groups had abnormalities, most of which persisted or worsened over the 3-year recovery period in clean air. Enlargement of airspaces and loss of interalveolar septa in proximal acinar regions were most severe in dogs that were exposed to NO_x and SO_x with irradiated exhaust (Hyde et al., 1978). These studies described a morphologic lesion that was degenerative and progressive in nature, not unlike that of chronic obstructive pulmonary disease (COPD)—a condition most often associated with lifelong tobacco smoking.

More recently, "sentinel" studies have been attempted whereby the animals live in the same highly polluted air to which people are exposed. This approach has had a troubled past, but newer studies appear to have better control for the problems of infection, inappropriate animal care (e.g., heat), and variable exposure atmospheres. One such study, conducted in rats exposed for 6 months to the air of São Paulo, Brazil, found considerable airway damage, lung function alterations, and altered mucus rheology (Saldiva et al., 1992). The concentrations of O_3 and PM in São Paulo frequently exceed daily maximum values (in the summer months of February and March) of 0.3 ppm and 75 μg/m^3, respectively. This collage of effects is not unlike a composite of injury one might suspect from a mixed atmosphere of oxidants and acid PM on the basis of controlled animal studies in the laboratory. However, the essential conclusion from most sentinel studies is that "pollution is unhealthy," since individual and mixed pollutant effects and interactions cannot be easily addressed.

Ozone *General toxicology* Ozone is the primary oxidant of concern in photochemical smog because of its inherent bioreactivity and concentration. Depending on the meteorologic conditions of a given year, 60 to 80 million Americans live in areas not in absolute compliance with the 1-h NAAQS of 0.12 ppm. (Formal compliance limits use one exceedence per year averaged over 3 years.) Los Angeles frequently attains and occasionally exceeds 1-h levels of 0.2 to 0.3 ppm. Unlike SO_2 and the reducing-type pollution profile discussed above, current mitigation strategies for O_3 have been largely unsuccessful despite significant reductions in individual automobile emissions. These reductions have been offset by population growth, which brings with it additional vehicles. With the spread of suburbia and the downwind transport of air masses from populated areas to more rural environments, the geographic distribution of those exposed has spread, as has the temporal profile of potential exposure. In other words, O_3 exposures are no longer stereotyped as brief 1- to 2-h peaks. Instead, there are prolonged periods of exposure of 6 h or more at or near the NAAQS level and may occur either downtown or in the formerly cleaner suburban or rural areas downwind. This recently noted shift has given rise to concerns that cumulative damage from such prolonged exposures may be more significant than brief pulse-like exposures, and that many more people are at risk than was previously thought. With the recent revision of the O_3 NAAQS in 1997 to include an 8-h maximum average of 0.08 ppm, even more cities and suburban areas find themselves in violation of the standard. The American Lung Association estimates that 132 million Americans live in O_3-noncompliant areas (State of the Air, 2000). Perhaps of greater significance is that of those who might be considered susceptible due to preexistent cardiopulmonary problems, 80 to 90 percent live in these areas that fail to comply with the present O_3 NAAQS.

Ozone has been the subject of considerable toxicologic interest because it induces a variety of effects in humans and experimental animals at concentrations that occur in many urban areas (Lippmann, 1989). These effects include morphologic, functional, immunologic, and biochemical alterations. Because of its low water solubility, a substantial portion of inhaled ozone penetrates deep into the lung, but its reactivity is such that about 17 percent and 40 percent is scrubbed by the nasopharynx of resting rats and humans, respectively (Hatch et al., 1994; Gerrity et al., 1988). The reason for the higher degree of scrubbing in humans is unclear, but the finding is reproducible. Moreover, mouth scrubbing does not differ from nasal scrubbing. However, regardless of species, the region of the lung that is predicted to have the greatest O_3 deposition (dose per surface area) is the acinar region, from the terminal bronchioles to the alveolar ducts, sometimes referred to as the proximal alveolar ductal region (Overton and Miller, 1988). Because O_3 penetration increases with increased tidal volume and flow rate, exercise increases the dose to the target area. Using $^{18}O_3$ (a nonradioactive isotope of oxygen), Hatch and coworkers have shown that the dose to the distal lung and the degree of damage to the lung as determined by extravasated protein into the alveolar space (as collected by bronchoalveolar lavage) in exercising human subjects exposed to 0.4 ppm for 2 h with intermittent periods of 15 min of exercise (threefold normal ventilation on average) are similar to those in resting rats exposed for the same length of time to 2.0 ppm. Thus, it is important to consider the role of exercise in a study of O_3 or any inhalant before making cross-study comparisons, especially if that comparison is across species. With so many years invested in the study of O_3, it is surprising that only now is the nature of species differences with regard to exercise-associated dosimetry being appreciated.

Animal studies indicate that the acute morphologic response to O_3 involves epithelial cell injury along the entire respiratory tract, resulting in cell loss and replacement. The pattern of injury parallels the dosimetry profile, with the majority of damage occurring in the centriacinar region. However, along the airways, ciliated cells appear to be most sensitive to O_3, while Clara cells and mucus-secreting cells are the least sensitive. Studies in the rat nose indicate that O_3 also is an effective mucus secretagogue. In the distal lung, the type 1 epithelium is very sensitive to O_3, in contrast to type 2 cells, which serves as the stem cell for the replacement of type 1 cells. Ultrastructural damage can be observed in rats after a few hours at 0.2 ppm, but sloughing of cells generally requires concentrations above 0.8 ppm. Recovery occurs within a few days, and there appears to be no residual pathology. Hence, from animal studies, it would appear that a single exposure to O_3 at a relatively low concentration is not likely to cause permanent damage. On a gross level, when a bronchoscope is used to peer into the human bronchus after O_3 exposure, the airways appear "sunburned" and, as with mild skin sunburn, recovery is typical. What is uncertain is the impact of repeated "sunburning"of the airways and lung.

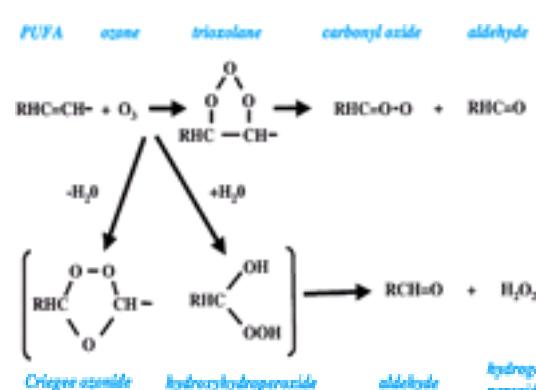
The mechanisms by which O_3 causes cellular injury have been studied using cellular as well as cell-free systems. As a powerful oxidant, O_3 seeks to extract electrons from other molecules. The surface fluid lining the respiratory tract and cell membranes that underlie the lining fluid contain a significant quantity of polyunsaturated fatty acids (PUFA), either free or as part of the lipoprotein structures of the cell. The double bonds within these fatty acids have a labile, unpaired electron which is easily attacked by O_3 to form ozonides that progress through a less stable zwitterion or trioxolane (depending on the presence of water); these ultimately recombine or decompose to lipohydroperoxides, aldehydes, and hydrogen peroxide. These pathways are thought to initiate propagation of lipid radicals and autooxidation of cell membranes and macromolecules (Fig. 28-10).


Figure 28-10. Major reactions pathways of O_3 with lipids in lung lining fluid and cell membranes. (Adapted with permission from the Air Quality Criteria

Evidence of free radical–related damage in vivo includes detection of breath pentane and ethane and tissue measurements of diene conjugates. Damage to the air-blood interface disrupts its barrier function and promotes inflammation. Inflammatory cytokines (e.g., interleukins 6, 8 and others) are released from epithelial cells and macrophages that mediate early responses and initiate repair. This inflammatory process is generally transient, but it may also interact with neurogenic irritant responses to affect lung function acutely. This latter response may have implications for those wtth preexistent inflammation or disease.

Pulmonary Function Effects Exercising human subjects exposed to 0.12 to 0.4 ppm O_3 experience reversible concentration-related decrements in forced exhaled volumes [forced vital capacity (FVC) and forced expiratory volume in 1 s (FEV$_1$)] after a 2 to 3 h of exposure (McDonnell et al., 1983). With the recent concern that prolonged periods of exposure (6 to 8 h) may lead to cumulative effects, similar protocols with lower exercise levels were extended up to 6.6 h. In these studies, exposures to 0.12, 0.10, and 0.08 ppm induced progressive lung function impairment during the course of the exposure (Horstman et al., 1989). The pattern of response was linearly cumulative as a function of exposure time such that changes not detectable at 1 or 2 h reached significance by 4 to 6 h. Decrements in FEV$_1$ after 6.6 h at 0.12 ppm averaged 13.6 percent and were comparable to that observed after a 2-h exposure to 0.22 ppm with much heavier exercise. Interestingly, the human lung dysfunction resulting from O_3 does not appear to be vagally mediated, but the response can be abrogated by analgesics such as ibuprofen and opiates, which function to reduce pain and inflammation (see below). Thus pain reflexes involving C-fiber networks are thought to be important in the reductions in forced expiratory volumes. On the other hand, animal studies suggest that cardiac as well as lung function effects of O_3 have a significant parasympathetic component. Other lung function indices, such as nonspecific airway reactivity to various pharmacologic agents, indicate hyperreactivity after acute 2- to 6-h exposures to O_3 to sub-NAAQS levels of 0.08, 0.10, and 0.12 ppm (by 56, 86, and 121 percent, respectively, to methacholine). It is widely thought that hyperreactive airways may predispose responses to other pollutants such as sulfuric acid or aeroallergens, but such evidence is limited.

When compared with field studies, chamber exposures may underestimate responses for a given exposure to O_3. For a given concentration of O_3, greater decrements in pulmonary function have been reported in children playing outdoors at summer camps than were observed in controlled exposure studies involving exercise (Lippmann, 1989). The reasons for this difference are uncertain but might relate more to cumulative exposure in the children at camp, as they were outside all day, or to the fact that the ambient exposures probably involve other haze copollutants, such as H$^+$. The responses to the ambient exposures also have slightly altered temporal patterns, whereby responses to O_3 are influenced by previous exposures (Kinney et al., 1988). Animal studies are consistent with the fact that both duration and concentration are important in assessing the response to O_3 exposure (Costa et al., 1989). Pulmonary function decrements increased with C × T (concentration times time) in rats exposed for 2, 4, or 8 h to ozone at 0.2, 0.4, and 0.8 ppm. Rats exposed for 7 h to 0.5 ppm with 8% CO_2 added to increase the respiratory rate produced functional decrements similar to those observed in human chamber studies of 6.6 h at 0.12 ppm when ventilation-adjusted C × T products were factored in. This would imply that rats and humans respond with about the same sensitivity and opens the door to the study of various scenarios of exposure to predict human responses under varied conditions. It should be cautioned, however, that it is unknown whether CO_2-stimulated breathing in the rat might alter response thresholds beyond mere incrementing of the dose. On the other hand, in related studies without stimulated breathing, lavage fluid protein content (an index of permeability) 24-h postexposure was also nearly linearly cumulative, with exaggerated responses at the higher concentrations suggestive of an exponential pattern (Highfill et al., 1992) common to other biological functions.

Inflammation of the Lung and Host Defense The mechanism by which O_3 produces decrements in pulmonary function is not fully understood. In contrast to sulfuric acid and SO_2, functional responses to O_3 do not correlate with responsiveness to bronchoconstrictor challenge and are not ostensibly enhanced in asthmatics, as appears to be the general case with the sulfated acids. Because the contribution of vagal mechanisms in the acute human lung functional response to O_3 appears to be minimal, attention has turned to the role of lung inflammation. Koren and colleagues (1989) found an eightfold increase in polymorphonuclear leukocytes (PMNs) in lavage fluid recovered from human subjects 18-h after a 2-h exposure to 0.40 ppm with intermittent exercise. There was also evidence of increased epithelial permeability (a twofold increase in serum proteins and albumin). The inflammatory markers did not correlate well with functional impairment among the individuals tested. Arachidonate metabolism products, including the prostaglandins PGE$_2$ and PGF$_{2a}$ and the leukotriene thromboxane B$_2$, have also been seen to increase in human bronchoalveolar lavage fluid after 0.4 ppm ozone for 2-h (Seltzer et al., 1986). Pretreatment with the anti-inflammatory agents indomethacin and ibuprofen (cyclooxygenase inhibitors) decreased the pulmonary function deficit and PGE$_2$, but other indicators of cell injury and vascular leak in lavage fluid (PMNs, extravasated protein, and lactate dehydrogenase) were not attenuated after exposure to a similar ozone challenge. Because PGE$_2$ can have either pro- or anti-inflammatory functions under certain conditions as well as bronchodilatory action on constricted airways, it remains to be seen whether there is any causal relationship between arachidonate metabolites and functional responses. Sensitivity to O_3 appears to have a genetic component as well. Studies in inbred stains of mice have shown that O_3-induced pulmonary neutrophilia and permeability are governed by a single gene linked to the Toll4 locus that has been associated with endotoxin sensitivity (Kleeberger et al., 2000). Advances in genetic mapping and molecular biology have yielded significant information on the nature of O_3 susceptibility in mice and may one day explain differences seen among humans.

The potential for O_3 to influence allergic sensitization or challenge-responses has received limited investigation in either humans or animals. In general, animal studies have shown the ability of O_3 to enhance the sensitization process under certain conditions (Osebold et al.,1980), but evidence of this in humans is lacking. Controlled studies of heightened antigen responsiveness in allergic subjects have only been suggestive, with enhancement of allergic rhinitis after 0.5 ppm for 4 h providing the only credible data to date. However, diary studies of asthmatic nurses report worsened allergy symptoms, as well as durations thereof, at concentrations of O_3 near the NAAQS (Schwartz, 1992).

Exposure to O_3 before a challenge with aerosols of infectious agents produces a higher incidence of infection than is seen in control animals (Coffin and Blommer, 1967). Studies have demonstrated that this effect in a mouse model using an aerosol of *Streptococcus* (group C) bacteria is a direct result of altered phagocytosis by macrophages in the O_3-exposed animals (Gilmour et al., 1993), allowing the bacteria to develop a thickened capsule that reduces their attractiveness to phagocytes and enhances their virulence. This host resistance model has shown responsiveness to an exposure as low as 0.08 ppm for 3 h. The susceptibility of mice and hamsters to *Klebsiella pneumoniae* aerosol is also increased by prior exposure to O_3. In the rat, altered microbe-killing ability may relate to membrane damage in macrophages, thus impairing the production of bactericidal superoxide anions. However, the rat appears to have a more vigorous PMN response to bacteria than do mice, which seems to compensate for macrophage impairments and lends the rat less sensitive to bacterial proliferation.

Chronic Effects Morphometric studies of the acinar region of rats exposed for 12 h per day for 6 weeks to 0.12 or 0.25 ppm ozone showed hyperplasia and hypertrophy of type I alveolar cells and major alterations in ciliated and Clara cells in small airways (Barry et al., 1988). When quantitative estimates of type I cell hypertrophy (thickness) from this study and those of another that employed a low-level, urban ambient profile of O_3 through 12 weeks were combined, hypertrophy appeared linearly cumulative to the O_3 C × T(Chang et al., 1991, 1992). This finding suggested that over a season, the impact of O_3 in the distal lung may be cumulative and perhaps more importantly may be without threshold. The biological significance of this change is unclear—it may be part of a compensatory response to "thicken" that part of the distal airway most affected by the oxidant. Although most of the morphologic changes induced by O_3 clearly regress over time when the animals are returned to clean air, there is evidence of interstitial remodeling below the epithelium in this centriacinar region, which may have long-term implications. Examination of autopsied lung specimens from young smokers shows many analogous tissue lesions that come to be described as the "smoldering" precursors of emphysema.

Studies involving episodic exposures of rats and monkeys using a pattern of alternating months of O_3 (0.25 ppm) for 18 months indicate that there may be carry-over effects, notably thickening of interstitial fibrous matrix (Tyler et al., 1988, 1991). These interstitial changes were quantitatively similar regardless of the twofold difference in the cumulative exposure dose (i.e., C × T). This would imply that a pattern of exposure resembling seasonal O_3 patterns might result in more serious lesions than predicted by dose alone—indeed more than would have occurred had the exposure been continuous. Hence, the concept of "more dose . . . more effect" may not hold in chronic scenarios, as it appears to do in acute exposures. The number of episodes experienced may well be more significant to long-term outcomes than total dose—a phenomenon not unlike that of repeated sunburning and deterioration of the skin.

Studies of lung function in animals exposed chronically to O_3 have been conducted but have yielded mixed results. Generally, the dysfunction is reflective of stiffened or fibrotic lungs, particularly at higher concentrations. There have been two prominent chronic O_3 studies—the EPA 18-month chronic study of a realistic urban exposure profile (Chang et al, 1992; Costa et al., 1995) and the National toxicology Program (NTP)—Health Effects Institute (HEI Report, 1994/1995) study of 0.125

to 1 ppm for 20 months (6 h/day; 5days/week). From an environmental relevance perspective, the C × T doses for these studies were similar, but the urban profile study produced evidence for centriacinar interstitial fibrosis suggesting a possible influence of the exposure pattern. There was no general biochemical evidence for fibrosis, however (Last et al., 1994), as observed in monkey and rat studies at higher concentrations. If one attempts to compare these results with the Cincinnati beagle study, one finds that the synthetic smog atmosphere showed degenerative and not fibrotic lung lesions. However, it should be noted that the mixture used in the beagle study was both more complex and involved considerably higher concentrations than most current-day rat and nonhuman primate studies.

One aspect of O_3 that is important in any assessment of potential long-term toxicity is ability of O_3 to induce tolerance to itself. Classic O_3 tolerance takes the form of protection against a lethal dose in animals that received a very low initial challenge 7 days before. The term *tolerance* is sometimes used to describe "adaptation" or acclimatization over time to near ambient levels of O_3. The process begins during and immediately after the initial exposure and progresses to completion in at most 2 to 4 days. This adaptive phenomenon has been reported a number of times for humans with regard to lung function tests and recently has been correlated with inflammatory endpoints (Devlin et al., 1993). Lavage lactate dehydrogenase (LDH; a marker of cell injury) and elastase (enzymatically active against lung matrix), interestingly, did not appear to adapt in humans. An analogous pattern of adaptation of functional and biochemical endpoints (including LDH and elastase) in rodents also takes place with repeated exposures up to a week. But to date, the linkages between acute, adaptive, and long-term process remain unclear, since over longer periods of exposure both morphologic and functional effects do appear to develop. In the short run, however, O_3 adaptation appears in part to be related to the induction of an endogenous acute-phase response (McKinney et al., 1997) as well as lung antioxidants (Wiester et al., 2000) such as ascorbic acid. The significance of this finding in humans is uncertain because ascorbic acid is not endogenously synthesized in humans as it is in the rat. Self-administration of ascorbate has been shown to reduce the lung function decrement to O_3 in humans (Mudway et al., 1999), but the potential role of a regimen of self-administered antioxidants (including ascorbate) to protect from ozone is not confirmed.

Ozone Interactions with Copollutants An approach simplifying the complexity of synthetic smog studies yet addressing the issue of pollutant interactions involves the exposure of animals or humans to binary or tertiary mixtures of pollutants known to occur together in ambient air. Such studies have had a number of permutations, but most have attempted to address the interactions of O_3 and nitrogen dioxide or O_3 and sulfuric acid. Depending on study design, there has been evidence supporting either augmentation or antagonism of lung function impairments, lung pathology, or other indices of injury. This apparent conflict only emphasizes the need to carefully consider the myriad of factors than might affect studies involving multiple determinants.

When O_3 and NO_2 (1 ppm and 14 ppm, respectively) were administered to rats from a premixed retention chamber, the resulting damage evident in bronchoalveolar lavage exceeded that of either toxicant alone, regardless of the temporal sequence of exposure (Gelzleichter et al., 1992). Fibrogenic potential also was increased (Last et al., 1994). Theoretically, the two oxidants formed an intermediate nitrogen radical that was more toxic than either gas alone. At much more realistic concentrations (0.3 ppm O_3 and 3.0 ppm NO_2), where this reaction would not be favored, the impact of these irritants on rabbits was only additive (Schlesinger et al., 1991). This contrast in response serves to illustrate that the tenet of dose-dependency that holds for any single-toxicant response is of equal or more importance when two or more pollutants coexist and have the potential to interact.

Studies of O_3 mixed with acid aerosols also have shown potentiative or antagonistic responses that were time-dependent during the period of exposure. On the one hand, as noted above, field studies of children in camps and asthma admissions in the Northeast and in Canada, have found an apparent interdependence of acid and O_3 underlying responses to summer haze. Yet, over an extended period, there was evidence of enhanced or antagonized secretory cell responses with combined O_3 (0.1 ppm) and sulfuric acid (125 µg/m^3) at different points in the 1-year exposure of rabbits (Schlesinger et al., 1992). As the number of interacting variables increases, so does the difficulty in interpretation. Studies of complex atmospheres involving acid-coated carbon combined with O_3 at relevant levels show variable strength of evidence of interaction on lung function and macrophage receptor activities (Kleinman et al., 1999). The difficulty with any multicomponent study is the statistical separation of the interacting variables and responses from the individual or combined components. However, it is the complex mixture to which people are exposed that we wish to evaluate for its toxicologic potential. Creative approaches to understanding mixture responses are a likely part of the new agenda that toxicologists will need to address in the next decade (Mauderly, 1999).

Nitrogen Dioxide ***General Toxicology*** Nitrogen dioxide, like O_3, is a deep lung irritant that can produce pulmonary edema if it is inhaled at high concentrations. It is a much less potent irritant and oxidant than O_3, but NO_2 can pose clear toxicologic problems. Potential life-threatening exposure is a real-world problem for farmers, as sufficient amounts of NO_2 can be liberated from silage. Typically, shortness of breath ensues rapidly with exposures nearing 75 to 100 ppm NO_2, with delayed edema and symptoms of pulmonary damage, collectively characterized as silo-filler's disease. Nitrogen dioxide is also an important indoor pollutant, especially in homes with unventilated gas stoves or kerosene heaters (Spengler and Sexton, 1983). Under such circumstances, very young children and their mothers who spend considerable time indoors may be especially at risk. Sidestream tobacco smoke can also be a source of indoor NO_2. In the outdoor environment, the levels of NO_2 needed to produce clear effects are in general far above those that occur in ambient air. However, more recently, protocols that simulate an urban (rush hour) or household (cooking) pattern of two daily peaks superimposed on a low continuous background concentration have produced effects in experimental animals when continuous exposure to NO_2 did not, suggesting an important dependency on exposure profile.

Although the distal lung lesions produced by acute NO_2 are similar among species, there are considerable differences in species sensitivity. Where a direct comparison is possible, guinea pigs, hamsters, and monkeys are more sensitive than are rats, although comparative dosimetry information might explain some of this difference. As in the case of O_3, theoretical dosimetry studies indicate that NO_2 is deposited along the length of the respiratory tree, with its preferential site of deposition being the distal airways. Not surprisingly, the pattern of damage to the respiratory tract reflects this profile: damage is most apparent in the terminal bronchioles, just a bit more proximal in the airway than is seen with O_3. At high concentrations, the alveolar ducts and alveoli are also affected, with type I cells again showing their sensitivity to oxidant challenge. In the airways of these animals there is also damage to epithelial cells in the bronchioles, notably with loss of ciliated cells, as well as a loss of secretory granules in Clara cells. The pattern of injury of NO_2 is quite similar to that of O_3, but its potency is about an order of magnitude lower.

Pulmonary Function Effects Exposure of normal human subjects to concentrations of £4 ppm NO_2 for up to 3 h produces no consistent effects on spirometry. However, a study has shown slightly enhanced airway reactivity with 1.5 to 2.0 ppm. Interestingly, ascorbic acid pretreatment of human subjects appeared to protect them from this hyperreactivity (Mohsenin, 1987). Whether asthmatics have a particular sensitivity to NO_2 is a controversial issue. A number of factors appear to be involved (e.g., exercise, inherent sensitivity of the asthmatic subject, exposure method). Some studies have reported effects in some individuals at 0.2 ppm, which is an ambient level in a household with an unvented gas stove. Recent meta-analyses, which have incorporated the findings of many studies to achieve a weight-of-evidence perspective, appear to support an effect of NO_2 on asthmatics. As for an appropriate animal model, only very high concentrations (10 ppm NO_2) invoke an irritancy response in guinea pigs (tachypnea); these levels are well above those a person probably would encounter in everyday life. Recently, NO_2 has been found to be associated with mortality in some time-series studies of air pollution attempting to tease out specific pollutant effects (focusing mainly on PM) (Gold et al., 2000). These studies have found correlates with cardiovascular deaths, which has raised new questions of the mechanisms by which pollutants might affect health in susceptible subgroups.

Inflammation of the Lung and Host Defense Unlike O_3, NO_2 does not induce significant neutrophilic inflammation in humans at exposure concentrations approximating those in the ambient outdoor environment. There is some evidence for bronchial inflammation after 4 to 6 h at 2.0 ppm, which approximates the likely highest transient peak indoor levels of this oxidant. Exposures at 2.0 to 5.0 ppm have been shown to affect T lymphocytes, particularly CD8[+] cells and natural killer cells that function in host defenses against viruses. Though these concentrations may be high, epidemiologic studies variably show effects of NO_2 on respiratory infection rates in children, especially in indoor environments. Animal models, by contrast, have for years shown associations between NO_2 and bacterial infection (Gardner, 1984). Susceptibility to infection appears to be governed more by the peak exposure concentration than by exposure duration. The effects are ascribed to suppression of macrophage function and clearance from the lung. Altered function in the form of killing and/or motility was apparent in macrophages from rabbits exposed to 0.3 ppm for 3 days (Schlesinger, 1987) and from humans exposed to 0.10 ppm for 6.6 h (Devlin et al., 1991).

Toxicologic studies of the interaction of NO_2 with viruses are suggestive of enhanced infectivity. Squirrel monkeys infected with nonlethal levels of A/PR-8 influenza virus and then exposed continuously to 5 or 10 ppm NO_2 suffered high mortality rates; 6/6 monkeys exposed to 10 ppm died within 3 days, while only 1/3 exposed to 5 ppm died (Henry et al., 1970). Other experiments suggest that the exposure of squirrel monkeys for 5 months to 5 ppm NO_2 depresses the formation of protective antibodies against the A/PR-8 influenza virus. Controlled human studies, however, have been inconclusive, generally because of low subject numbers. One study showed decreased virus inactivation by alveolar macrophages recovered from 4 of 9 subjects cultured in vitro and exposed to 3.5 h to 0.6 ppm NO_2. These same macrophages also produced interleukin-1, which is a known cytokine modulator of immune cell function (Frampton et al., 1989). Thus, the issue of enhanced viral

infection associated with NO_2 exposure remains of concern, especially during seasonal use of unvented gas-heating indoors, but full confirmation of this risk is absent at this time.

Chronic Effects Concern about the chronic effects of NO_2 stem from observations that 30-ppm exposures for 30 days produce emphysema in hamsters. Whether this has a bearing on human exposures at 100-fold lower exposure concentrations is questionable. An 18-month study in rats exposed to an urban pattern of nitrogen dioxide in which a background of 0.5 ppm for 23 h per day peaked at 1.5 ppm for 4 h each day showed little ultrastructural damage to the distal lung (Chang et al., 1988). Other studies utilizing peak-base patterns of exposure have found some effect at near-environmental levels of NO_2 using other biological endpoints. Mice exposed for a year to a base level of 0.2 ppm NO_2 with a 1-h spike of 0.8 ppm twice a day 5 days per week (Miller et al., 1987) yielded effects that differed between base-only and peak-only exposure groups. The base level produced no effects, while the peak-only group experienced slight functional impairment and augmented susceptibility to bacterial infection. Early studies (Ehrlich and Henry, 1968) showed that clearance of bacteria from the lungs is suppressed with 0.5 ppm NO_2 through 12 months of exposure. Interestingly, recent studies with a similar double diurnal peak design for NO_2, with NO used as a negative control, showed more pronounced effects of NO on alveolar septal remodeling than did NO_2 (Mercer et al., 1995). Apparently, NO as an intercellular signal can alter collagen metabolism; the potential for NO_2 to act in this manner is not known. These and similar studies utilizing peak-plus-baseline versus base-only or peak-only exposures indicate that, for NO_2 or its reduction product NO, the exposure profile may be an important determinant of response.

Other Oxidants While a number of reactive oxidants have been identified in photochemical smog, most are short-lived because of their reaction with available volatile organic compounds (VOCs), nitrogen oxides, and other reducing equivalents that have the effect of scrubbing them from the air before they can be breathed. One reactive, irritating constituent of the oxidant atmosphere is peroxyacetyl nitrate (PAN), which is thought to be responsible for much of the eye-stinging activity of smog. It is more soluble and reactive than ozone and hence rapidly decomposes in mucous membranes before it can get to tissues deep into the lungs. The cornea has many irritant receptors and responds readily, while the PAN absorbed into the thicker mucous fluids of the proximal nose and mouth presumably never reaches its target. A few studies with high levels of PAN have shown that it can cause lung damage and have mutagenic activity in bacteria, but it is not likely that this is relevant to ambient levels of PAN.

Aldehydes Various aldehydes in polluted air are formed as reaction products of the photooxidation of hydrocarbons. The two aldehydes of major interest are formaldehyde (HCHO) and acrolein (H_2C═CHCHO). These materials contribute to the odor as well as eye and sensory irritations of photochemical smog. Formaldehyde accounts for about 50 percent of the estimated total aldehydes in polluted air, while acrolein, the more irritating of the two, may account for about 5 percent of the total. Acetaldehyde (C_3HCHO) and many other longer-chain aldehydes make up the remainder, but they are not as irritating because of their low concentration and lesser solubility in airway fluids. Formaldehyde and particularly acrolein are found in mainstream tobacco smoke (about 90 and 8 ppm, respectively, per drag) and are likely to be found in sidestream smoke as well. Formaldehyde is also an important indoor air pollutant and can often achieve higher concentrations indoors than outdoors if due to outgassing by new upholstery or other furnishings.

Empiric studies have shown that formaldehyde and acrolein are competitive agonists for similar irritant receptors in the airways. Thus, irritation may be related not to "total aldehyde" concentration but to specific ratios of acrolein and formaldehyde. Their relative difference in solubility, with formaldehyde being somewhat more water-soluble and thus having more nasopharyngeal uptake, may distort this relationship under certain exposure conditions (e.g., exercise). On the other hand, acrolein is very reactive and may interact easily with many tissue macromolecules.

Formaldehyde Formaldehyde is a primary sensory irritant. Because it is very soluble in water, it is absorbed in mucous membranes in the nose, upper respiratory tract, and eyes. The dose–response curve for formaldehyde is steep: 0.5 to 1 ppm yields a detectable odor; 2 to 3 ppm produces mild irritation; and 4 to 5 ppm is intolerable to most people. Formaldehyde is thought to act via sensory nerve fibers that signal through the trigeminal nerve to reflexively induce bronchoconstriction through the vagus nerve. In guinea pigs, a 1-h exposure to about 0.3 ppm of formaldehyde induces an increase in airflow resistance accompanied by a lesser decrease in compliance (Amdur, 1960). Respiratory frequency and minute volume also decreased, but these changes do not become statistically significant until >10 ppm. The no observed effect level (NOEL) using these lung function criteria is about 0.05 ppm. The general pattern of the irritant response and its rapid recovery is similar to that produced by higher concentrations of SO_2. And also like SO_2, the introduction of formaldehyde through a tracheal cannula to bypass nasal scrubbing greatly augments the irritant response, indicating that deep lung irritant receptors can also be activated by this vapor.

Formaldehyde, like SO_2, can interact with water-soluble salts during inhalation and produce irritancy beyond that expected for the gas alone. When it was inhaled simultaneously with submicron sodium chloride aerosol, irritancy was augmented in proportion to the aerosol concentration, but this potentiation cannot be accounted for by a simple "carrier" effect of the aerosol (Amdur, 1960). Moreover, reversal of bronchoconstriction was slower than had been observed with SO_2. Thus it appeared that the aerosol itself constituted a new irritant species, the product of a chemical transformation of formaldehyde—perhaps methylene hydroxide (Underhill, 2000). In addition to interactions with water-soluble particles, formaldehyde has been shown to interact with carbon-based particles (Jakab, 1992) to augment bacterial infectivity in a murine model. In this case, the potentiation appears to correlate with the surface carrying capacity of the inhaled particle.

Two aspects of formaldehyde toxicology have brought it from relative obscurity to the forefront of attention in recent years. One is its presence in indoor atmospheres as an off-gassed product of construction materials such as plywood or improperly installed urea-formaldehyde foam insulation. This aspect is discussed at length in a review article (Spengler and Sexton, 1983). Complaints of formaldehyde irritation in industry have been reported at 50 ppb (Horvath et al., 1988). In studies relating household formaldehyde to chronic effects, children were found to have significantly lower peak expiratory flow rates (about 22 percent in homes with 60 ppb) than did unexposed children. Asthmatic children were affected below 50 ppb. Thus, this irritant vapor has the potential to cause respiratory effects at commonly experienced exposure levels (Krzyzanowski et al., 1990), and this may relate to evidence that formaldehyde is a weak allergen.

Nasal cancer has been induced empirically with formaldehyde vapor in rodents. In a 2-year study, rats were exposed to 2, 6, or 14 ppm formaldehyde 6 h per day, 5 days per week. The occurrence of nasal squamous cell carcinomas was zero in the control and 2-ppm groups, 1 percent in the 6-ppm group, and 44 percent in the 14-ppm group. An exposure-related induction of squamous metaplasia occurred in the respiratory epithelium of the anterior nasal passages in all exposed groups. Rats exposed 6 h per day for 5 days to 14 ppm had a greater than 20-fold increase in cell proliferation in the nasal epithelium. Mice were much less sensitive; only one carcinoma was seen at 14 ppm. The detection of DNA adducts in the two species paralleled the difference in the incidence of tumors as well as regional dosimetry. With this collection of data, formaldehyde has been designated as a probable human carcinogen by the IARC. The implications of these findings have been reviewed by Starr and Gibson (1985), but recent epidemiology studies have generally failed to find an increased incidence of nasal cancer in exposed workers.

Acrolein Because acrolein is an unsaturated aldehyde, it is more irritating than formaldehyde. Concentrations below 1 ppm cause irritation of the eyes and the mucous membranes of the respiratory tract. Exposure of guinea pigs to ³0.6 ppm reversibly increased pulmonary flow resistance and tidal volume and decreased respiratory frequency (Murphy et al., 1963). With irritants of this type, flow resistance is increased by concentrations below those that cause a decrease in frequency. This suggests that increases in flow resistance would be produced by far lower concentrations of acrolein than were tested. The mechanism of increased resistance appears to be mediated through a cholinergic reflex. Atropine (muscarinic blocker) and aminophylline, isoproterenol, and epinephrine (sympathetic agonists) partially or completely reversed the changes, while the antihistamines pyrilamine and tripelennamine had no effect.

Exposures of rats to 0.4, 1.4, or 4.0 ppm for 6 h per day 5 days per week for 13 weeks resulted in apparently paradoxical effects on lung function (Costa et al., 1986). The lowest concentration resulted in hyperinflation of the lung with an apparent reduction in small-airway flow resistance, while the highest concentration resulted in airway injury and peribronchial inflammation and fibrosis. The intermediate concentration was functionally not different from the control, but airway pathology was evident. It appears that the high-concentration response reflected the cumulative irritant injury and remodeling as a result of the repeated acrolein, while the low-concentration group had little overt damage and appeared to have slightly stiffened airways, perhaps a result of the protein cross-linking action of acrolein. The pathology in these animals contrasts with that found in formaldehyde studies of similar duration in that there was much more upper airway involvement. Ambient exposure to acrolein probably would be about fivefold to tenfold lower than the low concentration used in the subchronic study discussed above. Thus, as a class the aldehydes can be very irritating and may constitute a significant fraction of the discomfort and sensation experienced during an oxidant episode, especially in mixed atmospheres containing particles.

Carbon Monoxide Carbon monoxide is classed toxicologically as a chemical asphyxiant because its toxic action stems from its formation of carboxyhemoglobin, preventing oxygenation of the blood for systemic transport. The fundamental toxicology of CO and the physiologic factors that determine the level of carboxyhemoglobin attained in the blood at various atmospheric concentrations of carbon monoxide are detailed in Chap. 11.

The normal concentration of carboxyhemoglobin (COHb) in the blood of nonsmokers is about 0.5 percent. This is attributed to endogenous production of CO from heme catabolism. Uptake of exogenous CO increases blood COHb as a function of the concentration in air as well as the length of exposure and the ventilation rate of

the individual. Uptake is said to be ventilation-limited, implying that virtually all the CO inspired in a breath is absorbed and bound to the available hemoglobin. Thus, continuous exposure of human subjects to 30 ppm CO leads to an equilibrium value of 5 percent COHb. The Haldane equation is used to compute the COHb equilibrium under a given exposure situation. The equilibrium values generally are reached after 8 h or more of exposure. The time required to reach equilibrium can be shortened by physical activity.

Analysis of data from air-monitoring programs in California indicates that 8 h average values can range from 10 to 40 ppm CO. Depending on the location in a community, CO concentrations can vary widely. Concentrations predicted inside the passenger compartments of motor vehicles in downtown traffic were almost 3 times those for central urban areas and 5 times those expected in residential areas. Occupants of vehicles traveling on expressways had CO exposures somewhere between those in central urban areas and those in downtown traffic. Concentrations above 87 ppm have been measured underground garages, tunnels, and buildings over highways.

No overt human health effects have been demonstrated for COHb levels below 2 percent, and levels above 40 percent can be fatal due to asphyxia. At COHb levels of 2.5 percent resulting from about 90-min exposure to about 50 ppm CO, there is an impairment of time-interval discrimination; at approximately 5 percent COHb, there is an impairment of other psychomotor faculties. At 5 percent COHb in nonsmokers (the median COHb value for smokers is about 5 percent), however, maximal exercise duration and maximal oxygen consumption are reduced (Aronow, 1981). Cardiovascular changes also may be produced by exposures sufficient to yield COHb in excess of 5 percent. These include increased cardiac output, arteriovenous oxygen difference, and coronary blood flow in patients without coronary disease. Decreased coronary sinus blood PO_2 occurs in patients with coronary heart disease, and this would impair oxidative metabolism of the myocardium. In the early 1990s, a series of studies in subjects with cardiovascular disease were conducted in several laboratories under the sponsorship of the Health Effects Institute (HEI) to determine the potential for angina pectoris when they exercised moderately with COHb levels in the range of 2 to 6 percent (Allred et al., 1989). The results of these studies indicate that premature angina can occur under these conditions but that the potential for the induction of ventricular arrhythmias remains uncertain. Thus, the reduction in ambient CO brought about by newer controls should reduce the risk of myocardial infarct in predisposed persons.

The recent introduction of fuel oxygenates like MTBE and related ether compounds into gasoline was an attempt to enhance fuel combustion and reduce CO emissions. The ensuing problems with MTBE have been discussed earlier, but the goal of achieving lower CO was only partially successful. This finding reinforces the need to carefully consider whether resolution of one problem has the potential for generating others.

Hazardous Air Pollutants Hazardous air pollutants (so-called air toxics or HAPs) represent an inclusive classification for air pollutants that are of anthropogenic origin, are of measurable quantity, and are not covered in the Criteria Pollutant list. Some of the regulatory aspects of the HAPs were discussed above. The inclusive nature of this group of pollutants complicates a discussion of their toxicology because the group includes various classes of organic chemicals (by structure, e.g., acrolein, benzene), minerals (e.g., asbestos), polycyclic hydrocarbon particulate material [e.g., benzo(*a*)pyrene], and various metals and metal compounds (e.g., mercury, beryllium compounds) and pesticides (e.g., carbaryl, parathion).

Most toxic air pollutants are of concern because of their potential carcinogenicity, as shown in chronic bioassays, mutagenicity tests in bacterial systems, structure-activity relationships, or—in a few special cases (e.g., benzene, asbestos)—their known carcinogenicity in humans. These cancers need not be, and generally are not, pulmonary. Noncancer issues frequently relate to direct lung toxicants that, upon accidental release or as fugitive emissions over time, might induce lung damage or lead to chronic lung disease. The assessment of noncancer risk by air toxics to any organ system is based on the computation of long-term risk reference exposure concentrations (RfCs) to which individuals may be exposed over a lifetime without adverse, irreversible injury. This approach to hazardous air pollutant assessment is discussed in detail by Jarabek and Segal (1994). A short-term RfC method for brief or accidental exposures is currently being developed.

Accidental versus "Fence-Line" Exposures The relationship between the effects associated with an accidental release of a large quantity of a volatile chemical into the air from a point source such as a chemical plant and the effects associated with a chronic low-level exposure over many years or a lifetime is not clear. With regard to cancer, which defaults to a linearized model of dose and effect (through some alternative models can be used if there is some data), the issue is fairly straightforward. Any exposure must be minimized if not eliminated if cancer risk is to be kept as close to zero as possible. With noncancer risks, the roles of nonspecific or specific host defenses, thresholds of response, and repair and recovery after exposure complicate the assessment of risk. In large part the issue here relates to C × T. Can we better relate disease or injury to *cumulative dose* or *peak* concentration for protracted exposures? Is there an exposure peak beyond which a cumulative approach fails (i.e., the effect is concentration-driven), or is concentration always the dominant determinant? Many of these questions have yet to be answered, not to mention their specificity with regard to individual compounds and tissues affected.

Methyl isocyanate provides a contrast between the effects of a large accidental release versus those produced by a small release of fugitive vapor such that it is detectable in ambient air, but at very low levels. The reactive nature of methyl isocyanate with aqueous environments is of such magnitude that upon inspiration, almost immediate mucous tissue corrosion can be perceived. The vapor undergoes hydrolysis within the mucous lining of the airways to generate hydrocyanic acid, which destroys the airway epithelium and causes acute bronchoconstriction and edema. The damage is almost immediately life-threatening at concentrations above 50 ppm; at 10 ppm, it is damaging in minutes. These concentrations are in the range of the dense vapor cloud that for several hours enshrouded the village of Bhopal bordering the Union Carbide pesticide plant. Studies in guinea pigs showed the immediate irritancy of this isocyanate, which in just a few minutes also resulted in significant pathology (Alarie et al., 1987). Rats exposed to 10 or 30 ppm for 2 h also showed severe airway and parenchymal damage, which did not resolve in surviving rats; transient effects were seen at 3 ppm. Even 6 months after exposure, the airway and lung damage remained, having evolved into patchy, mostly peribronchial fibrosis with associated functional impairments (Stevens et al., 1987). There was also cardiac involvement secondary to the damage to the pulmonary parenchyma and arterial bed. As a result, there was pulmonary hypertension and right-sided heart hypertrophy. This same spectrum of health effects appeared in the surviving exposed residents of Bhopal and is in large part associated with their above-average death rate.

In the United States, methyl isocyanate has been measured in Katawba Valley, Texas, as a result of small but virtually continual fugitive releases of the vapor into the community air ("fence-line") from an adjoining region with several chemical plants. While these levels of methyl isocyanate are not sufficient to cause the damage seen in Bhopal, there is concern that low-level exposure over many years may have more diffuse, chronic effects. Residents complain of odors and a higher frequency of respiratory disorders, but clear evidence of injury or disease is lacking.

Phosgene is best known for its use as a war gas, but it is also one of the most common intermediate reactants used in the chemical industry, particularly in pesticide formulation. It is also a constituent of photochemical smog. Because of its direct pulmonary reactivity, it lends itself to use as a model pulmonary toxicant for studies addressing C × T relationships. These studies suggest that there may be a threshold below which compensatory and other bodily defenses (e.g., antioxidants) may be able to cope with long-term low-level exposure (tolerance). For phosgene this appears to be at or below the current threshold limit value of 0.1 ppm for 8 h. At higher concentrations, however, concentration appears to be the primary determinant of injury or disease regardless of duration. Thus, even though there is some adaptation with time, there continues to be a concentration-driven response that exceeds that predicted by C × T. This relationship appears to be different from that of ozone at ambient levels, which can be approximated acutely by the C × T paradigm.

WHAT IS AN ADVERSE HEALTH EFFECT?

Any attempt to establish criteria to define an "adverse effect" of air pollution is likely to be questioned. Some effects would pass uncontested, e.g., death, life-threatening dysfunction or disease, irreversible impairment, and pain. Other effects that may reflect minor and temporary dysfunctions or discomfort could be argued by some as not warranting significant or costly concern, especially if effects are minor or transient. The goal of air-quality management is clearly to avoid or, at worse, limit negative impacts of air pollution on public health. However, one must appreciate the distinction between risk to the individual and to a population. Clearly, risk to an individual can be beyond an acceptable limit and can put that person's health in jeopardy, but this response may be lost in a population index. On the other hand, risk to a population is the summation of individual risks such that there is a shift in the normal distribution putting unspecified individuals at risk. These two forms of risk are clearly related, but most often in practice, the population risk is considered most appropriate and most reasonably quantifiable. This population-based risk is that used in the CAA of 1970.

In 1985, the American Thoracic Society issued a position paper that attempted to define an adverse effect related to air pollution. This has recently been revised because of the many advances in clinical medicine and empiric health sciences (ATS, 2000). This statement considers seven broad areas: biomarkers, quality of life, physiologic impacts, symptoms, clinical outcomes, mortality, and population health versus individual risk. The summary conclusion states that caution should be exercised in evaluating the many new biomarkers of effect (especially cell and molecular markers), as there is need for validation that *small* changes in these markers represent a progression along a course to disease or permanent impairment. Admittedly, in the clinical environment many of these markers may appear as salient features of a disease or injury, but the health implications of minor changes in these biomarkers remains uncertain. Significant alterations of standard clinical measures of health due to pollution are clearly adverse. However, a shift from the 1985 ATS statement is that transient pulmonary function deficits (where a 10

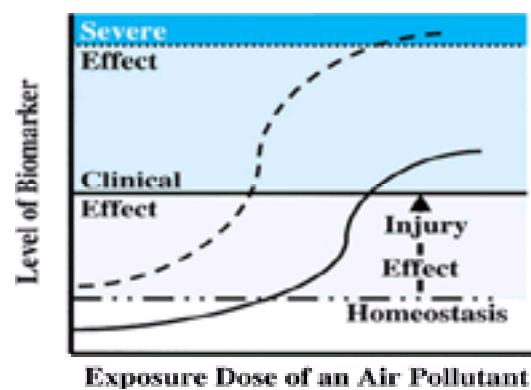
percent or more drop in FVC was defined as adverse) may not necessarily be adverse. On the other hand, any irreversible reduction in pulmonary function would be adverse either for an individual or across a population. Any population for which a significant mortality risk can be detected must be considered adverse. Of course, a common thread through all of these subject areas is the influential role of susceptibility, which can take the form of hyper-responsiveness or loss of reserve. What was a minor reversible effect may now be a dysfunction that cannot be reversed or compensated (Fig. 28-11). Obvious examples would be cardiopulmonary compromised individuals who function with little or no reserve. In the end, however, the ATS statement realizes the limits of definitions and the importance of value judgment in the final assessment. Implied in this position is that a loss of quality of life due to air pollution as well as enduring its associated effects may also be designated as adverse.


Figure 28-11. Schematic illustration of the elements of a dose response to an air pollutant(s) by a susceptible versus a healthy individual.

The hypothetical susceptible individual has both a *loss of reserve* and an *inability to maintain homeostasis.* The *leftward shift in the slope* of the dose-response curve also suggests an increase in responsiveness. These response elements of the susceptible individual may contribute to apparent sensitivity to challenge and the likelihood of progressing from subtle to severe effects.

CONCLUSIONS

In writing this textbook chapter on air pollution toxicology, the author's goal has been to relate empiric studies in animals to phenomena known to occur in humans through epidemiologic or controlled clinical study. The breadth and complexity of the problem of air pollution—from the development of credible databases to supporting regulatory action and decision making—has been the theme throughout. The classic and still most important air pollutants provide a foundation for understanding and appreciating the nuances of the issues and strategies for air pollution control and protection of public health. The key role of the toxicologist is to develop sensitive methods to assay responses to low pollutant concentrations, apply these methods to relevant exposure scenarios and test species, and develop paradigms to relate empiric toxicologic data to real life through an understanding of mechanism. Last, the toxicologist must continually integrate laboratory data with those of epidemiology and clinical study to ensure their maximum utility.

ECOTOXICOLOGY

Ronald J. Kendall, Todd A. Anderson, Robert J. Baker, Catherine M. Bens, James A. Carr, Louis A. Chiodo, George P. Cobb III, Richard L. Dickerson, Kenneth R. Dixon, Lynn T. Frame, Michael J. Hooper, Clyde F. Martin, Scott T. McMurry, Reynaldo Patino, Ernest E. Smith, and Christopher W. Theodorakis

INTRODUCTION TO ECOTOXICOLOGY

The field of environmental toxicology, particularly as related to the area of ecotoxicology, continues to be a rapidly developing discipline of environmental science (Connell and Miller, 1984; Duffus, 1980; Guthie and Perry, 1980; Hoffman et al., 1995; Moriarity, 1988; Truhaut, 1977). The term *ecotoxicology* was introduced by Truhaut in 1969 (Truhaut, 1977) and this field is a natural extension of toxicology. It is best defined as the study of the fate and effects of toxic substances on an ecosystem and is based on scientific research employing both field and laboratory methods (Kendall, 1982; Kendall, 1992; and Hoffman et al., 1995). Environmental toxicology as it is related to ecotoxicology requires an understanding of ecologic principles and theory as well as a grasp of how chemicals can affect individuals, populations, communities, and ecosystems (Kendall and Lacher, 1994; Hoffman et al., 1995). Measurements of biological impact are accomplished using either species-specific responses to toxicants (Smith, 1987) or impacts on higher levels of organization from individuals to populations, and so on. Ecotoxicology builds on the science of toxicology and the principles of toxicologic testing, though its emphasis is more at the population, community, and ecosystem levels (Moriarty, 1988). The ability to measure chemical transport and fate and exposure of organisms in ecotoxicologic testing is critical to the ultimate development of an ecologic risk assessment (U.S. EPA, 1992 a, 1992 b, 1992 c; Suter, 1993; Maughan, 1993).

Descriptions of ecotoxicologic methods and procedures have been offered by Cairns (1978) and Cairns et al. (1980) and more recently by Hoffman et al. (1995). Unlike standard toxicologic tests, which seek to define the cause-effect relationship with certain concentrations of toxicant exposure at a sensitive receptor site, ecotoxicologic testing attempts to evaluate cause and effects at higher levels of organization, but particularly on populations (National Academy of Sciences, 1975; Hoffman et al., 1995). To a large extent, the early tests (such as evaluating the effects of pesticides in fish and wildlife populations) generally employed species-specific tests in the laboratory (Smith, 1987). Tests of species included aquatic species such as *Daphnia magna,* fathead minnows (*Pimephales promelas*), the mosquitofish (*Gambusia affinis*); and, among wildlife, the northern bobwhite (*Colinus virginianus*) and mallard duck (*Anas platyrhynchos*) (Lamb and Kenaga, 1981). Arguments have continued over the last decade concerning the relevance of these few organisms to the larger ecosystem at risk. Methods for laboratory bioassays to measure the impact of chemical and nonchemical stressors on aquatic and terrestrial plants and animals continue to evolve. In addition, extrapolation of the results of these assays to field conditions and their utility in an ecologic risk assessment are active areas of research. To an even larger degree, the interrelationship or signals of animal sentinels responding to environmental toxicants as related to human health is an area of increasing interest and under rapid development (Kendall et al., 1998).

A critical component in ecotoxicologic testing is the integration of laboratory and field research (Kendall and Akerman, 1992). Laboratory toxicity bioassays define toxicant impact on individual organisms and on their biochemistry and physiology. Knowledge acquired in the laboratory is integrated with what is occurring under field conditions and is critical to understanding the complex set of parameters with which an organism must deal in order to reproduce or survive under toxicant exposures. Laboratory testing often limits the complexity of stress parameters except perhaps for isolating the toxicant. It is therefore difficult to interpret potential ecotoxicologic effects resulting from laboratory studies without data from pertinent field investigations. For these reasons, integrating laboratory and field research ensures that ecotoxicologic testing methods produce relevant data (Kendall and Lacher, 1994). Demands on ecotoxicologic testing methodologies will continue to increase as concern for environmental protection and chemical impacts increases. Scientific journals continue to publish increasing numbers of manuscripts on ecotoxicologic studies. Furthermore, there is an increasing interest in the relationship of the environment and potential environment toxicant stressors in human health implications. Therefore, this chapter, in addition to outlining some test methodologies for evaluating the effects of toxicants on invertebrates, vertebrates, and plants in aquatic and terrestrial ecosystems, also addresses the relationship of these endpoints to potential human health implications. The complexity and testing strategy in the aquatic versus terrestrial environment can be quite different, and this is one of the challenges currently faced by ecotoxicologic research. For this reason the chapter addresses both aquatic and terrestrial ecotoxicology to reflect the often different parameters involved in evaluating chemical impacts on aquatic versus terrestrial habitats. In recent years, the creation of major new environmental legislation—including the Food Quality Protection Act of 1996 and amendments to the Safe Drinking Water Act—has dictated a renewed evaluation of the relationship between environmental toxicants and potential impacts on the environment as related to human health implications. For this reason, the current chapter addresses some questions and issues related to the integration of environmental signals for toxicant stress and human health implications; in addition, discussion of ecologic risk assessment as related to applications of environmental toxicology data are expanded upon. Those reading this chapter should be aware that the increasing interest on sublethal impacts of contaminants on the environment, including those of biological and nonbiological origin, is being dealt with to a large degree by new environmental laws and by new strategies in risk assessment. These new strategies in risk assessment include probabilistic approaches and increased emphasis on relating environmental information to human health. These issues are addressed in the present chapter.

CHEMICAL MOVEMENT, FATE, AND EXPOSURE

To characterize chemical behavior, it is necessary to measure the chemical in different environmental compartments (e.g., air, soil, water, and biological systems), understand the movement and transport of the chemical within and among these compartments, and follow the chemical as it is metabolized, degraded, stored, or concentrated within each compartment. During the past half-century, intensive effort has been directed toward developing analytic techniques to detect and quantify minute concentrations of chemicals in environmental matrices (Murray, 1993; Blaser et al., 1995). One need only look at the myriad of studies investigating parts per quadrillion (ppq) concentrations of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) to realize that environmental analytic chemistry has progressed substantially to complement the ever-increasing sensitivity of measurable toxicologic endpoints. Consider, for illustrative purposes, the fact that 1 ppq is 1 billion times smaller than a part per million (ppm), equating to approximately 1 g of salt in a billion metric tons of sugar. Nevertheless, it is well documented that environmental concentrations below 1 ppm of certain chemicals can have deleterious effects on different components of the ecosystem.

Chemodynamics

Chemical transport occurs both within environmental compartments (intraphase) and between them (interphase) (Thibodeaux, 1996; Mackay, 1991) and is critical to understanding and interpreting environmental toxicology data. A likely scenario for a chemical released into the environment entails its release into one environmental compartment; it is subsequently partitioned among environmental compartments; it is involved in movement and reactions within each compartment; it is partitioned between each compartment and the biota that reside in that compartment; and it finally reaches an active site in an organism at a high enough concentration for long enough to induce an effect. Chemodynamics is, in essence, the study of chemical release, distribution, degradation, and fate in the environment.

Contaminant transport through the environment is often predicted assuming thermodynamic equilibrium. While this assumption often does not hold, the approach is relatively straightforward and easy to apply. Although intraphase chemical transport is most easily approximated assuming thermodynamic equilibrium, better accuracy is possible using a steady-state model (Mackay, 1991). Abiotic and biotic reactions, which occur within a phase, result in significant changes in the physical and chemical properties of the compound, such as the oxidation state, lipophilicity, and volatility.

Combining these approaches facilitates prediction of the chemical concentration within the immediate vicinity of a particular organism. Chemodynamics can also describe chemical movement or absorption into organisms. Detoxification mechanisms, such as partitioning into adipose tissue, metabolism, and accelerated excretion, can significantly reduce, eliminate, or in some cases increase the toxic action of the chemical. Thus, an appreciation of chemodynamics aids in the prediction of chemical concentrations in compartments and serves as a resource for designing toxicologic experiments using the appropriate concentrations and forms of the chemical in question.

Single-Phase Chemical Behavior

Once a synthetic chemical enters the environment, it is acted upon primarily by natural forces. Models are used to predict the effect of natural forces on the movement of chemicals in the environment. This requires the incorporation of abiotic variables into valid models. These variables include temperature, wind and water-flow directions and velocities, incident solar radiation, atmospheric pressure and humidity, and the concentration of the chemical in one of four matrices: atmosphere (air), hydrosphere (water), lithosphere (soil), and biosphere (living organisms). Intraphase movement consists of mass transfer, diffusion, or dispersion within a single phase (Atkins, 1982). Concentration gradients result in movement within the medium. Contaminant persistence is a function of the stability of that chemical in a phase and its transport within that phase. Stability is a function of the physicochemical properties of a particular chemical and the kinetics of its degradation in the phase; these vary widely in and between classes of chemicals (Howard et al., 1991). Stability issues are difficult to predict and are often better handled by observation rather than modeling. Transport of chemicals in the environment, in contrast, is more predictable and is discussed in detail below.

Air The primary routes of contaminant entry into the atmosphere are through evaporation, stack emissions, and other matrices. Contaminant transport in air generally occurs much more rapidly than in the hydrosphere, as air has lower viscosity. Contaminant transport in air occurs primarily by diffusional processes or advection. Diffusion dominates in the very thin boundary layer between air and the other phases, the thickness of which is less than that of equivalent water-phase interfaces. The diffusion rate for a contaminant in air is approximately 100-fold faster than for the same contaminant in water and is a function of phase viscosity and existing concentration gradients. The contaminant diffusivity in air depends on its molecular weight compared to air, air temperature, the molecular separation at collision, the energy of molecular interaction, and Boltzmann's constant (Atkins, 1982). Wind currents transport airborne contaminants much more rapidly than does diffusion (Wark and Warner, 1981). Atmospheric stability affects the amount of turbulence and thus the degree of vertical mixing in the atmosphere. The stability of the atmosphere is considered neutral when the convective forces—heat transfer from warm ground surfaces and radiative cooling from the top of the cloud layer—are equal. Vertical mixing is at a maximum when heat transfer is greater than radiative cooling and at a minimum during inversion conditions. It is the latter condition that can trap higher concentrations of contaminants near the earth's surface.

Water Contaminants enter the hydrosphere by direct application, spills, wet and dry deposition, and interphase movement. In addition, chemicals enter the hydrosphere by direct dissolution of lighter-than-water spills in the form of slicks or from pools on the bottom of channels, rivers, or other waterways. Chemical movement in the hydrosphere occurs through diffusion, dispersion, and bulk flow of the water. In any flow, a stagnant boundary layer exists at the interface between phases or artificial boundaries. Overlying this layer is a section in which flow is laminar. Finally, above the laminar flow, the fluid is in turbulent flow. Contaminant movement in a mobile phase, in this case, water, is dominated by the turbulence of the mobile phase. If the water is stagnant, (e.g., in close proximity to a stationary phase such as soil or an artificial boundary), the chemical moves by molecular diffusion. As described for the other fluid environmental compartment, air, the diffusion rate depends on fixed characteristics such as the molecular weight of the contaminant (solute), the molecular weight of the water (solvent), water temperature, viscosity, and the association factor for water and dynamic characteristics such as the magnitude of the concentration gradient of the contaminant. These characteristics are referred to as the *diffusivity* of the contaminant-water mixture. Diffusional processes in water are several orders of magnitude faster than in soil.

Away from the boundaries of other media (i.e., air and soil), transport in water is dominated by turbulence. Even in seemingly still water, water is constantly moving in vertical and horizontal eddies. These eddies are small pockets of water that form and subside and, during the process, transport the contaminant. This mode of transport is defined as *eddy diffusion*. In addition, the contaminant can be rapidly transported by bulk flow (also referred to as *advection*) in the cases of streams and rivers. In advection, the rate of transport is proportional to stream velocity.

Soil Chemicals enter the lithosphere by processes similar to those for the hydrosphere. Soils have varying porosities due to their composition (percent sand, silt, clay, organic matter), but pores are invariably filled with either gas or fluids. Chemical movement in the soil occurs by diffusion in these fluids or by the movement of water through the voids between soil particles. Fluid-borne contaminants partition with the solid fraction of soil by processes closely resembling chromatography, in that chemical solubility in pore water, adsorption to soil particles, and pore-water velocity affect the rate of transport (Willard et al., 1988). The direction of diffusion will be from areas of high to areas of low concentration. The chemical diffusion rate in soil depends on molecular weight, soil temperature, the length of the path, and the magnitude of the concentration gradient (Shonnard et al., 1993), among other issues. Contaminants leave the soil by interphase transport or decomposition. Transformation of contaminants (as through microbial degradation) can be significant in soil due to the density and diversity of microorganisms in this compartment compared with water and air.

Chemical Transport between Phases

Once released, a chemical can enter any of the four matrices: the atmosphere by evaporation, the lithosphere by adsorption, the hydrosphere by dissolution, or the biosphere by absorption, inhalation, or ingestion (depending on the species). Once in a matrix, the contaminant can enter another matrix by interphase transport. Absorption by biota is considered under "Chemical Behavior and Bioavailability," below.

Air–Water A chemical can leave the water by volatilization. Conversely, an airborne contaminant can move into an aqueous phase by absorption. At equilibrium, the net rates of volatilization and absorption are equal and the total mass transfer of the contaminant is zero. In nonequilibrium conditions, the rate of net movement of a chemical from one phase to another depends on how far the system is away from equilibrium as well as the magnitude of the overall mass transfer coefficient (Mackay, 1991). In turn, this mass transfer coefficient depends on the physical properties of the solute (such as vapor pressure and solubility) and the magnitude of the bulk flow of both the air and the water. For example, ammonia desorbs most quickly from shallow, rapidly flowing streams with a brisk cross wind. Alternatively, the water–air interface (surface microlayer) can be a concentration point for materials, both natural and anthropogenic (Hardy, 1982; Gever et al., 1996).

Soil–Water A contaminant can leave the soil and enter the water through the process of desorption. Water-borne contaminants can also adsorb on soil particles. Again, the rate of mass transfer depends on the contaminant-specific overall mass transfer coefficient, the bulk flow velocity of the water over the water-soil interface, and physicochemical properties of the soil, such as particle size distribution and organic matter content. Partitioning of contaminants from water to soil or sediment is one of the key processes controlling exposure.

Soil–Air A contaminant may leave the soil and be transported into the overlying air through the process of volatilization. This process is dependent on the vapor pressure of the chemical and its affinity for the soil. Environmental processes that affect the thickness of the soil–air boundary layer (i.e., wind velocity) or contaminant sorption (i.e., soil moisture content), in turn, influence movement from soil to air. For example, more contaminant will be released from contaminated soil at higher wind velocities as well as from wet versus dry soil.

Chemical Behavior and Bioavailability

An appreciation of how physicochemical properties influence contaminant behavior is necessary to anticipate chemical concentrations and speciation in different environmental compartments. Such an appreciation is also valuable in developing an exposure characterization for the contaminant(s) of interest. Ultimately, the goal is to assess the potential bioconcentration (uptake of contaminants from the external environment), bioaccumulation (uptake of contaminants from the external environment and food), and biomagnification (increasing contaminant concentrations at higher trophic levels) in organisms. An investment in careful exposure characterization is worth the expense and effort.

In the environment, only a portion of the total quantity of chemical present is potentially available for uptake by organisms. This concept is referred to as the *biological availability* (or bioavailability) of a chemical. Chemical bioavailability in various environmental compartments ultimately dictates toxicity; therefore it is important to characterize exposure on a site-specific basis. For example, total mercury concentration in aquatic sediments does not necessarily correlate with mercury concentration in midge larvae of the genus *Chironomus*. Important considerations in the case of mercury include the mercury species (e.g., the oxidation state, whether organic or inorganic) as well as physical and chemical characteristics of the sediment matrix (e.g., acid volatile sulfide concentration, pH, pE) (Tinsley, 1979). To complicate matters, in most cases mercury will not exist as a single species but will be distributed among several stable forms. Hence, a simple analytic result of total mercury content does not sufficiently describe the hazard associated with the presence of the metal in sediment. The multiple influences of soil, sediment, and

water quality on the bioavailability of environmental chemicals are important research areas.

Chemical bioavailability in the water column has been studied for years, yet many questions are still unanswered. The behavior of dissolved metals, for example, has been studied for over two decades. In the early seventies, much research concerned the influence of pH and water hardness on metal toxicity to algae and other aquatic organisms. This work led to the development of a model to predict metal toxicity based on pH and water hardness [U.S. Environmental Protection Agency (EPA), 1986a].

The behavior and bioavailability of contaminants in the water column have been shown to relate directly to their water solubility. However, the presence of certain constituents in water may affect the apparent water solubility of toxicants. Johnson-Logan and coworkers (1992) demonstrated the apparent solubility of the organochlorine insecticide chlordane (1,2,4,5,6,7,8,8-octachloro-2,3,3a,4,7,7a hexahydro-4,7-methano-1 *H*-indene) to be enhanced almost 500 percent in groundwater containing 34 mg/L total organic carbon. This enhanced solubility resulted directly from partitioning of this hydrophobic insecticide into the dissolved organic carbon (DOC) fraction within the water column. The apparent increase in water solubility did not necessarily indicate an increase in pesticide bioavailability. Dissolved organic carbon may increase transport and mobility of organic contaminants in the water column but also reduce their bioavailability.

The behavior and bioavailability of sediment-incorporated xenobiotics is a complex phenomenon studied only recently. The awareness that many aquatic contaminants settle into sediments has prompted studies of metals and organics to characterize their fate and disposition within the complex sediment matrix. Deposition is a combination of physical, chemical, and biological processes that may ultimately change the form of the xenobiotic. Many metals are abiotically or biotically reduced as they are incorporated into sediments. Mercury is methylated through microbial reactions in the sediment. Methylmercury is typically more bioavailable and more toxic than inorganic mercury.

Characterization of processes that control metal bioavailability in sediments would facilitate the development of models to predict toxic threshold concentrations of metals in different sediments. Work with sediment-incorporated metals has emphasized divalent cations in anaerobic environments. Under these conditions, acid volatile sulfides (AVS) preferentially bind divalent cations. Initial work with AVS focused on cadmium (DiToro et al., 1990), which can react with the solid phase AVS to displace iron and form a cadmium sulfide precipitate:

$$Cd^{2+} + FeS(s) \leftrightarrow CdS(s) + Fe^{2+}$$

If the AVS quantity in sediment exceeds the quantity of added cadmium, the cadmium concentration in the interstitial water is not detectable and the cadmium is not bioavailable, hence it is not toxic. This process can be extended to other cations including nickel, zinc, lead, copper, mercury, and perhaps chromium, arsenic, and silver (Ankley et al., 1991). Furthermore, there is thermodynamic evidence that the presence of one divalent cation, copper for example, may displace a previously bound divalent cation with weaker binding strength such as cadmium. This results in a greater concentration of bioavailable cadmium while sulfide-bound copper is less bioavailable. Thus, the bioavailable fraction of metals in sediments can be predicted by measuring AVS and the simultaneously extracted metals (SEM) that result during AVS extraction. If the molar ratio of SEM to AVS is < 1, little or no toxicity should be expected; if the molar ratio of SEM to AVS is > 1, the mortality of sensitive species can be expected (DiToro et al., 1992). This approach is not without controversy and, while many scientists believe that AVS plays a significant role in the bioavailability of divalent cations in anaerobic sediment, most would agree that AVS alone does not predict metal bioavailability. Other sediment factors including oxide and hydroxide layers undoubtedly play a role in metal bioavailability. In addition, the ability of sediment-dwelling organisms to oxidize their surrounding environment, thus breaking metal-sulfide bonds, should be further studied.

Organic chemicals residing in the sediment matrix undergo a variety of abiotic and biotic transformations. Predicting the intraphase movement of organics in sediments is extremely difficult, and in general, the processes that control such movement are poorly understood. For nonionic, nonmetabolized, nonpolar organics, however; equilibrium partitioning theory has been proposed as the basis for developing sediment quality criteria. This theory suggests that, in the sediment matrix, certain chemicals partition between interstitial water and the organic carbon fraction of the solids. At equilibrium, this partitioning can be predicted using laboratory-generated partitioning coefficients (e.g., K_{OC}). The resulting interstitial water concentration should induce the same exposure as a water-only exposure. Thus, the toxicity of chemicals in interstitial water can be predicted using the results of water column bioassays with the chemical. One assumption of this theory is that, for these chemicals, exposure of sediment-dwelling organisms occurs through interstitial water only and that chemicals partitioned onto solids are not bioavailable. A good review of this theory and supporting data can be found in the 1991 report of DiToro and colleagues.

In soils, sorption also controls the bioavailability of contaminants. An example of the importance of site-specific exposure characterization is highlighted by a series of experiments designed by researchers at the United States Environmental Protection Agency (U.S. EPA) (Weis et al., 1994). The finding that many forms of environmental lead are not well absorbed across the gastrointestinal tract disproved the assumption that all forms of lead in contaminated surface soil are equally hazardous (Table 29-1). Other lead forms were shown to be nearly as well absorbed as freely soluble lead acetate. Using an immature swine model as a surrogate (Weis and LaVelle, 1991) and a series of highly controlled animal studies, these investigators measured soil lead bioavailability ranging from less than 6 percent to greater than 90 percent relative to a soluble lead acetate reference substance (Fig. 29-1).

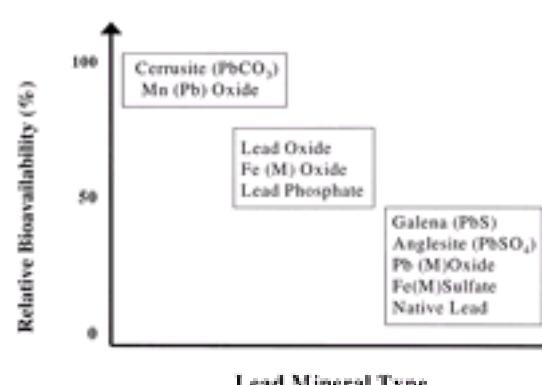
Table 29-1 Studies of Endocrine Disruption in Representative Wildlife Species


Figure 29-1. Gastrointestinal bioavailability of soil lead as a function of the physical and chemical nature of the exposure material (From Weis et al., 1994, with permission.)

Highly oxidized lead forms found in soils near mining and/or smelting sites is absorbed into blood nearly as well as freely soluble lead, while more reduced forms are only poorly absorbed.

Tight sorption or sequestration of contaminants with increasing residence time in soil, often referred to as "aging," has also been documented (Pignatello et al., 1993; Hatzinger and Alexander, 1995), especially for lipophilic organic contaminants. Although the amount of contaminant in soil remains fairly constant, the fraction of the contaminant available to soil organisms is reported to significantly decrease with time. An important issue currently being addressed is the development of methods to assess the magnitude of available contaminant residues in soil (Kelsey and Alexander, 1997), including the use of sampling devices based on passive diffusion (Johnson et al., 1995; Awata et al., 1999).

BIOMARKERS

A fundamental challenge in environmental toxicology is relating the presence of a chemical in the environment with a valid prediction of ensuing hazard to potential biological receptors. Adverse health effects in biological receptors begin with exposure to a contaminant and can progress to damage or alteration in function of an organelle, cell, or tissue. Exposure of wildlife by contact to contaminated environmental media is defined as an *external dose,* whereas internalization of the contaminated media, via inhalation, ingestion, or dermal absorption, results in an *internal dose*. The amount of this internal dose necessary to elicit a response or health effect is referred to as the *biologically effective dose*.

Traditionally, environmental risk was assessed by chemical residue determination in samples of environmental media, combined with comparison to toxicity observed in species in contact with the media. This approach, although it yields useful information, has several limitations. The determination of chemical residues in environmental matrices is not simple and may require extensive sample cleanup leading to high per sample costs (U.S. EPA, 1986b). The availability of the chemicals in the environmental matrix to the biological receptor, or bioavailability, cannot be quantified by this approach. Depending upon the chemical, the environmental matrix, and the species, bioavailability may range from 100 percent to a fraction of a percent. To overcome this problem, chemical residue analysis of tissues containing the biological receptor may be performed [Agency for Toxic Substances and Disease Registry (ATSDR), 1994]. This approach, however, is often more difficult and expensive than the cost of the analysis of environmental matrices and yields no information on toxicologic response. In addition, the toxicokinetics and toxicodynamics of a contaminant in a particular species determines whether an exposure is capable of an adverse response. A biomarker-based approach resolves many of these difficulties by providing a direct measure of toxicant effects in the affected species (Dickerson et al., 1994).

The National Academy of Sciences defines a biomarker or biological marker as a xenobiotically induced alteration in cellular or biochemical components or processes, structures, or functions that is measurable in a biological system or sample (Committee on Biological Markers, 1987). To this list may well be added xenobiotically induced alterations in behavior. Therefore, biomarkers can be broadly categorized as markers of exposure, effects, or susceptibility (ATSDR, 1994). The selection of appropriate biomarkers to be used for hazard evaluation is based on the mechanism of a chemically induced disease state. Moreover, growing awareness of the possibility of using wildlife as sentinels for human environmental disease has created a demand for biomarkers that are nonlethal and correlate with adverse effects in humans.

Dosing with an adequate concentration of a toxicant produces a continuum of responses beginning with exposure and perhaps resulting in the development of a disease. These events begin with external exposure, followed by the establishment of an internal dose leading to delivery of a contaminant to a critical site. This is followed either by reversible or irreversible adverse alterations to the critical site, resulting in the development of recognizable disease states. A clearer understanding of a chemically induced disease state in a species leads to an increase in the number of specific and useful biomarkers that may be extrapolated to other species. It is readily apparent that the earlier these effects can be measured at a critical site, the more sensitive the prediction of hazard or disease. However, in many cases the exact mechanism by which a toxicant induces injury is not well understood and nonspecific indicators of disease must be used.

Biomarkers of Exposure

The presence of a xenobiotic substance or its metabolite(s) or the product of an interaction between a xenobiotic agent and some target molecule or cell that is measured within a compartment of an organism can be classified as a biomarker of exposure (ATSDR, 1994). In general, biomarkers of exposure are used to predict the dose received by an individual, which can then be related to changes resulting in a disease state. In many cases, biomarkers of exposure are among the most convenient to determine because the contaminant or its metabolites can be quantified from nonlethally obtained samples of exhaled air, urine, feces, blood, or breast milk as well as tissues obtained through biopsy or necropsy. The former sources are the most desirable because they can be used for multiple determinations over time, thus making the biomarker more useful by providing more information on the effects of the toxicant with time and by reducing variability.

Some very useful biomarkers of cancer involve detecting the ability of chemical carcinogens to form adducts with cellular macromolecules such as DNA or protein. Most chemical carcinogens are either strong electrophiles or are converted to an electrophilically active substance through metabolic activation (Miller and Miller, 1981). These carcinogens react with nucleophilic biomacromolecules to form adducts. If the biomacromolecule is sufficiently stable, adducts can then be detected by a variety of means and used to determine exposure profiles. Stable biomacromolecules can also provide measurement of the dose of a chemical carcinogen received by animals and humans. Adduct detection can be accomplished by total hydrolysis of the protein to alkylated amino acids (histidine, cysteine adducts), mild hydrolysis to release adducts (adducts that form esters to carboxyl groups or sulfonamides), immunodetection, or modified Edman degradation (adducts to N terminal valines on Hb). These techniques have been used to identify adducts formed by simple alkylating agents and their metabolites, aromatic amines, nitrosamines, and polynuclear aromatic hydrocarbons. One major advantage to this method of cancer risk determination is that blood samples are easily obtained and multiple samples can be obtained to determine patterns of exposure. In addition, the presence of adducts can often be detected by the creation of a point mutation. An example of this is the G-to-T transversion created following the formation of a N7 guanine adduct by benzo[*a*]pyrene 7,8-dihydrodiol-9,10-epoxide (BPDE) (Shibutani et al., 1993). Such point mutations can be detected by restriction fragment length polymorphisms.

Biomarkers of Effect

Biomarkers of effect are defined as measurable biochemical, physiologic, behavioral, or other alterations within an organism that, depending on their magnitude, can be recognized as an established or potential health impairment or disease (ATSDR, 1994). Ideally, a biomarker result must be able to stand alone. As such, it does not need chemical analysis or additional biological tests for confirmation. These tests are highly specific for individual chemicals and thus have a fairly limited application. Examples of such biomarkers include inhibition of brain cholinesterase by organophosphate or carbamate insecticides, induction of delta aminolevulinic acid synthetase and inhibition of aminolevulinic acid dehydratase by lead and certain other metals, and eggshell thinning by 1,1-dichloro-2,2-bis(*p*-chlorophenyl) ethylene (DDE), a metabolite of 1,1,1-trichloro-2,2-bis(*p*-chlorophenyl)ethane (DDT) (Scott, 1977).

Less specific biomarkers are also well validated, but they have wider applications and tend to respond to broader classes of chemicals. Examples of these biomarkers are the induction of mixed-function oxidases, the formation of DNA adducts, other DNA alterations such as sister chromatid exchange and strand breakage, porphyrin profile alterations, induction of vitellogenin in oviparous vertebrates, and immunologic changes such as immunosuppression and hypersensitivity. These assays require either additional biomarker studies or chemical residue analysis in order to link causative agent to adverse effect. For example, the induction of cytochrome P4501Al (CYP1A1) enzymes in fish liver is generally recognized as a useful biomarker of the exposure of fish to anthropogenic contaminants, but these results are not compound-specific, as they may be induced by a variety of polynuclear and halogenated aromatic hydrocarbons as well as by hypoxia (HIF response element; Collier et al., 1995; Chan et al., 1999).

Finally, there is a long list of biomarkers that are under development or have been used with varying degrees of success but require further validation before they can be used in hazard evaluation. Thyroid function, retinol levels, plasma sex steroids, and stress proteins fall into this classification. Challenges exist in interpreting data from measurements of these endpoints because of normal circadian and seasonal variation, multiple known factors involved in the control of these endpoints, and marked interindividual variability.

Biomarkers of Susceptibility

Biomarkers of susceptibility are endpoints that are indicative of an altered physiologic or biochemical state that may predispose the individual to impacts of chemical, physical, or infectious agents. These biomarkers can be useful in predicting human disease states from wildlife sentinels. Low-level exposure to a cytochrome P4501A1 or 1A2 inducer, for example, may result in elevated enzyme activity in wildlife but no observable adverse effects. Such elevations in enzyme activity in humans have been linked to greater risk of a number of cancers due to increased bioactivation of procarcinogens. Similar observations have been made for decreases in conjugation enzymes and their high-energy substrates (Frame et al., 1998). In addition, a number of xenobiotic compounds inhibit the activities of the immune system and thus increase susceptibility to infectious agents, parasites, and cancer. Admittedly, the distinction between biomarkers of effect and susceptibility may be blurred. However, the distinction may be based upon whether the xenobiotic causes a physiologic or biochemical change that is directly indicative of a

disease state or whether it reduces resistance to other biological, physical, or chemical agents.

Biomarker Interpretation

Caution must be used in interpreting biomarker results and extrapolating from one species to another. The same chemical may induce different proteins in one species when compared to another and the same enzyme may have different substrate specificities in species as closely related as the mouse and rat. For example, the common environmental contaminant *p,p'*-DDE induces cytochrome P4502B in the laboratory rat (*Rattus rattus*) but induces cytochrome P4501A1 in the deer mouse (*Peromyscus maniculatus*). Moreover, TCDD is a cytochrome P4501A1 inducer in the rat but induces both 1A1 and 2B in the deer mouse as determined by Western blotting, Northern blotting, and enzymatic activities (Nims et al., 1998, Dickerson et al., 1999). Similar differences exist between laboratory rats and birds, fish, and reptiles. Extrapolation of results requires a thorough knowledge of comparative physiology and biochemistry.

Alternatively, an important application of biomarkers is their ability to integrate multiple chemical exposures across an area with a variety of chemical contaminants, the scenario found at most chemical waste sites. CYP1A1 responses to sediments contaminated with dioxin, polychlorinated biphenyls (PCBs), or polynuclear aromatic hydrocarbons (PAHs) can provide insight to the status of the contaminants on site, their bioavailability, and the overall risk that they pose. Similarly, porphyrin profile alterations, metallothionein content, and immune function can provide insight to the combined effects of metals found on mine waste-contaminated sites. It is thus essential in the use of biomarkers to understand both the strengths and the limitations of the techniques and to be cautious in extrapolating between species.

Beyond the current predominance of functionally based biomarkers, new trends in biomarker development appear distinctly molecular. A review of the most recent biomarker literature lists molecular biomarkers for a great many diseases and environmental contaminants ranging from secondhand smoke to suicide. The integration of biomarkers with epidemiology has resulted in a new discipline, molecular epidemiology, which has the potential for creating worldwide databases for environmental and genetic diseases (Albertini, 1999). The integration of biomarkers with molecular biology has revolutionized both medicine and biology by providing new tools by which to determine mechanisms of action (Costa, 1998). Moreover, these techniques can be applied to samples as small as one cell (Rao et al., 1998). Increasing emphasis is being placed upon nonlethal biomarkers such as enzyme-linked immunosorbent assay (ELISA) techniques for measuring fecal steroids in deer mice. A recent study defined four major needs in the development of biomarkers (Ward et al., 1996). New biomarkers are needed to monitor the continuum between exposure and overt disease. An increased knowledge is needed of the relationship between biomarker responses and disease pathology. In addition, better validation and increased sensitivity are required from existing biomarkers in order to better predict disease development. Last, as biomarkers become better tools for predicting environmental and genetic risk, a need to integrate science with policy emerges due to ethics of furnishing risk data to employers and insurance providers.

ENDOCRINE AND DEVELOPMENTAL DISRUPTORS

Endocrine disruption has recently emerged as a major issue, in terms of both science and public policy. A number of compounds, both natural and anthropogenic, cause alterations of the endocrine system (Colborn, 1996). Profound endocrine effects, both in individuals and at the population level, have been documented after exposure to high levels of certain compounds. All available evidence indicates that this issue will continue to evolve because of the controversial nature of the topic and the current insufficiency of data with which to make sound policy decisions (Kendall et al., 1998).

Mechanisms of Endocrine Toxicity and Sensitive Life Stages

It is evident that endocrine-disrupting compounds (EDCs) may interact with multiple targets. There is evidence for EDCs acting at every level of hormone synthesis, secretion, transport, site of action, and metabolism. Some examples of known mechanisms for EDCs include the following.

Receptor-Mediated Effects of EDCs A xenobiotic compound may exert effects at the receptor level through multiple mechanisms beyond the classic ligand-receptor interaction. These include differential effects at multiple receptor types or direct effects on intracellular signaling pathways, thereby directly influencing hormone action at the target tissue. Xenobiotic compounds may act on the endocrine system by affecting transcription and signal transduction and can act through receptor-mediated or nonreceptor-mediated mechanisms. For example, genistein has been shown to be a weak estrogen receptor agonist; however, it also modulates the activity of tyrosine kinases and DNA topoisomerases (Makela et al., 1994; Makela et al., 1995; Okajima et al., 1994; Olsen et al., 1994; Piontek et al., 1993; Whitten et al., 1995).

Effects of EDCs on Hormone Synthesis and Metabolism A compound may adversely alter levels of critical endogenous hormones by inducing or inhibiting biosynthetic or metabolic enzyme activities. Some phytoestrogens can interact with the 17b-dehydrogenase that regulates estradiol and estrone levels, suggesting that they can modulate overall estrogen levels in addition to acting as a ligand for the estrogen receptor. Perchlorate competitively inhibits thyroidal iodine uptake, thereby disrupting thyroid hormone synthesis (Lamm et al., 1999).

Effects on Hormone Secretion and Transport It has been known for many years that Cd^{2+} is a nonselective Ca^{2+} blocker that can disrupt Ca^{2+}-dependent exocytosis in hypothalamic neurosecretory neurons and pituitary endocrine cells, for example. Alternatively, EDCs can affect hormone-binding (sex hormone binding globulin, SHBG; corticosteroid binding globulin, CBG) proteins in blood, thereby disrupting hormone transport by increasing or decreasing the bound-to-free ratio of the hormone in plasma (reviewed in van der Kraak et al., 1998).

Timing of Exposure

There is substantial evidence that the sensitivity of an individual to gonadal steroids is dependent on the life stage of that individual. Specifically, the fetus appears to be the most sensitive life stage for lasting impacts of gonadal steroids or agonists/antagonists (Birnbaum, 1994; Blanchard and Hannigan, 1994; Ojasoo et al., 1992). For example, a compound may have little effect at environmentally relevant concentrations on a postpubescent animal but may prevent normal development if exposure occurs during fetal development or puberty. Research with polychlorinated biphenyls (PCBs) and dioxin has shown that gestational exposure is more critical than lactational exposure in eliciting developmental effects (Bjerke et al., 1994a; Bjerke and Peterson, 1994; Bjerke et al., 1994b). Sensitivity to EDCs is generally higher in fetal and perinatal individuals than in adults. However, in some cases, the presence of fetal serum-binding proteins may result in lower sensitivity to these compounds. For example, the ability of a-fetoprotein to bind 17b-estradiol protects the fetal male rat from maternal estrogen (Herve et al., 1990). Recent U.S. EPA workshops have identified the development of reproductive capability as the highest research priority in consideration of the features discussed above (Ankley et al., 1998).

Hormone Regulation and Feedback Control

There are several important control mechanisms that regulate estrogen biosynthesis during pregnancy. Estrogen levels are not feedback-regulated in a typical homeostatic mechanism; rather, there is a feed-forward mechanism resulting in steadily increasing serum levels of estradiol across most of pregnancy in rodents and humans (Casey et al., 1985). Thus, an exogenous dose of any estrogen agonist will be additive with the endogenous level because feedback will not reduce endogenous production in a compensatory way. Additionally, in rodents and humans, the specific estradiol (E2) serum-binding proteins, a-fetoprotein (AFP), and testosterone-estradiol binding globulin (TEBG), also increase steadily during pregnancy, serving to protect the fetus from the high circulating estrogen level of pregnancy. Xenoestrogens that fail to bind effectively to these proteins have increased bioavailability (Sheehan and Young, 1979). Diethylstilbestrol and ethynylestradiol bind AFP with about 100-fold lower affinity than E2. Hence their bioavailability in newborn rats with high AFP levels is increased to about the same extent as E2, the bioavailability of which is decreased (Sheehan and Barnham, 1987). A fungal estrogen (i.e., Zearalenone) is about 0.066 percent as potent as E2 for adult uterotrophic responses, while equol, a plant estrogen, is about 0.25 percent as potent. In the neonatal rat, these numbers are 5 and 25 percent, respectively (Sheehan et al., 1984).

Species-Dependent Sex Determination

There are major differences in the control of sex determination among vertebrate classes. In mammals, sexual determination is based on the XY/XX system with the female as the homogametic sex. This system requires the synthesis of testosterone and dihydrotestosterone (through modification of testosterone by the action of 5a-reductase) in some target tissues and the presence of functional androgen receptors in the undifferentiated gonad, secondary sexual tissues, and brain (Norris, 1997). In rodents (but not necessarily in primates), the presence of estrogen receptors in the brain is essential for establishing male-type behavior. In order for this to occur, testosterone or a precursor must be aromatized to 17b-estradiol. Failure of any component results in the development of genetic males whose external phenotype or behavioral sex is not concordant with chromosomal sex (Norris, 1997). The sensitivity of this system is so exquisite that effects on reproductive

development after in utero exposure may drive the risk assessment for EDCs (EC, 1996). In contrast, birds have a WZ/WW sex chromosomal system with the male as the homogametic sex. In birds, the ability to synthesize and recognize 17b-estradiol is necessary for female central nervous system (CNS) and gonadal sexual development to occur. A number of environmentally relevant chemicals can affect sexual differentiation and behavior in avian species. For example, masculinization of behavior in female birds may be observed following exposure to certain halogenated aromatic hydrocarbons (Fry, 1995; Nisbet et al., 1996; Rattner et al., 1984).

A nonheterogametic chromosome sex determination pathway exists in some reptilian species, predominantly the crocodilians, some turtles, and lizards. In these oviparous species, the temperature of incubation determines the sex of the embryo—a mechanism referred to as *environmental* or *temperature-dependent sex determination* (TSD). The window of sex determination for most animals is fairly narrow, comprising approximately 25 percent of the total incubation period (Norris, 1997). In some species, such as the American alligator (*Alligator mississippiensis*), the relationship between incubation temperature and sex is fairly linear, with lower incubation temperatures producing female offspring and higher incubation temperatures producing male offspring (reviewed in Matter et al., 1998). Moreover, incubation temperatures below 26°C and above 36°C result in embryonic death. For the red-eared slider (*Trachemys scripta*), the relationship is opposite. In other reptilian species, the relationship between sex and incubation temperature is more complex, with intermediate incubation temperatures producing predominantly male offspring and incubation temperatures on either extreme resulting in predominantly female offspring. The molecular mechanism of TSD is not well understood but may be the result of temperature-dependent control of aromatase (Rhen et al., 1999; Chardard and Dournon, 1999; Bergeron et al., 1999; Jeyasuria and Place, 1998). A number of compounds found in the environment can cause a reversal of sex determination in these species. Feminization of alligator and turtle embryos by DDE and hydroxylated PCBs has been reported (Guillette et al., 1999; Bergeron et al., 1994).

Endocrine disruption was initially observed in wildlife species and has received much attention in both the lay and scientific press. Although there are species differences in the response to EDCs, wildlife are sensitive to the effects of EDCs. Studies in wildlife are an important tool in determining the risk posed by EDCs in the environment. Table 29-1 lists a number of studies in various species, the causative agent (if known), and effects observed.

Further Issues on Endocrine and Developmental Toxicants

The Endocrine Disruptor Screening and Testing Advisory Committee (EDSTAC) was formed to develop strategies for evaluating the thousands of products and intermediates currently in use or in development that have the potential of human or environmental exposure. EDSTAC became necessary when the U.S. Congress mandated testing for endocrine-active substances in the Food Quality Protection Act (1996) and the Safe Drinking Water Reauthorization Act and Amendments (1996). These acts required that the U.S. EPA develop a screening program by August 1998, implement the program by August 1999, and report results back to Congress by August 2000. EDSTAC was chartered by the U.S. EPA administrator to provide advice and council to the U.S. EPA on these issues. This legislation increased the number of compounds likely to be tested from a few hundred to most chemicals in production or trials.

Currently, the most widely used tests are the Developmental Toxicology Test and Multigenerational Tests. These have been described previously in this volume. The limitations of the Developmental Toxicology Test are insufficient exposure during sexual differentiation and limited evaluation of reproductive and/or endocrine systems. Limitations of multigenerational tests include not enough diversity in the species tested, insufficient sensitivity of some endpoints, and failure to identify malformations elicited by known endocrine disrupting compounds (e.g., eggshell thinning).

EDSTAC recommended a two-tiered approach, with the first tier concerned with detecting—through the use of a battery of assays in mammalian and nonmammalian organisms—compounds that may be endocrinologically active, affecting the estrogen, androgen, and thyroid hormone systems. The second tier is designed to characterize the dose-response relationship of endocrine-disrupting compounds in wildlife and humans. Compounds are being selected (prioritized) for testing based upon their production volume, potential for exposure, result of high-throughput prescreening, structure, chemical class, and other relevant information. Once selected, the compounds will be evaluated by a series of in vitro and in vivo tests. These in vitro tests include estrogen receptor (ER) binding/transcriptional activation, androgen receptor (AR) binding/transcriptional activation, and steroid hormone synthesis using minced testis. Proposed in vivo tests include uterotrophic assay in adult ovariectomized rat, pubertal female rat assay including thyroid tests, (anti)androgen assay in castrate-T-treated male rat, frog metamorphosis assay for EDCs with thyroid hormone action, and a short-term fish gonadal recrudescence assay.

TERRESTRIAL AND AQUATIC ECOTOXICOLOGY

Many environmental studies include the analysis of contaminant exposure and effects on relatively small scales. However, contaminants can affect ecologic systems over large areas, including ecosystems and landscapes (Holl and Cairns, 1995). Ecosystems are composed of groups of all types of organisms that function together as well as interact with the physical environment, including energy flow and cycling of material between living and nonliving components (Odum, 1983). In turn, ecosystems collectively constitute landscapes with their own functional (nutrient and energy flow) and structural (patches, corridors) attributes. Movement of biotic and abiotic components within these large systems varies depending on several factors, including the species of animal and physical features of the system. Large vertebrates may roam over hundreds of square kilometers, integrating many habitat types within their home range. The area used by small animals may be small on an individual basis; however, dispersal individuals can maintain rather extensive connectivity among otherwise distinct local populations. Cycling and flow of materials maintain varying levels of connectivity within ecologic systems, such that disturbances to one component may be realized at another seemingly distinct component (Holl and Cairns, 1995). In general, ecologic systems are in a constant state of communication, which can potentially facilitate the large-scale effects of pollution.

Ecotoxicology includes all aspects of aquatic and terrestrial systems while attempting to elucidate the effects on biota following contaminant exposure. Exploring exposures to terrestrial systems and the effects of environmental contaminants within them is a recent endeavor relative to work that has been conducted historically in aquatic systems. Studies in aquatic and terrestrial toxicology rely heavily on interdisciplinary scientific exploration. Such research encompasses a variety of topics, including toxicity testing, sublethal responses of individual organisms, effects on populations and communities, and field research (Kendall and Lacher, 1994). A plethora of measurement endpoints exist that can be used to determine exposure and effects in different organisms or ecologic systems (Holl and Cairns, 1995; Melancon, 1995). These biological indicators of pollution may include individual-based measurements of some biochemical, physiologic, or morphologic endpoint (as previously discussed) or higher-order endpoint measurements including perturbations at population or higher levels. Thus, pollution may result in a cascade of events, beginning with effects on homeostasis in individuals and extending through populations, communities, ecosystems, and landscapes. This complexity and potential for large-scale effects extending through ecosystems results in a challenging research environment for environmental toxicologists.

Separation of aquatic and terrestrial environments in ecotoxicology is often impossible, as contaminants can be readily transported between these two systems. For example, contaminants in terrestrial environments may be transported to aquatic systems through surface runoff, resulting in exposure and effects in aquatic organisms located considerable distances from the source of contamination. Conversely, contaminants originating in aquatic environments may move into terrestrial environments following flood events or evaporation. One mechanism of contaminant movement of considerable interest in ecotoxicology is the transfer of contaminants through trophic levels, both within and between aquatic and terrestrial systems. Life-history strategies of many vertebrate and invertebrate organisms routinely integrate aquatic and terrestrial systems, resulting in exposure and effects scenarios that can be quite complex. Thus, although aquatic and terrestrial ecotoxicology are often considered separately, they are often intimately connected through abiotic and biotic mechanisms, examples of which can be found throughout the scientific literature.

Toxicity Tests

Acute and chronic toxicity tests are designed to determine the short- and long-term effects of chemical exposure on a variety of endpoints, including survival, reproduction, and physiologic and biochemical responses. Toxicity testing of terrestrial animal and plant species serves a number of purposes in terrestrial toxicology. Understanding the effects of a single compound provides a foundation for assessing the effects of contaminant mixtures. Because of the complex possibilities under typical field conditions, acute and chronic toxicity testing provides a critical foundation for evaluating the exposures and effects encountered in the field and for linking cause and effect to specific chemicals. For example, brain and plasma cholinesterase (ChE) inhibition has proven to be an excellent tool for monitoring exposure and in some cases for diagnosing the effect in animals exposed to organophosphate and carbamate pesticides (Mineau, 1991). Advances in toxicology have resulted in an expanding search for new sentinel plant and animal species for assessing contaminant exposure and effects. In turn, new sentinel prospects require testing to determine their sensitivity and the precision of their responses. Acute and chronic toxicity testing represents the initial steps toward validating new animal and plant species as useful sentinels of environmental contamination.

Results derived from acute and chronic tests can be used to determine the pathologic effects of contaminants, to provide data necessary to analyze the effects discovered in field tests, identify the potential effects to be aware of under field conditions, and provide dose-response data for comparison to exposure levels in the field. Although they measure effects at the individual level, acute and chronic toxicity tests were designed for the purpose of protecting natural ecosystems from perturbation due to anthropogenic contamination. There are concerns raised by some researchers that laboratory toxicity tests are not realistic predictors of effects in

complex field ecosystems. On the other hand, others have argued that short-term toxicity data provide conservative indices by which to judge potential effects of chemicals and effluents on natural populations and ecosystems (Cairns and Mount, 1990). It has even been found that toxicity tests can sometimes be used as indicators of potential effects on community structure (Norberg-King and Mount, 1986; Hartwell, 1997).

Sublethal Effects

Mortality represents a nonreversible endpoint of interest in ecotoxicology. However, documenting die-offs can be challenging, as success is affected by search efficiency and rapid disappearance of carcasses (Rosene and Lay, 1963). Also, many contaminants exist in smaller, nonlethal amounts or in relatively unavailable forms, such that acute mortality is unlikely. Thus, understanding and monitoring the sublethal effects of contaminant exposure in aquatic and terrestrial systems is of great interest. The existence of sublethal effects in exposed organisms has been used as an advantage in monitoring strategies. Biochemical and physiologic measurement endpoints have been developed or adapted from other sources and, in turn, used with various plant and animal sentinels to assess exposure and effect in many different species (Lower and Kendall, 1990; Kendall et al., 1990; Huggett et al., 1992; Adams et al., 1992; Theodorakis et al., 1992). Inhibition of ChEs has proven an excellent marker that is both sensitive and diagnostic for organophosphate and carbamate insecticide exposure (Mineau, 1991). Induction of enzyme systems, such as the mixed-function oxygenases, are also useful as sublethal biomarkers of exposure to many types of environmental pollutants (Elangbarn et al., 1989; Rattner et al., 1989). Other strategies for monitoring sublethal effects include monitoring immune function (McMurry et al., 1995), genotoxicity (McBee et al., 1987), and reproductive endpoints (Kendall et al., 1990). Even though these effects may not result in immediate mortality, they can affect fecundity and reproductive success of aquatic and terrestrial organisms and ultimately have effects on population structure and function. Chemicals may also affect the growth rate of organisms. Because growth rate and body size are related to reproductive maturity in juvenile organisms and its attainment as well as relative fecundity in adults, chemical stressors that inhibit growth rates can also affect the reproductive potential of the population.

Sublethal effects of contaminant exposure reach beyond the intrinsic physiologic and biochemical responses to many behavioral traits of the individual. Decreased predator avoidance capability may expose individuals to increased susceptibility to predation (Bildstein and Forsyth, 1979; Preston et al., 1999). Foraging behavior may be altered by chemicals, such that foraging efficiency or success in prey capture is diminished (Peterle and Bentley, 1989; Smith and Weis 1997). Migration and homing also may be affected, decreasing the general fitness of the individual (Snyder, 1974; Willette, 1996; Vyas et al., 1995). Altered breeding behavior may decrease fecundity through impaired nest-building and courtship behavior, territorial defense, and parental care of the young (McEwen and Brown, 1966; Jones and Reynolds, 1997). In addition, changes in fish behavior patterns or avoidance of contaminated water have been used as indicators of aquatic pollution (Gruber et al., 1994; DeLonay et al., 1996). These may occur at earlier times or at lower doses than overt mortality, providing an early-warning indicator of toxic effects (Gerhardt, 1998).

Determination of sublethal effects is an important component of risk assessments for two reasons. First, these responses may provide information not available from measurements of contaminant tissue concentrations. This is because (1) it may not be possible to measure tissue concentrations of some chemicals because they are rapidly metabolized and (2) the toxic effects of many chemicals, especially when present in complex mixtures (as is usually the case in the environment) may not be predicted from tissue concentrations alone (Lower and Kendall, 1990). Second, alterations of biochemical and molecular physiology have been associated with reductions of fecundity, growth, and bioenergetic status of affected organisms (Adams et al., 1989, Theodorakis et al., 1996, Steinert et al., 1998). Hence, perturbations of subcellular function may affect fitness and health of fish and wildlife, and may ultimately be translated as effects on populations and communities.

Although they are quite similar, sublethal effects in aquatic and terrestrial organisms do differ in some important aspects. For example, there are a number of suborganismal (cellular, molecular, histologic) effects that can be detected in aquatic and terrestrial organisms, and many of these are commonly studied in both types of organisms—e.g., liver mixed function oxidase induction (Goksøyr and Förlin, 1992). However, aquatic and terrestrial organisms may differ in the relative magnitude of these responses. DNA-repair enzyme activity may be lower in fish than in mammals (Wirgin and Walden, 1998). Additionally, some toxicant-responsive genes in terrestrial vertebrates may not have homologs in aquatic organisms, possibly leading to species-specific differences of toxic effect or induction of these genes (Hahn et al., 1992). There are also differences between aquatic and terrestrial biomarkers in relation to the attention given to various endpoints. For example, studies that examine acetylcholinesterase inhibition mainly focus on terrestrial organisms, whereas studies examining DNA damage (Shugart and Theodorakis, 1994) and metallothionein induction (Roesijadi, 1992) are more heavily represented in aquatic studies. Another class of protein that can be induced by contaminant exposure are the stress or "heat-shock" proteins (Sanders, 1993), which participate in the renaturation of damaged proteins. Although they are highly conserved in all organisms from bacteria to mammals and are a major focus of study in the biomedical field, in the field of ecotoxicology, studies on the induction of stress proteins focus almost exclusively on aquatic organisms. Aquatic toxicology studies also differ from those in terrestrial toxicology because aquatic organisms respire through gills. Gills may be constantly exposed to water-borne contaminants and are highly permeable to dissolved substances. As a result, gills may accumulate certain contaminants (Robinson and Avenant-Oldewage, 1997) or their structure and function may be impaired (Karan et al., 1998; Li et al., 1998). Conversely, terrestrial organisms will realize most of their exposure through ingestion of contaminated media.

Population and Community Effects

One of the major objectives of ecotoxicology is the detection and prevention of pollutant effects on population structure and function. These effects may be determined by collection of empiric data or simulated with the use of population models (Albers et al., 2000). In the former case, natural populations are sampled in order to determine the effects of environmental contamination on density, abundance, or biomass of indigenous organisms (Rask, 1992; Welsh and Ollivier, 1998). These values from contaminated populations are then compared with those from reference populations (with no history of contamination) in order to determine pollution effects. Such effects may also be manifest as changes in age structure or sex ratios, which may affect the reproductive potential of the population (DeAngelis et al., 1990). The age structure of populations (relative number of individuals of each age class) may give an indication of pollutant effects, such as reproductive failure or perturbations in recruitment of juveniles into the population (Vuori and Parkko, 1994; Hesthagen et al., 1996). The pattern of population response to pollution may also provide information as to the mechanism of population effect, such as changes in adult mortality, juvenile recruitment, food availability, etc. (Gibbons and Munkittrick, 1994).

Alternatively, effects of pollutants on populations can be predicted or simulated using mathematical models. These models use empiric data such as abundance, age distribution, and age-specific mortality and fecundity in order to predict effects of pollutant exposure on abundance of individuals and rate of population change (growth or decline). The empiric data are gathered from organisms grown in laboratory cultures or from natural populations, and population parameters are calculated using linear or matrix algebra (DeAngelis et al., 1990). Models also exist that use toxicity test data derived from laboratory exposures in combination with population parameters in order to predict effects of pollutants on populations (Barnthouse et al., 1990). Other models use physiologic and behavioral parameters of individuals in order to predict such effects (DeAngelis et al., 1990).

Any effects on populations may ultimately be manifest as effects on communities because, by definition, communities are collections of interacting populations. Environmental contaminants can affect the structure of communities as well as the interactions of species within them. For example, it is well known that exposure to chemicals may cause a reduction of community diversity (relative number of species) and changes in community composition (e.g., LaPoint et al., 1984; Hartwell et al., 1997; Beltman et al., 1999). In addition, the trophic structure of fish and invertebrate communities may also be affected by exposure to anthropogenic chemicals (Camargo, 1992; Paller et al., 1996).

The trophic structure of communities is related to the relative abundance of species that feed on various food items (piscivores, omnivores, detritivores, insectivores, etc.) or have various foraging methods (shredders, scrapers, etc.). These changes in species/ trophic composition may come about by direct or indirect mechanisms. The direct effects involve loss of some species due to an increase in pollution-induced mortality or reduced reproductive output. In this case the communities will be dominated by species that are less affected by pollutant exposure. This is the basis of a phenomenon termed *pollution-induced community tolerance,* or PICT (Blanck and Wangberg, 1988), in which algal communities become more pollution-tolerant over time due to the replacement of pollution-sensitive species with more tolerant ones. Some evidence of this phenomenon has also been observed in terrestrial systems where shifts in the composition of rodent communities appears to indicate contaminant-induced reductions of select species in the community in favor of resistant or resilient species (Allen and Otis, 1998).

Alternatively, community structure may change through indirect mechanisms. For example, a species may be absent from a community because the organisms upon which it feeds are exterminated by pollutant exposure. Indirect effects may also be affected by changes in dynamic interactions between species—for example, predator/prey interactions. Analogously, if competing species differ in relative sensitivity to a pollutant, environmental contamination may give one species a competitive edge over the other, resulting in local extinction of the less tolerant species. Finally, it has been suggested that such changes in community structure come about because some species are more genetically adaptable than others and so are better able to adapt to novel stressors such as pollution (Luoma, 1977). Thus, the more sensitive species would not be able to adapt to this stressor and become locally extinct. These types of perturbations in community structure and dynamics may ultimately compromise the stability, sustainability, and productivity of affected ecosystems.

Chemical Interactions and Natural Stressors

As more information becomes available on chemical effects in aquatic and terrestrial organisms, there is increasing interest in understanding the interactive effects of exposure to multiple contaminants as well as the interactions between contaminants and inherent stressors (e.g., nutritional stress, disease, predation, climate, water quality). This area of ecotoxicology is one of the least understood because of the a priori need to understand the more direct exposure and effects scenarios. Nevertheless, it represents an expanding part of ecotoxicology and is generating interest in the research community.

Perhaps the greatest inherent stressors faced by many species of wildlife are nutritional restriction and seasonal shifts in climatic extremes. Daily food restriction of as little as 10 percent below normal intake has been shown to enhance the overall decline in courtship behavior, egg laying and hatching, and number of young fledged by ringed turtle doves (*Streptopelia risoria*) exposed to DDE (Keith and Mitchell, 1993). Antagonistic relationships also exist. Methionine supplementation effectively negated the detrimental effects of selenium toxicity on mortality in mallard ducklings (Hoffman et al., 1992). Similarly, relative magnitude of biomarker responses and tissue distribution of contaminants in fish may be influenced by nutritional status and food deprivation (Joergensen et al., 1999). Effects have also been found for the interaction between temperature and chemical exposure. Cold stress has been shown to augment the effects of pesticide exposure, resulting in increased mortality of several wildlife species (Fleming et al., 1985; Rattner and Franson, 1984; Montz and Kirkpatrick, 1985). However, more subtle interactive effects on energy acquisition and allocation were less conclusive in deer mice exposed to aldicarb—2-methyl-2-(methylthio)propanal *C*-[(methylamino)carbonyl] oxime—and cold stress (French and Porter, 1994). Unlike many wildlife species, fish and aquatic invertebrates are poikilotherms, so their metabolic rate is more dependent on ambient temperature than that of birds or mammals. As a result, toxicity, accumulation, and metabolism of aquatic contaminants may be influenced by water temperature (Odin et al., 1994; Sleiderink et al., 1995; van Wezel and Jonker, 1998). Other environmental variables, such as salinity and pH, may also affect uptake and toxicity of aqueous chemicals (Norrgren et al., 1991; Hall and Anderson, 1995). Conversely, exposure to pollutants may affect an organism's ability to tolerate natural environmental variables such as water oxygen concentrations (Bennett et al., 1995). Other areas of interest include interactions between chemical exposure and social stress (Brown et al., 1986) and interactions between different chemicals (Stanley et al., 1994).

Trophic-Level Transfer of Contaminants

Although contaminant exposure may occur through inhalation, dermal contact, or ingestion from preening or grooming behavior, significant exposure also occurs through food-chain transport. Depending on specific chemical properties, contaminants may accumulate in either soft or hard tissues of prey species. Species not normally in direct contact with contaminated media may become exposed through ingestion of contaminated prey, promoting accumulation or magnification of contaminants into higher trophic levels. Earthworms in soils contaminated with organochlorines and heavy metals can accumulate quantities of contaminants known to be deleterious to sensitive species (Beyer and Gish, 1980; Beyer and Cromartie, 1987). The use of pesticides to control plant pests often coincides with the reproductive periods of many wildlife species, enhancing exposure potential in juveniles that often rely on invertebrates as a primary food source (Korschgen, 1970).

The foraging habits of individual species dictate the potential for contaminant exposure through food-chain transport. In a field study in Canada, Daury and coworkers (1993) found a higher percentage of ring-necked ducks (*Aythya collaris*) with elevated blood lead concentrations compared to American black ducks (*Anas rubripes*). The difference was attributed primarily to foraging habits, as ring-neck ducks are divers and may consume up to 30 percent invertebrates in their diet, compared with American black ducks, which forage on the surface of the water. Even when contaminated prey is ingested, exposure may be minimal in certain species. Adult American kestrels (*Falco sparverious*) fed pine voles (*Microtus pinetorum*) with mean body burdens of 48 µg/g DDE, 1.2 µ/g dieldrin, and 38 µg/g lead accumulated approximately 1 µg/g lead in bone and liver tissue but 232 µg/g DDE and 5.9 µg/g dieldrin in carcasses after 60 days. Mean lead concentration in regurgitated pellets from kestrels was 130 µg/g, demonstrating their lack of lead accumulation from contaminated prey (Stendell et al., 1989). Secondary poisoning from food-chain transfer has also been implicated in the mortality of endangered species. Lead poisoning was apparently responsible for the deaths of several California condors (*Gymnogyps californianus*) found in California. The probable source of the lead was considered to be bullet fragments consumed by condors feeding on hunter-killed deer (Wiemeyer et al., 1988).

The potential exposure of predatory species may be enhanced by the altered behavior of contaminant-exposed prey. Affected prey may be easier to catch, leading predators to concentrate their foraging efforts on contaminated sites and thus increasing their direct exposure and the transfer of contaminants through trophic levels (Bracher and Bider, 1982; Mendelssohn, 1977). As contaminants move through food chains, they may be translocated from their source. Migrating individuals may transport contaminants considerable distances, resulting in potential exposure and effects in organisms that otherwise would not be in contact with contaminated sites (Braestrup et al., 1974).

Genotoxicity

Ecogenotoxicology is a relatively young field that has benefited tremendously from the growth of molecular biology and molecular genetics. It is concerned with the effects of pollutants or chemicals (mutagens, clastogens, aneuogens, and teratogens) on the genetic material of organisms. Such genetic material is usually defined as DNA, RNA, and chromosomes but may also include modifications of proteins. Such effects may be manifest as DNA strand breaks, base modifications, chromosomal rearrangements or fragmentation, and aneuploidy (Shugart and Theodorakis, 1994). While it is possible to damage the genetic material of an organism without any subsequent effect on that individual, it is also possible that mutations in the DNA can result in somatic effects such as cancers. If these effects occur in germinal tissues, this can also result in heritable effects and an increase in the genetic load (i.e., relative frequency of deleterious mutations in the population). Other types of multigenerational effects may not occur by direct interaction of contaminants with the DNA molecule but by selection pressure from chemical contaminants. Because this can change the evolutionary nature of a species, Bickham and Smolen (1994) coined the phrase *evolutionary toxicology* to describe this phenomenon. They proposed that selection resulting from the stress of somatic effects of contaminants could lead to population genetic changes that are not predictable from a knowledge of the mechanisms of toxicology of the contaminants. Also, individuals that have the pollutant-resistant genotypes may be more susceptible to natural stressors (Weis et al., 1982). Furthermore, because changes in the genetic makeup of the population involve alterations in survival and recruitment, such changes may be indicators of adverse chronic effects on population structure and dynamics. Selection for pollutant-resistant genotypes, as well as genetic bottlenecks—a result of reductions in population size or recruitment—may reduce genetic variability in affected populations (Guttman, 1994; Theodorakis and Shugart, 1998). These effects may be indicators of community-level effects, because it has been found that patterns of genetic diversity and community-level pollution effects are correlated in contaminated streams (Krane et al., 1999). These were termed *emergent* effects.

Besides selection and genetic bottlenecks, an elevated mutation rate may also alter population genetic structure. The search for methods to detect mutations easily among millions of base pairs is one of the primary needs of genotoxicology. The mitochondrial DNA has the least effective repair mechanism and should be among the fragments of DNA that permit detection of an elevated mutation rate. However, it is often difficult to detect an increase in the mutation rate because baseline mutation rates are so low that even highly contaminated environments may fail to induce significant changes (reviewed in Cotton, 1997). For example, studies of Chernobyl mice experiencing doses in excess of 15 rads per day (Chesser et al., 2000) failed to detect statistically significant elevation of mutation rates (Baker et al., 1999). In addition, mini-satellite and microsatellite mutation frequencies are among the highest documented for the nuclear genome, and this phenomenon appears to have potential in genotoxicology. Makova et al. (1998), however, failed to find an elevated mutation rate in mice at Chernobyl. Dubrova et al. (1996) reported an elevated mutation rate in minisatellite loci in children born to survivors of the Chernobyl disaster.

It is appealing to use native species living in a highly polluted environment to determine multigenerational effects on the genome (McBee and Bickham, 1990). The basic assumption is that living in a polluted environment will result in reduced fitness and deterioration of health of the sentinel species. With an adequate array of biomarkers such as alterations in the DNA (Shugart et al., 1994), mini- and microsatellites (Dubrova et al., 1996; Bickham et al., 1998), micronuclei frequency (Heddle et al., 1991, MacGregor et al., 1995; Rodgers and Baker, 2000), flow-cytometry values (Bickham et al., 1992), enzymatic assays (Jensen et al., 1997; Langlois et al., 1993), and population genetic characteristics (Matson et al., 2000), it should be possible to estimate risk and genotoxicologic damage.

However, the issue is not simple because life is resilient and often highly polluted environments are modified and devoid of other human activities. Some areas with extremely high levels of radioactivity, like Chernobyl, may support population densities and levels of biodiversity reminiscent of conservation parks, suggesting that human activities can be more detrimental to natural ecosystems than the world's worst nuclear power plant disaster. The problem of using native species as sentinel species may be further complicated by adaptation of the local populations to the polluting chemicals (Theodorakis et al., 1998). Undoubtedly, studies that resolve reduced fitness and health issues of wildlife will require excellent experimental design using control populations and multigenerational data.

Terrestrial Ecotoxicology

Terrestrial toxicology is the science of the exposure to and effects of toxic compounds in terrestrial ecosystems. Investigations in terrestrial toxicology are often

complex endeavors because of a number of intrinsic and extrinsic factors associated with terrestrial systems. All organisms function at several levels, from the individual level to the level of the ecosystem, interacting with others within the constraints of social ranking, food webs, and niches. Many terrestrial species are very mobile, covering significant areas while defending territories, foraging, migrating, and dispersing. Terrestrial toxicology includes all aspects of the terrestrial system while attempting to elucidate the effects on the biota following contaminant exposure. Exploring exposures to and the effects of environmental contaminants in terrestrial systems is a recent endeavor relative to work that has been conducted historically in aquatic systems. Like aquatic toxicology, however, terrestrial toxicology relies heavily on interdisciplinary scientific exploration.

The early 1900s witnessed the relization that chemicals used in the environment could affect nontarget organisms. Studies were conducted on the exposures to and effects of arsenicals, pyrethrums, mercurials, and others on terrestrial organisms (Reviewed in Peterle, 1991). In later years, synthetic pesticides became increasingly important in controlling pest species in agricultural crops, although little was known about their effects on nontarget organisms. As pesticide development and use continued, however, reports of wildlife mortalities and declining avian populations spawned concern among biologists internationally. Studies were conducted that documented residues of DDT and DDT metabolites, other chlorinated hydrocarbon insecticides, and industrial chemicals, including PCBs, in the tissues of wildlife species. Although reduced nesting success was apparent in some avian species (e.g., osprey, bald eagles, Bermuda petrels, herring gulls, and brown pelicans) (Ames, 1966; Peterle, 1991; Wurster and Wingate, 1968; Keith, 1966; Schreiber and DeLong, 1969), the underlying mechanism was not completely understood until later.

The study of the toxic effects of chemicals on terrestrial organisms witnessed its most dramatic growth in the 1980s (Kendall and Akerman, 1992). Requirements for detailed and accurate information on the effects of pesticides on terrestrial wildlife species played a large part in the development of terrestrial toxicology methodologies. Persistent pesticides such as DDT and mirex [1,1a,2,2,3,3a,4,5,5,5a,5b,6-dodecachlorooctahydro-1,3,4-methano-1 H-cyclobuta(cd)pentalene] were shown to accumulate in wildlife species. Development of new insecticides, such as organophosphates, lessened the problem of persistence, although toxicity was still a concern. An obvious need existed by which scientifically sound investigations could be conducted to explore the direct and indirect effects of chemicals on terrestrial wildlife populations.

Chemical effects on avian populations were the primary focus for many years. This problem became more apparent as the link was established between DDT contamination and declining bird populations. The classic case of eggshell thinning in raptor eggs was established by Ratcliffe (1967) in studies on declining sparrow hawk (*Accipiter nisus*) and peregrine falcon (*Falco peregrinus*) populations in the United Kingdom. Other studies soon followed and it became apparent that many avian species suffered reduced productivity resulting from eggshell thinning and decreased hatching success. Studies continue to be conducted on the exposure and effects of these persistent pesticides in wildlife species (Bergman et al., 1994; Custer and Custer, 1995; Auman et al., 1997; Allen and Otis, 1998; Elliott and Norstrom, 1998, Creekmore et al., 1999).

Acute and Chronic Toxicity Testing Terrestrial organisms are typically exposed to contaminants through ingestion of some contaminated media, although inhalation and dermal absorption of contaminants do occur. Thus, toxicity tests for terrestrial species are usually designed to test the effects of a chemical dose, administered by oral gavage or injection. Exposure can also be accomplished through consumption of contaminated food or water, resulting in dosages calculated from consumption rates or simply exposure over time to a given concentration of contaminant in the diet. Methods for measuring endpoints in toxicity tests include the LD_{50} and LC_{50}, the ED_{50} and EC_{50}, and reproductive tests (fertility, egg hatchability, neonate survival). These endpoints can be used to assess toxicity in a variety of terrestrial animals, including earthworms (*Eisenia foetida*), honeybees (*Apis mellifera*), northern bobwhite, mallards, mink, and European ferrets (*Mustela purofius furo*) (Menzer et al., 1994). Likewise, specialized tests for determining toxicity in plants are used to assess lethal and nonlethal response to contaminants. Standardized tests for toxicity in plants include germination assays for lettuce seeds (*Latuca sativa*), root elongation in seedlings, and analysis of whole plants such as soybean (*Glycine max*) and barley (*Hordeum vulgare*) (Wang, 1985; Greene et al., 1989; Pfleeger et al., 1991; Ratsch, 1983). Other plant and animal species, including domestic and wild types, can be used in standardized testing systems as dictated by specific site requirements (Lower and Kendall, 1990).

Standardized laboratory toxicity tests performed under U.S. EPA guidelines include acute oral LD_{50}s and dietary LC_{50}s on northern bobwhite quail and mallard ducks. Also, mammalian toxicity tests include acute oral LD_{50}s on rats using estimated environmental concentrations of the chemical in question. Avian and mammalian reproductive toxicity testing may be required under certain circumstances, depending on such factors as food tolerance, indications of repeated or continued exposure, the persistence of chemicals in the environment, and chemical storage or accumulation in plant or animal tissues (U.S. EPA, 1982).

Field Testing Field studies are designed to address exposure to contaminants and resulting effects to organisms outside the highly controlled environment of the laboratory. Field studies may be designed specifically to address concerns suggested by laboratory studies or to test modeled or predicted exposure and effects based on site contaminant levels. As the effects of environmental contaminants on wild populations of animals have become more apparent, the need for more useful field testing methodologies has led to improved assessment strategies. Whether the U.S. EPA requires field testing depends both on laboratory testing results, professional judgment, or the degree of consensus on anticipated exposure and effects. Chemical properties of the compound, intended use patterns (e.g., pesticides), difference between the estimated environmental concentration (EEC) and the lowest observed effect level (LOEL), and dose-response relationships are considered in combination when exploring the need for conducting field studies.

Field studies are conducted in complex ecologic systems where plants and animals are affected by numerous natural stressors (e.g., nutrient restriction, disease, predation) that might possibly confound the measurement of contaminant exposure and effects. In addition, life history characteristics vary dramatically among species. Issues of habitat use, home range size, foraging characteristics, and other factors must be considered in designing a field study. Field study design must be robust to noncontaminant influences, and some important considerations include censusing techniques, sampling units, site replication, scale ecologic similarity among sites, and choice of study organisms. Results from several studies indicate the potential complexity involved with censusing animals exposed to contaminants, as alterations in behavior and observation difficulties may bias results (Grue and Shipley, 1981; Fryday et al., 1996; Hawkes et al., 1996; Madrigal et al., 1996).

Traditional methods used by biologists and wildlife ecologists have been used successfully in terrestrial ecotoxicology field studies, and resources are available that describe the various techniques for trapping, remote sensing, and sampling terrestrial biota (Bookhout, 1994; Menzer et al., 1994). Ligature techniques used for birds have improved the process of collecting food from nestlings raised on contaminated sites, allowing researchers to better determine the composition of the diet and to ascertain the contaminant loads in foodstuffs (Mellott and Woods, 1993). The published results of field studies have provided information on the impacts of contaminants on wildlife abundance and survival (Rowley et al., 1983), acute mortality (Babcock and Flickinger, 1977; Kendall et al., 1992), food-chain relationships (Korschgen, 1970), reproduction (Clark and Lamont, 1976; Hooper et al., 1990), and behavior (Grue et al., 1982). Basic laboratory techniques are often integrated with field methods to determine the ecologic significance and mechanisms of exposure and effects on populations (Hooper et al., 1990).

Techniques for the assessment of wildlife exposure and its effects must incorporate sufficient flexibility to allow their use on sites with a wide variety of physical and chemical characteristics (Fite et al., 1988; Warren-Hicks et al., 1989). To accomplish this goal, three approaches to wildlife assessments are generally used to provide the required breadth. These are the use of (1) endemic species occurring naturally on contaminated sites, (2) enhanced species attracted to the site by creating more favorable breeding habitat, and (3) enclosed species derived from clean laboratory-bred populations (Hooper and La Point, 1994).

Field studies are often designed to study populations of organisms living on contaminated sites, which are then compared with other populations living on noncontaminated reference sites. The primary benefit in these studies is the use of endemic species that receive lifelong exposures to site contaminants of concern. Detracting from the utility of these studies is the lack of control over such factors as exposure history or genetic background of individuals. Although some control is available over other factors such as the test species and habitat type, study design is still subject to the local conditions dictated by the contaminated site. Further, the small sizes of some sites can preclude effective use of some native wildlife species that roam over large areas.

Enhanced species studies generally include assessing the reproductive effects of contaminant exposure on species that inhabit nest boxes, such as the European starling (*Sturnus vulgaris*), which provides a model for assessing other cavity-nesting passerines with similar life history traits (Kendall et al., 1989). Cavity-nesting birds readily occupy artificial nest cavities and will often colonize study sites when provided with nest boxes. Increased numbers of adults and nestlings are thus available, from which information on reproductive success, behavioral response, exposure routes, and physiologic and biochemical perturbations can be obtained during the breeding season. Numerous studies have taken advantage of these traits in other avian species, including eastern bluebirds (*Sialia sialis*), American kestrels, and—more recently—tree swallows (*Tachycineta bicolor*). Tree swallows have been used extensively to assess exposure and effects from a number of contaminants (Shaw, 1984; DeWeese et al., 1985; Custer et al., 1998; Bishop et al., 1999, McCarty and Secord, 1999).

Use of enclosures has greatly enhanced control over many of the environmental factors that can complicate field studies. Enclosure studies incorporate a variety of outdoor, open-air facilities to enclose test organisms during toxicologic testing. The purpose of using enclosures is to simulate natural field conditions while maintaining a level of control over experimental conditions (e.g., exposure period, nutritional condition, test organism, sex ratios, age, genetic similarity, habitat type).

In essence, enclosure-based experiments can be used to bridge the gap between laboratory and field investigations. Study organisms are more readily accessible when housed in enclosures, making it easier to take multiple samples from individuals, administer treatments to them, and monitor their behavior and reproduction. The flexibility afforded under these conditions makes it possible to explore a number of questions regarding the potential interactions between the contaminant and natural stressors in the environment. Enclosure studies may be required by the U.S. EPA under the Federal Insecticide, Fungicide and Rodenticide Act (FIFRA) guidelines for pesticide registration if they can potentially yield useful information about pesticide impacts on wildlife.

Enclosure studies have been used successfully with aquatic and terrestrial species to explore the effects of pesticides and chemical contaminants on abundance, reproduction, immune function, and biochemical response (Barrett, 1968; Pomeroy and Barrett, 1975; Barrett, 1988; Dickerson et al., 1994; Gebauer and Weseloh, 1993; Weseloh et al., 1994; Hooper and La Point, 1994; Edge et al., 1996; Caslin and Wolff, 1999). Basic approaches to using enclosures to study the impacts of chemicals on terrestrial organisms vary widely. There is considerable variation in enclosure size; they range from less than 1 m ^{2} to more than a hectare. Small stainless steel enclosures, approximately 0.5 by 1.5 in, have been used to house laboratory-raised deer mice (*Peromyscus maniculatus*) for the assessment of contaminant uptake and biomarker response in mice on sites contaminated with polynuclear aromatic hydrocarbons (Dickerson et al., 1994). Larger enclosures can be used to monitor population-level responses and community interactions. Barrett (1988) and Pomeroy and Barrett (1975) used large enclosures to assess population and community responses of several rodent species to controlled applications of Sevin (1-naphthyl- *N*-methylcarbamate) insecticide. Studies incorporating pinioned ducks on contaminated waste ponds provide an equivalent method for avian species (Gebauer and Weseloh, 1993; Weseloh, 1994).

Although large enclosures offer the advantage of addressing population- and community-level issues of toxicant effects, they can be restrictive in cost and space. Smaller enclosures are affordable and can be beneficial for site-specific evaluations. They can be easily moved among locations, making them an excellent strategy for short-term testing and determining the efficacy of site remediation. However, the design of enclosures depends on the goals of the study.

Aquatic Ecotoxicology

Aquatic toxicology is the study of effects of anthropogenic chemicals on organisms in the aquatic environment. The aquatic ecosystem is of particular concern because this is where most contaminants released into the environment are eventually deposited, either from direct discharge into bodies of water or from terrestrial runoff and atmospheric deposition (Pritchard, 1993). Furthermore, there are certain features of the aquatic environment that make it unique. First, certain chemicals are not volatile in air but are soluble in water (e.g., metals), so aquatic organisms may be exposed to chemicals via routes that are not present in their terrestrial counterparts. Also, many contaminants are readily degraded in an aerobic environment, but the aquatic environment frequently contains little or no oxygen. Therefore, some contaminants can persist in aquatic ecosystems far longer than in terrestrial systems (Ashok and Saxena, 1995). Finally, aquatic organisms are frequently restricted in their habitat and home range, so they often cannot avoid contaminated areas. These attributes of aquatic systems present unique circumstances and problems that are not applicable to terrestrial systems.

The physiology and anatomy of aquatic organisms can also present problems that are different from those faced in the study of terrestrial organisms. For example, aquatic organisms have highly permeable skin and gills and so are particularly susceptible to the effects of ambient contamination (Pritchard, 1993). Furthermore, aquatic communities are dominated by ectothermic organisms (e.g., invertebrates, fish, amphibians, and, to a lesser extent, aquatic reptiles), whose metabolic rate is determined by ambient water temperature. Thus, the accumulation of contaminants and their toxic effects are influenced by water temperature, which can vary both spatially and temporally. Finally, fish and amphibians are unique among the vertebrates in that they have a highly permeable anamniotic egg (an egg without a shell or amniotic membrane), and the embryo develops while the egg is completely immersed in water. They are also unique in that they are the only vertebrates that have an aquatic larval life stage that undergoes metamorphosis. For these reasons, the embryo/larval stages are often very sensitive to chemical insult and may be vulnerable to effects experienced by terrestrial vertebrates.

Acute and Chronic Toxicity Testing In aquatic toxicity tests, fish, invertebrates, or algae are exposed to aqueous chemicals in the laboratory. Designs for these tests include static (in which the test water is not renewed for the duration of the test), static renewal (test water is renewed periodically), and flow-through systems (test water is renewed continually). The organisms may be exposed for short (acute toxicity tests) or long periods (chronic toxicity tests). Static designs are usually restricted to acute toxicity tests, and chronic tests frequently have a flow-through design. Acute and chronic tests not only differ in duration but also in the endpoints that are measured. In acute tests, survival is often the only endpoint (ASTM, 1992a). However, in chronic tests, effects on growth and reproduction are also determined. To accomplish this, the duration of the chronic test is designed to span the entire life cycle of the organism (i.e., from zygote to age of first reproduction; U.S. EPA, 1989). However, chronic tests are often difficult to perform because of their long duration (9 to 30 months for fish tests) and are very expensive, which makes their routine use prohibitive. Hence, three alternatives to full life-cycle tests have been developed: partial life-cycle tests, early-life-stage tests, and short-term chronic tests. Partial life-cycle tests are used for fish that require >12 months to reach reproductive maturity. They begin with immature fish prior to gonadal maturation and end after the first reproduction in order to determine the effects of aquatic contaminants on reproductive potential of the fish. Early-life-stage tests determine toxicity in fish exposed from the embryonic through juvenile stages and are typically 1 to 2 months in duration (ASTM, 1992b). The rationale is that the embryo and larvae of fish are thought to be the life-cycle stage that is most sensitive to toxic effects (McKim et al., 1978). Short-term chronic assays are static-renewal tests developed by the EPA that commonly use fathead minnows (*Pimephales promelas*), *Daphnia magna*, or *Ceriodaphnia dubia* (small planktonic crustaceans) and a green algae (*Selenastrum capricornutum*) as test organisms (Birge et al., 1985; U.S. EPA, 1989). These assays examine growth (fathead minnow and algae), survival (minnow and *C. dubia*), and reproduction (*C. dubia*) after a 4- to 7-day exposure. The fathead minnow tests are basically truncated versions of the early-life-stage tests. However, *C. dubia* reach sexual maturity and begin to reproduce within a week of hatching, so the 7-day test for this species essentially encompasses the full life cycle.

Unlike tests on terrestrial organisms, where subjects are dosed with test chemicals via oral or inhalation routes, in aquatic toxicity tests the subjects are immersed in a solution of the contaminant. Therefore, the endpoints of aquatic toxicity tests are not recorded as LD_{50} or ED_{50} but as LC_{50} or EC_{50} (lethal and effective concentration). Results of the chronic tests are sometimes expressed as the maximum allowable toxicant concentration (MATC). This is a range of toxicant concentrations bounded by the *lowest observed effect concentration* (LOEC) at the upper end and the *no observable effect concentration* (NOEC) at the lower end. The LOEC and NOEC are determined by statistical analysis and are defined as the lowest toxicant concentration that elicits an effect that is statistically significantly different from the control and the highest concentration for which the effect is not significantly different from control, respectively (Mount and Stephan, 1967).

Toxicity tests have been used to measure toxic effects of individual chemicals or contaminated water collected from the field. Single-chemical tests are typically used for the purposes of chemical registry, while testing of contaminated water is commonly used for environmental monitoring purposes and to verify compliance with permitting requirements. In the latter case, water can be collected from the source of wastewater discharge ("effluent") or from the body of water receiving the effluent ("receiving water"). In these tests, the water to be tested is collected on site and test organisms are exposed to various concentrations diluted with clean water (ASTM, 1992c). Toxicity tests of undiluted effluent (referred to as *whole-effluent tests* or WETs; U.S. EPA, 1991a) are mandated by the Clean Water Act as part of the requirements for a permit to release effluents—a National Pollutant Discharge and Elimination System (NPDES) permit. Effluents are complex mixtures of multiple chemicals, some of which may contribute to the toxicity and some may not. Identification of toxic components of effluents may be facilitated by a process known as toxicity identification evaluation (TIE; U.S. EPA, 1993). In this process, different samples of the effluent are treated to remove various constituent chemicals (e.g., chelation to remove metals, extraction to remove organic contaminants) and each sample is tested. Reduction of the toxicity in any treated sample indicates that particular constituent has contributed to the toxicity of the whole effluent. TIEs are then followed by a Toxicity Reduction Evaluation (TRE). In this procedure, the source of the toxic constituents in the effluent may be identified and possible methods to remove these toxic components from the effluent or reduce their toxicity are evaluated. This is followed by implementation of methods to control output of the toxic constituents or treat the effluent to reduce its toxicity. Follow-up toxicity testing is used to assess the efficacy of these remedial actions (U.S. EPA, 1991b).

Another type of test used for monitoring purposes is sediment toxicity testing. In this case, sediment is collected from the bottoms of lakes, rivers, bays, etc., and brought into the laboratory. Benthic invertebrates—commonly oligochaet worms, chironomid (midge fly) larvae, amphipod crustaceans, or mollusks—are then subjected to chronic or acute exposures and endpoints such as survival, growth, reproduction, and burrowing or other behaviors are recorded (ASTM, 1995). Important applications of sediment tests include determination of toxicity of sediments that are dredged from one location (e.g., in clearing shipping channels) and need to be disposed of at another location, environmental risk assessments of contaminated areas, and as a part of biomonitoring programs for the purpose of compliance to environmental regulations.

Sublethal Effects In the aquatic environment, concentrations of contaminants in the water or sediment may not be high enough to elicit mortality but may still induce sublethal effects on the health of aquatic organisms. One method by which these health effects can be determined is via histologic evidence of tissue damage or dysfunction (Teh et al., 1997). This type of damage can lead to diseases such as tumors or infectious and parasitic infestations. Tumor prevalence is commonly reported in bottom-dwelling fish and bivalve mollusks from contaminated areas (Van Beneden et al., 1993; Baumann, 1998; Wirgin and Waldman, 1998). Tumors are generally reported more often in feral populations of aquatic than terrestrial organisms. This is perhaps due to the less efficient DNA repair capacity of aquatic organisms (Wirgin and Waldman, 1998). Tumors are commonly reported in organisms that live within or in close proximity to the sediment, which is often highly

contaminated with carcinogenic materials such as PAHs. Unlike cancers, infectious and parasitic diseases are not directly induced by contaminant exposure, but such exposure may increase the occurrence and severity of these infections. This is possibly due to suppression of leukocyte function (Chu and Hale, 1994; Couillard et al., 1995). The effects may be physically manifest as deterioration of the fins, skin lesions, or a high load of ecto- and endoparasites (Couillard et al., 1995; Landsberg et al., 1998). These detrimental effects on the health of aquatic organisms do not necessarily result in immediate mortality, but the life expectancy and relative reproductive output of the affected organisms may be compromised. If significant numbers of individuals are affected, this could ultimately have effects at the population level.

Field Studies Aquatic field studies can be classified as either manipulative or observational. In manipulative studies, previously unexposed organisms are used, and the experimenter determines the level of contamination to which they are exposed. In contrast, in observational studies, the level of contamination to which the organisms are exposed is not under the control of the experimenter. The objective of these studies may be collection of data for independent research projects or for monitoring organismal health and environmental quality as mandated by a regulatory authority. In the latter case, these studies are referred to as *biomonitoring.*

Aquatic field experiments in which treatments are applied by the experimenter include microcosms and mesocosms. The difference between microcosms and mesocoms is size. Microcosms are composed of large tanks, aquaria, or artificial pools. Mesocosms are artificially constructed ponds, plastic enclosures in lakes or ponds, or artificial streams. The attributes common to both are that they typically (but not always) contain more than one species of test organism, are located outdoors (although microcosms may also be located indoors), and are more complex than simple aquaria. They frequently contain sediment and/or vegetation or other structures and substrates that provide some degree of complexity and realism. The rationale is to produce a test system that contains some of the realism of the natural environment but is not so complex. Endpoints examined may include comparative acute toxicity (Stay and Jarvinen, 1995), biomarker expression (Eggens et al., 1996), or effects on aquatic populations and communities (Juettner et al., 1995; Barry and Logan, 1998). Although they are useful in providing information in some instances, their utility for regulatory purposes is controversial (Shaw and Kennedy, 1996).

Biomonitoring involves sampling aquatic organisms in the natural environment as an indication of the impact of anthropogenic contamination. Such activities may include confining test organisms in cages or sampling indigenous populations at contaminated sites. The relative advantages of using caged versus field-collected aquatic organisms are basically the same as those expounded in the preceding discussion on terrestrial enclosure studies. One endpoint that is particularly well suited to caging studies is acute and chronic toxicity. These endpoints are assessed by exposing caged organisms to contaminated water, sediment, or both and noting mortality and reproductive impairments. These types of tests are termed *ambient toxicity tests* (Stewart, 1996).

Evidence of overt toxicity is more difficult to determine in indigenous populations except during fish kills or other episodes of massive mortality. Consequently, endpoints other than mortality are more commonly documented in biomonitoring studies. One of the endpoints commonly measured is tissue concentrations of contaminants of concern (van der Oost, 1996a). These data are useful in determining whether chemicals present in the water or sediment are in a form that is bioavailable to aquatic organisms, for determining possible health risks to humans that might consume these organisms, or for modeling accumulation and effects in organisms at higher trophic levels. In addition, biomarkers or other sublethal effects may also be incorporated into aquatic biomonitoring programs (van der Oost et al., 1996b). This provides additional information as to whether the accumulated chemicals may be producing detrimental effects, assessing possible effects of complex mixtures and abiotic variables (e.g., water temperature) on toxic response. Additional endpoints used in biomonitoring may include effects on populations or communities (described above) or calculation of indices of water quality. One such index is known as the *Index of Biotic Integrity* (IBI). The variables used to calculate this index include percent pollution-tolerant species, percent of species from various trophic levels (e.g., herbivores, omnivores, top predators) or with various reproductive strategies, and occurrence of individuals with deformities, diseases, or other lesions (Karr, 1987). Each variable is given a numerical score that reflects its relative similarity to the reference sites. The scores are then summed to give a relative overall score for each sampling site. Analogous indices for benthic invertebrates are Hilsenhoff's biotic index and the Ephemeroptera-Plecoptera-Trichoptera (EPT) index, both of which rely on relative abundances of taxa that are thought to be pollution-tolerant and pollution-sensitive (Hoiland and Rabe, 1992).

A related idea in biomonitoring is the concept of indicator species. These can be species that are particularly tolerant or sensitive to environmental contamination such that their presence or absence is indicative of environmental degradation (Lang and Reymond, 1996). In this regard, indicator species may be used as a basis for biotic indices. For example, insects in the orders Ephemeroptera, Plecoptera, and Trichoptera are indicator species used in the EPT index. Alternatively, indicator species may be those in which biomarker responses to specific chemicals are well characterized, or species that are known to accumulate environmental contaminants. One such application is the Mussel Watch program (Wade et al., 1999) enacted by the United States National Oceanic and Atmospheric Administration (NOAA) in 1985. This program monitors contaminant tissue concentrations of coastal mussel populations as an indication of marine contamination. Indicator organisms such as these are useful in the detection of environmental contamination and its changes over time, and as early-warning indicators of possible ecologic effects.

The most efficacious methods of biomonitoring are those methods that integrate multiple endpoints at various levels of biological organization (e.g., chemical concentrations, biomarkers, community composition). For example, the *sediment quality triad* approach (Chapman, 1989) incorporates analysis of sediment chemical concentrations, acute toxicity, and benthic invertebrate community structure to assess the level of sediment contamination. Concordance between all three endpoints is taken as strong evidence that there are contaminants present in the sediment that could have detrimental effects on the aquatic ecosystem. There are analogous studies in fish that integrate endpoints at multiple levels of organization such as water and tissue chemical concentrations, biomarker expression, and population/community level effects (Adams et al., 1992). Integrated approaches such as these are necessary to evaluate environmental contamination in natural settings accurately, because the aquatic environment is too complex to be accurately assessed by one endpoint alone.

GOOD LABORATORY PRACTICES IN TERRESTRIAL AND AQUATIC ECOTOXICOLOGY

Good scientific practices, which result in high-quality data collection and interpretation, are of paramount importance in the field of toxicology. There is a great public demand for personal and environmental requirements under FIFRA and the Toxic Substances Control Act (TSCA), among other environmental legislation. With regulatory agencies increasingly being held accountable for environmental standards, there is a corresponding strong demand for formal and legal assurance that the toxicologic data generated are accurate and that sufficient documentation exists to support the study conclusions. Requirements are designed to ensure that the studies are conducted under high ethical and scientific standards. It is thus critical in today's regulated environment that toxicologic data are produced and reported in a manner that ensures the study is reconstructible and that there are sufficient assurances of the quality and integrity of the data.

The principles and practices of quality assurance and quality control are perhaps best exemplified by the Good Laboratory Practice Guidelines (GLPs). The GLPs are regulation standards that define conditions under which a toxicology study should be planned, conducted, monitored, reported, and archived. They have been adopted by many national and international governments and agencies. The GLPs outline study management procedures and documentation practices that, if followed, will limit the influence of extraneous factors on study results and interpretations. GLPs include provisions for such factors as personnel management and training, facilities support and operation, equipment design, maintenance and calibration, independent quality assurance monitoring, handling of test systems and materials, documentation of study conduct, written standard operation procedures and study protocols, reporting study results, and retention of records and samples.

The U.S. EPA implemented GLP regulations in 1983 under the mandate of FIFRA (40 CFR Part 160) and TSCA (40 CFR Part 792) for pesticide and toxic chemical registration and use. By 1989, these regulations were amended to cover field studies as well as laboratory studies. Today, significant efforts are under way to provide international harmonization of the regulations/standards in the field of ecotoxicology.

MODELING AND GEOGRAPHIC INFORMATION SYSTEMS

Modeling in ecotoxicology allows the prediction of effects of toxic compounds on the environment, which can be characterized by various ecosystems. Terrestrial ecosystems include forests, grasslands, and agricultural areas, whereas aquatic ecosystems include lakes, rivers, and wetlands. Each of these systems is a collection of interconnected components, or subsystems, that functions as a complete entity. Because the dynamics of real systems are quite complex, an understanding of the impacts of toxicants on a system can be enhanced by modeling that system.

The components, or compartments, of a system are represented by state variables that define the system. Once we have defined the system, it is possible to identify stimuli or disturbances from exogenous toxic substances, called *inputs,* from outside the system. These inputs operate on the system to produce a response called the *output*. The adverse effects of many toxic inputs are directly related to their ability to interfere with the normal functioning of both physiologic and environmental systems. For example, emissions of heavy metals from a lead ore-processing complex caused perturbations to the litter-arthropod food chain in a forest ecosystem (Watson, et al., 1976). Elevated concentrations of lead (Pb), zinc (Zn), copper (Cu), and cadmium (Cd) caused reduced arthropod density and microbial activity,

resulting in a lowered rate of decomposition and a disturbance of forest nutrient dynamics.

In applying modeling to ecotoxicology, we are interested in studying a "real world" system and the effects of various toxicants on that system. A model is a necessary abstraction of the real system. The level of abstraction, however, is determined by the objectives of the model. Our objective is to stimulate the behavior of a system perturbed by a toxicant. This requires a mechanistic approach to modeling.

The modeling process involves three steps: (1) identification of system components and boundaries, (2) identification of component interactions, and (3) characterization of those interactions using quantitative abstractions of mechanistic processes. Once the model has been defined, it is implemented on a computer. Measurements obtained from the real system are compared with the model projections in a process of model validation. Improvements are then made to the model by changing parameter values or modifying equations in the model. Several iterations of comparing model behavior to that of the real system are usually required to obtain a satisfactory or "valid" model.

Types of Models

Models can be used to obtain qualitative or quantitative information about a complex system. Qualitative models emphasize the relationship between the variables of interest while minimizing the requirement for tremendous accuracy in the parameters of the model. The disadvantage is that there can be no reliance on the numbers produced from such a model. Quantitative ecotoxicologic models can be classified as (1) individual-based versus aggregated models, (2) stochastic versus deterministic models, and (3) spatially distributed versus lumped models. Such models often have hundreds of thousands of lines of code and are used only at the final stages of a system simulation. The results of such simulations are always regarded with suspicion until they are verified by actual data obtained in real systems. The development of such models usually takes place over a number of years as opposed to hours or days for models that are used for qualitative information.

Individual-Based versus Aggregated Models Models that stimulate all individuals simultaneously are referred to as *individual-based models* (e.g., Huston et al., 1988; DeAngelis and Gross, 1992). Each individual in the simulation has a unique set of characteristics: age, size, condition, social status, and location in the landscape as well as its own history of daily foraging, reproduction, and mortality. The individual-based approach has several advantages. It enables the modeler to include complex behavior and decision making by individual organisms in the model. But importantly, it allows one to model populations in complex landscapes, where different individuals may be exposed to very different levels of toxicant concentration (DeAngelis, 1994).

Models of individuals can be extended to a population as a whole by (1) simulating not just one individual but all individuals that make up the population of interest or (2) aggregating various population members into classes, such as age classes. *Aggregated models,* then, follow not individual organisms but variables representing the numbers of individuals per age class. In simulating a complex environmental system, both individual-based and aggregated models will be needed. Usually individual-based models are used to represent vertebrate species while aggregated models are used to represent organisms at lower classification levels.

Stochastic versus Deterministic Models Model coefficients can be functions not only of other variables but also of random variables; thus they can be random variables themselves. In this way of classifying models, those with random (stochastic) variables are called *stochastic models* and those without are called *deterministic models.* Random variables are used to represent the random variation or "unexplained" variation in the state variables. Stochastic models also can include random variables expressed either as random inputs or as parameters with a random error term.

In a stochastic model, random variables representing state variables, model parameters, or both will take on values according to some statistical distribution. In other words, there will be a probability associated with the value of the parameter or state variable.

Monte Carlo is a numerical technique of finding a solution to a stochastic model. For those random features of the model, values are chosen from a probability distribution. Repeated runs of the model then will result in different outcomes. A probability distribution can be calculated for a state variable in the model along with its mean and variance. Suppose the model has random variables for parameters $p_1, p_2, p_3, \ldots p_n$; the state variable will then be a function of the n parameters. A value for each parameter is calculated by sampling from its individual distribution function. A value for the state variable X then is obtained by running a simulation of the model. We repeat the process until we have N values of the state variable X. Finally we determine the mean (μ) and variance (s^2) for X.

Spatially Distributed versus Lumped Models Lumped models spatially integrate the entire area being modeled (Moore et al., 1993). Parameters for lumped models are averaged over the same spatial area. Spatially distributed models are based upon identifiable geographic units within the area being modeled. These subunits can represent physiographic areas, such as hydrologic or atmospheric basins, which can be identified using a geographic information systems (GIS). A GIS can be used to further identify homogeneous polygons or grid cells based upon soil and terrain features. Model parameters for each subunit can be geographically referenced and stored in the GIS database. The distributed model can then be used to simulate the response to a spatially distributed toxicant by replicating the model for each geographic subunit. Responses to toxicants are likely to be spatially nonlinear. Therefore, a lumped model using mean parameter values will not yield the expected value of the combined results of a distributed model. Modeling in ecotoxicology usually will involve individual-based, stochastic, spatially distributed models.

Modeling Exposure

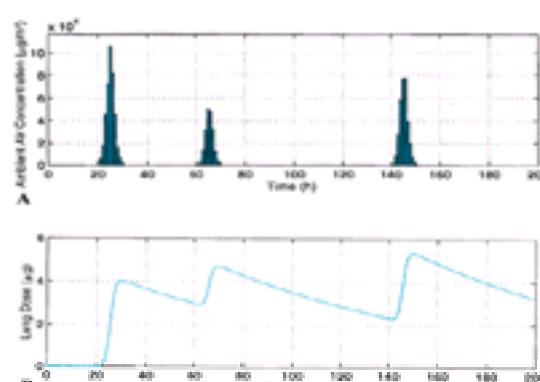
Exposure of organisms to toxicants requires contact between organisms and the toxicant of concern. Modeling exposure requires a model that will predict the spatial and temporal distributions of the toxicant and a model that will predict the organism's geographic position relative to the toxicant concentration. Transport and fate models are used to predict the spatial distribution of toxicants. Atmospheric transport models (for example, CALPUFF (U.S. EPA, 1995a) and ISC3 (U.S. EPA, 1995b) predict ground-level concentrations of toxicants from stack emissions. Dixon and Murphy (1979) used an atmospheric transport model to predict exposure concentrations as a series of "plume events" at any point on the ground (Fig. 29-2A). Exposure can occur from inhalation, immersion, ingestion, or a combination of these. Some vegetation models CERES (Dixon et al., 1978a,b, Luxmoore et al., 1978) and PLANTX (Trapp et al., 1994) can predict uptake of atmospheric and soil concentrations of toxicants. Surface hydrologic models HSPF (Donigian et al., 1983) and GLEAMS (Leonard et al., 1987) predict the runoff of toxicants from the land surface. Lake and stream models obtain input from surface runoff models and predict the change in toxicant concentration within the water body.


Figure 29-2. (A). Ambient air concentrations of toxicant predicted by discrete-event gaussian plume model over time. Each pulse represents the ground-level concentration at a given location. The shape of the pulse depends upon wind direction, wind speed, and atmospheric stability. (B). Lung dose of toxicant predicted from the lung model [Eq. (2)] with input from the plume model. The dose increases as plume passes over animal's location. The dose decreases as plume changes direction and concentration in lung decreases by diffusion to the bloodstream.

Most vertebrates are mobile enough to move from an area of high toxicant concentration to an area of low toxicant concentration (or vice versa). The actual exposure of an animal will depend upon the concentration levels at the geographic locations visited by the animal at the time of the visit. An integrated time- and space-averaged exposure E can be calculated using the model (Ott et al., 1986; Henriques and Dixon, 1996):

$$E_i = \sum_{j=1}^{J} c_j t_{ij} \tag{1}$$

where c_j = exposure concentration in microenvironment j
t_{ij} = time spent by animal i in microenvironment j
J = total number of microenvironments occupied by animal i

The prediction of real-time exposure requires linking transport models with behavioral models of animal movement (Sathe, 1997). Models of animal movement can be based upon matching spatial patterns of observed behavior (Siniff and Jessen, 1969), rules based upon mechanisms governing the response of an individual to its environment (Wolff, 1994), or theoretical constructs such as random-walk models (Holgate, 1971; Tyler and Rose, 1994).

Modeling Effects

The effect of a toxicant on an organism depends upon the dose (the concentration reaching the target organ) and the physiologic response to the dose. The dose depends upon the concentration of the chemical at the exposure site and the duration of the exposure. To predict the concentration reaching the target organ, we need to know how much of the chemical is taken up and absorbed by the organism. We also need to know where the chemical is distributed among the organism's tissues and organs, and the rate at which the chemical is excreted from the same tissues and organs.

The dynamics of the disposition of a toxicant in the body of an organism is the subject of toxicokinetics. The dynamics involve the concentration changes over time of a toxicant in various tissues and the rate processes that control the movement from one part of the organism to another. For example, the dynamics of a toxic gas or vapor in the lungs, dC/dt (μg/h), can be simulated with the model:

$$\frac{dC}{dt} = 10^{-6} Y \cdot V_T \cdot f - k \cdot C \tag{2}$$

where Y = exposure concentration (μg/m^3)
V_T = tidal volume (milliliters per breath)
f = breathing frequency (breaths per hour)
k = transfer rate from lungs to bloodstream (L/h).

A solution to Eq. (2), with the input from the discrete-event atmospheric exposure model, can be obtained by integrating over a defined time period and initial concentration (Fig. 29-2 B).

Linking Models to Geographic Information Systems

Geographic information systems (GISs) can be used to map the observed and predicted concentrations of toxic substances as well as the resulting effects of exposure to these concentrations. By linking models with GISs, the ability to explicitly model spatial dynamics of toxicant concentrations is greatly enhanced. There are different levels of integration of models with a GIS. First, a set of utility programs, external to both the model and the GIS, can be used to transfer data between the model and the GIS. Second, routines and macros can be written in the GIS language to run the models and analyze the results. And third, the GIS computer code can be modified to run the models and display the results of the simulations as part of the GIS procedures.

Mapping Exposure and Effects Results from simulation models with spatially referenced output can be mapped as static or dynamic data. Static data are spatially explicit but are expressed as a point (snapshot), an average, or a summed response over time. Dynamic data consider responses of state variables at points in space or a sum of the responses for an area and can be graphed as a function of time, or time series.

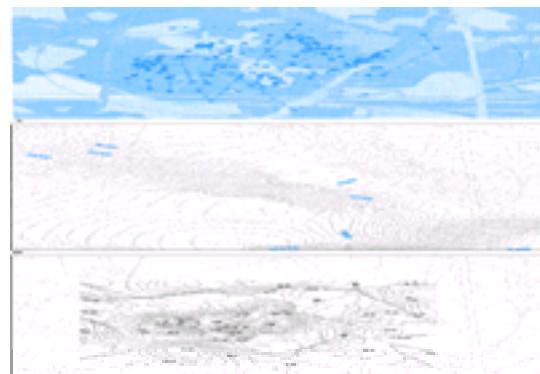
In our lung-model example, static exposure can be mapped using the spatial behavior model (Fig. 29-3 A) and the discrete-event gaussian plume model (Fig. 29-3 B). The resulting effect (lung dose) also can be mapped spatially (Fig. 29-3 C). The results from the discrete-event plume model and the lung model can be graphed as a time series (Fig. 29-2 A, Fig. 29-2 B). This response is a result of the animal moving in space and time and the different concentrations of toxicant to which it is exposed at those places and times. A population response can be predicted by repeating the procedure for all the individuals in the exposed population. A spatial map of the steady-state lung concentrations in the population (Fig. 29-4 A) shows a static response. The population response can also be expressed as a probability distribution (Fig. 29-4 B) to show the variability in the population that results from the different individual responses.


Figure 29-3. Example of an animal's movement predicted by a spatial behavior model (A). **Example of static ambient ground-level concentrations of a toxicant predicted by Gaussian plume model** (B).

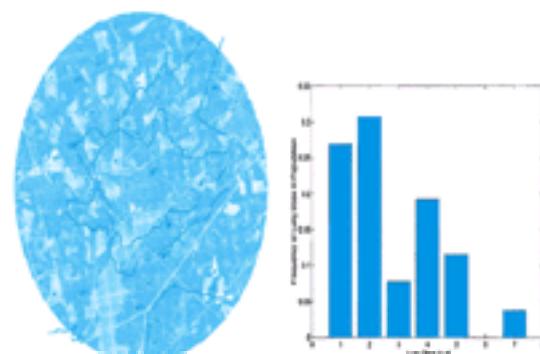
Isopleths show lines of equal concentration (units are in micrograms per cubic meter.) (From Henriques and Dixon, 1996.) Predicted dose to the lungs from exposure to ambient toxicant concentration as the animal moves according to the pattern in (A). Dose depends upon the exposure concentration (B) and the time the animal spends at each location in (A). Isopleths are lines of equal lung dose in units of μg (C). Predicted dose to the lungs from exposure to ambient toxicant concentration as the animal moves according to the pattern in (A) depends upon the exposure concentration (B) and the time the animal spends at each location in (A). Isopleths are lines of equal lung dose in units of micrograms.


Figure 29-4. (A). **Predicted static population lung dose for 26 individual animals. Dose is the maximum for that individual and mapped at the center of the**

animal's home range. Individual in Fig. 29-2A is found in the northwest quadrant. **(B).** *Frequency of occurrence of lung dose in population mapped in* **(A).**

Displaying both spatial and temporal responses simultaneously is more difficult, although recent developments in the area of computer visualization make this possible. Dynamic shifts in spatial maps of animal behavior (home range) and ambient concentrations can be illustrated in a "movie" sequence of maps. It is also possible to use visualization methods to show "real time" movement of an animal in space and simultaneously display the time-series graph of lung dose. These techniques can enhance our understanding of the effects of toxicants in the environment and provide for more realistic estimates of risk to those toxicants.

ECOLOGIC RISK ASSESSMENT

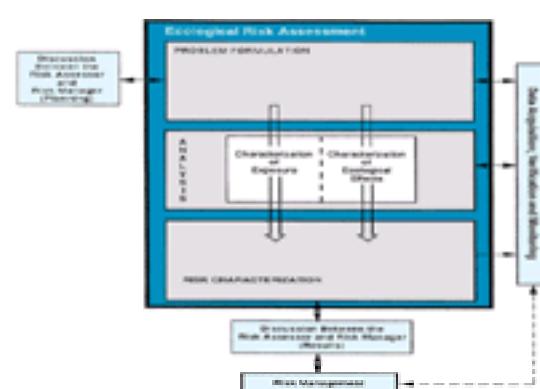
With the growth of environmental toxicology comes the need to appropriately assess and quantify the impact of toxic chemicals on organisms, their populations, and communities in ecosystems. Earlier techniques to conduct risk assessments utilizing human health approaches were not appropriate for ecologic systems. For this reason, the U.S. EPA issued a framework for conducting ecologic risk assessment (U.S. EPA, 1992a). This framework, which was expanded and modified in 1998 (U.S. EPA, 1998), allows for the assessment of the impact of toxic chemicals as well as other stressors on ecologic systems (Fig. 29-5). In the problem-formulation phase, the potential pathways and species that might be affected by the toxic substance are considered. As part of the problem-formulation phase, a conceptual model is usually developed describing routes of exposure, biota of concern, and anticipated effect endpoints. The actual risk of chemicals to wildlife or other biota is then determined using exposure data and toxic effects of the chemicals of interest (Table 29-2 demonstrates for agriculture chemicals). Toxicity data for species of concern at either the individual or population level are also incorporated (Kendall and Akerman, 1992). In the risk-characterization phase, exposure and effect data accumulated in the analysis phase are combined and the risk potential is characterized. Based on the resulting risk, risk-management steps can be taken, generally involving decreasing the exposure portion of the assessment, in order to decrease the overall risk.


Figure 29-5. Generalized framework for ecologic risk assessment. (From U.S. EPA, 1998.)

Table 29-2 Ecotoxicological Assessment Criteria for Pesticides

One example involving the assessment of the ecologic risk to wildlife of exposure to the insecticide carbofuran (a carbamate) has been published by the U.S. EPA (Houseknecht, 1993). Ecologic risk assessment revealed widespread and repeated mortality events, particularly in locations where birds ingested carbofuran granules in agricultural ecosystems. According to legislation promulgated by FIFRA and extended to the international sphere by the Migratory Bird Treaty Act, environmental regulations do not permit the killing of migratory songbirds or waterfowl with a pesticide. Under FIFRA, through a special review, the U.S. EPA took regulatory action against a carbamate, carbofuran (2,3-Dihydro-2,2-dimethyl-7-benzofuranol methylcarbamate), used in a large number of agroecosystems in which such use was associated with wildlife mortality.

Under the U.S. EPA's risk-assessment paradigm, risk characterization offers the opportunity to put the ecologic risk in perspective and to identify uncertainty in the development of the risk assessment. Although carbofuran could not be proven to cause significant adverse effects on bird populations, widespread and repeated mortality was evident and regulatory action was taken (Houseknecht, 1993; U.S. EPA, 1989). Evidence of carbofuran killing bald eagles (*Haliaeetus leucocephalus*) added to the overall concern for this chemical. Under the auspices of the Endangered Species Act, endangered species in the United States required special consideration because of their limited numbers and possible susceptibility to extinction.

The quotient method of assessing risk is often utilized in ecologic risk assessment (Bascietto et al., 1990). The quotient method employs the formula of the expected environmental concentration divided by the toxic impact of concern (e.g., LC_{50} or EC_{50}). If the quotient exceeds 1, then a significant risk may be indicated. Indeed, granular carbofuran products utilized in a broad range of agricultural uses resulted in quotients exceeding 1, and, as mentioned earlier, wildlife mortality was identified (Houseknecht, 1993).

Probabilistic Risk Assessment

Ecologic risk assessment continues to evolve as a science (Suter, 1993). Probabilistic risk assessments are used to further refine risk assessments so that they reflect actual risk in the environment. Probabilistic risk assessments have been used for several years in other disciplines such as predicting accidents, systems failure, and weather forecasting, but they have been used in ecologic risk assessments only recently. Probabilistic risk assessments can range from the use of probability distributions in place of point estimates in the Quotient Method to overlapping distributions of exposure and toxicity to stochastic simulation models.

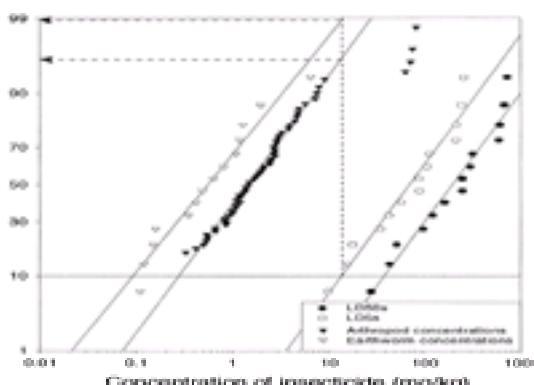
Overlapping Distributions Overlapping probability distributions have been described in detail (Cardwell et al., 1993; SETAC, 1994; Parkhurst et al., 1995) and have been used in a number of ecologic risk assessments (Solomon et al., 1996; Giesy et al., 1999). In this approach, cumulative frequencies of environmental exposure concentrations (EECs, generally in milligrams per kilogram on food items) and toxicity values (LC_{50}, LC_{10}, or LC_5 transformed to a value of milligrams per kilogram per day) are plotted on the same graph. Frequencies are plotted on the *Y* axis using a probability scale and the concentrations plotted on the *X* axis using a logarithmic scale (Fig. 29-6). Toxicity values are ranked in ascending order and then transformed to cumulative percentages using the transformation:


Figure 29-6. Graph showing distributions of insecticide toxicity to birds (expressed as concentration in food items) compared to actual concentrations reported in collected food items.

Comparing the distributions, the 10th centile of avian toxicity (LD$_5$ values) would be exceeded 1 percent of the time for earthworm consumption and 5 percent of the time for other invertebrates.

$$\frac{100 \times i}{n + 1}$$

where i = ith observation of a total of n observations, starting with the lowest toxicity value. The resulting plots show an approximate linear relationship between frequency and the exposure and toxicity data, and linear regression can be used to fit straight lines to the data. The area of overlap between the two lines (if any) then can indicate the level of risk to the organisms exposed to the EECs. In the example shown in Fig. 29-6, exposure concentrations are the residues from the insecticide chlorpyrifos found on arthropods and earthworms. These data were ranked in the same way as the toxicity data. In this example, there is very little overlap of the two distributions. Using the 10th centile as an exceedance level, the LD$_5$s would exceed this level about 1 percent of the time for consumption of arthropods and about 5 percent of the time for consumption of earthworms (ECOFRAM, 1999).

Stochastic Simulation In probabilistic risk assessments using simulation, probability distributions are measured (or estimated) for parameters to account for natural variation, lack of knowledge, or uncertainty. The actual parameter values used in a simulation are obtained by sampling their distributions in a Monte Carlo process. The resulting model output will contain endpoint values, one value for each set of parameter values in a given simulation (see "Modeling and Geographic Information Systems," above). Several simulations will yield a probability distribution of endpoint values, such as mortality percentage in the simulated population. By altering the mean value of the model parameters and running additional sets of simulations, the percentage of outcomes that exceed a certain level of mortality can be estimated (Fig. 29-7). This curve can be compared with a graph of the "threshold of acceptability" defined by the risk manager to determine whether there is the potential for unacceptable risk.

Figure 29-7. Illustration of risk manager's threshold of acceptability (shaded line) and predicted risk from a simulation model (data points).

A comparison of the two curves shows an area where the predicted risk exceeds the acceptability threshold, indicating a potentially unacceptable risk. (Adapted from ECOFRAM, 1999.)

Examples of probabilistic ecologic risk assessments include the effects of the herbicide atrazine [6-chloro- N-ethyl-N-(1-methylethyl)-1,3,5-triazine-2,4-diamine] on aquatic ecosystems in the midwestern U.S. corn belt (Solomon et al., 1996) and the insecticide chlorpyrifos [O,O-diethyl O-(3,5,6-trichloro-2-pyridinyl) ester] on aquatic ecosystems (Giesy et al., 1999), also in the midwestern United States.

The key to understanding ecologic risk assessment in ecotoxicology is considering more than just chemical toxicity. We must consider ecologic risk assessment in the context of exposure and other issues such as sublethal effects or ecosystem impacts. Indeed, we now know that predator-prey relationships can be affected by chemical exposure in prey (Galindo et al., 1985). In addition, "biomarkers" offer new technologies to assess sublethal impacts of chemicals on fish and wildlife populations (Dickerson et al., 1994).

The availability of data from laboratory and field ecotoxicologic experiments generated under GLPs, as discussed above, will improve the quality and ultimate value of ecologic risk assessments. In probabilistic risk assessments, the amount of data required increases substantially as the point estimates for toxicity and exposure are replaced by distributions and model parameters with error terms. Good Laboratory Practices data may offer new opportunities to integrate validated information into ecologic effect or exposure models for use in risk assessment (Kendall and Lacher, 1994). The contribution of ecologic models in the ecologic risk assessment process is in its infancy and offers significant opportunities for the extrapolation of data from laboratory and field experiments to a broader range of applications for the protection of the environment and its fish, wildlife, and other biotic resources.

ENVIRONMENTAL TOXICOLOGY AND HUMAN HEALTH

Links between wildlife and human health serve as a premise for extrapolation in risk assessment. Humans share many cellular and subcellular mechanisms with wildlife species. Humans and wildlife also overlap in their physical environment and therefore are exposed to many of the same contaminants. There is evidence to suggest that when highly conserved systems are targeted by environmental toxicants, both ecosystem and human health suffer.

There are obvious challenges and concerns in the extrapolation of wildlife data to humans. When there are contaminant-specific alterations in wildlife health, concerns about coordinate adverse effects in humans tend to focus on susceptible developmental periods, including in utero, neonatal, pubertal, lactational, and menopausal stages (Colburn et al., 1993). There is also a real concern about an increased risk of various cancers caused by environmental contaminants (Kavlock et al., 1996) and populations with genetic or environmental susceptibility (Frame et al., 1998). The overall rate of some cancers is increasing, particularly in industrialized countries. Based on animal models, chemical exposure figures in the etiology of many cancers; therefore a link to human cancer incidence seems plausible. Unfortunately, linking known contaminant exposures to an affected human population is difficult, particularly when effects are not identified for many years. By the time human effects are identified, the causative agent may not be present or detectable.

As with wildlife, some human health effects may be reversible while others may involve irreversible changes. In some instances, this may be a matter of dose. A high dose may lead to irreversible direct effects, such as malformations. However, low doses may manifest as subtle or latent functional changes in susceptibility that are not apparent until after the exposure has passed and the individual is "challenged." Particularly because of the longevity of humans, even low-dose exposures may

result in a human health risk, predisposing elderly individuals to chronic disease processes. Wildlife may not be affected in the same ways because of their generally shorter life span.

Regardless of species, the process of risk assessment requires four steps: hazard identification, dose-response assessment, exposure assessment, and risk characterization. Often, these processes are difficult in human populations and extrapolations are required, including qualitative interspecies extrapolation from test animal to human and quantitative extrapolation from high to low dose. Uncertainties in these two extrapolations have sometimes resulted in a low confidence in risk estimates for humans. When human data are of low quality or not available, wildlife sentinels can serve a useful role in assessing human risk. For the future, however, much more information is needed to develop the human database regarding exposure, susceptibility, metabolism and disposition, site and mechanisms, tissue repair processes, compensatory responses, and adaptive mechanisms. Obviously, the more human data available for risk assessment, the better, and the more generalized and relevant to real human health effects, the easier it is to define a risk-management strategy (Smith and Wright, 1996).

Thus far, the best wildlife-to-human extrapolations have relied on strong, consistent human data available from high-dose accidental exposures for comparison with wildlife effects from monitoring studies; the Yusho and Yu-Cheng PCB incidents (Masuda et al., 1979; Kuratsune et al., 1976; Hsu, 1985); the TCDD accident in Seveso, Italy (Mocarelli et al., 1991); and human exposure to diethylstilbestrol (DES). The dose-response data collected, the large numbers of affected individuals, and an understanding of biological mechanisms in each of these cases make the comparisons possible. For most low-dose exposures, the ability to show causation is still poor. Future research relating the environmental health problems of wildlife and humans should recognize the scope of environmental disease processes and species-specific endpoints that reflect the divergence as well as the conservation of systems.

The interconnections between ecologic health and human health should not be overlooked. The indirect effects of environmental pollution may, in the end, be more important than the direct effects for human health. The environment is thought to act as a buffer for both toxicants and disease. However, even a buffer has its limits. For instance, the human population is at greater risk for emerging diseases as the natural environment dwindles in relative area. In the future, it is important that researchers focus on closing the artificial gap that views "environmental" or "human" health issues separately.

FOOD TOXICOLOGY

Frank N. Kotsonis, George A. Burdock, and W. Gary Flamm

INTRODUCTION TO FOOD TOXICOLOGY

This chapter describes the general principles of food toxicology and explains how those principles have been shaped by existing food laws and applied to the safety assessment of foods, food ingredients, and food contaminants. Food toxicology is different from other subspecialties in toxicology largely because of the nature and chemical complexity of food. The necessity for practical and workable approaches to the assessment of food safety is addressed throughout the chapter.

The typical western diet contains hundreds of thousands of substances naturally present in food and many more which form in situ when food is cooked or prepared. Many of these substances affect the nutritional and esthetic qualities of food, including appearance and organoleptic properties (i.e., conferring flavor, texture, or aroma) that determine whether or not we will even try the food or take a second bite, respectively. While these or other substances present in food may be nutritional and/or gratifying, they may not necessarily be "safe" in *any* amount or for *any* intended use. The Federal Food, Drug and Cosmetic (FD&C) Act gives the federal government the authority to ensure that all food involved in interstate commerce is safe. Congress, in writing the FD&C Act (and its subsequent amendments), understood that safety cannot be proved absolutely and indicated instead that the safety standard for substances added to food can be no more than a reasonable certainty that no harm will occur. As pointed out in other sections of this chapter, the language of the FD&C Act effectively provides for practical and workable approaches to the assessment of safety for food, food ingredients, and food contaminants. Because food is highly complex, the legal framework provided by Congress for the regulation of food and substances in food was kept simple so that it would work. The basic element of the framework is that food, which is defined as articles or components of articles used for food or drink for humans or animals, bears the presumption of safety [sections 201(f) and 402(a)(1) of the FD&C Act]. This means that a steak or a potato is presumed to be safe unless it contains a poisonous or deleterious substance in an amount shown to make it *ordinarily injurious* to health. In essence, this presumption of safety was born of necessity. If the hundreds of thousands of substances naturally present in food were subject to the same strictures and limitations that apply to added substances, food shortages could easily result. To avoid such crises, Congress developed a safety standard that would not force regulatory authorities to ban common, traditional foods.

In cases where the substance is not naturally present in food but is a contaminant or added ingredient, the safety standard is quite different. This standard decrees a food to be adulterated if it contains any poisonous or deleterious substance that *may render it injurious.* Therefore, the presence of a substance that is not a *natural* component of a food demands a far higher standard of safety. The mere possibility that such a substance *may* render the food injurious to health is sufficient to ban the food containing that substance. Thus, for additives and contaminants, Congress recognized that these substances are not as complex as food and must, therefore, meet a higher standard of safety.

An understanding of the term *safe* is necessary in deciding how many and what types of studies must be conducted to determine that an added substance is safe. Wisely, the act does not give explicit instructions about how safety should be determined and does not explicitly define safety. Because neither the law nor the U.S. Food and Drug Administration (FDA) or the U.S. Department of Agriculture (USDA) regulations explicitly define the term *safety* for substances added to food, scientists and their legal and regulatory counterparts have worked out operational definitions for the safety of food ingredients. The one principle on which there has been nearly unanimous agreement is that safety concerns in regard to an added substance should focus on both the nature of the substance *and* its intended conditions of use. It is recognized that substances are not inherently unsafe, it is only the quantity at which they are presented that makes them unsafe. The quantity (or "level") present in the diet is determined by the intended conditions of use and limitations of use of the substance.

As with food, practical and workable solutions must be found for the constituents of additives, because all substances contain a myriad of impurities at trace and even undetectable levels. Decisions concerning the safety of impurities and the development of appropriate specifications for food and color additives to assure that they are of suitable purity must similarly constitute a workable approach. In this case, the workable approach involves setting specification limits on contaminants—limits that are intended to exclude the possibility that the level of contaminants present in an additive *may* render the food to which the substance is added unsafe. As a practical matter and because of time and cost considerations, established specifications must be relatively simple and straightforward and must provide reasonable assurance that an ingredient is of suitable purity for its intended conditions of use. However, it generally is not necessary or practical to require extensive analysis and identification of all individual impurities to establish the fact that a substance is of "food-grade purity." It should be emphasized that specifications can serve their purpose of assuring suitable purity only if the manufacturing processes used are adequately controlled to assure consistency in the quality and purity of the product. It should be understood that the philosophy by which specifications are established for substances added to food embodies the belief that not all risks are worthy of regulatory concern and control. Implicit in this philosophy is the concept of *threshold of regulation,* which is an important unifying concept in food safety assessment (Flamm et al., 1994).

To understand the meaning in the FD&C Act of the phrase "safe for intended conditions of use" as applied to a substance added to food, it is important to recognize that such a determination must rest on a general understanding of the risks posed by food itself. The requirement that substances added to food be safe (to a reasonable degree of certainty) demands consideration of the far higher theoretical risk posed by food itself. Food, as stated earlier, contains hundreds of thousands of substances, most of which have not been fully characterized or tested. The presumption that a food is safe is based on a history of common use and on the fact that the consumption of certain foods is deeply rooted in tradition (e.g., "ethnic" foods or those foods traditionally consumed for a holiday celebration). When the uncertainty about the risk of the added substance is small compared with the uncertainties attending food itself, the standard of "reasonable certainty of no harm" for the added substance has been satisfied. Thus, for food-like substances, the presumption is that the substance resembles food, is digested and metabolized as food, and consequently raises fewer toxicologic and safety-related questions than do substances that are not food-like. And such substances are added either directly or indirectly (substances that may migrate into food from packaging or other food contact surfaces) to foods in only very small or trace amounts, the low levels of exposure aid in demonstrating that the intended conditions of use of these substances are safe. These broad generalizations, however, do not suffice to exempt these

food ingredients from the requirements of thorough safety testing. The FDA requires that such testing be done but it is tempered by considerations of (1) the basic nature of the substance, (2) the level to which consumers will be exposed as the result of the intended use, and (3) the inherent safety of food and constituents of food.

Over the past several years, there has been increasing interest on the part of consumers in the health-enhancing properties of foods and the components they contain. Substances such as phytosterols from vegetable oils and isoflavones from soy have been isolated and added to other foods at elevated levels to impart cholesterol-lowering abilities. Such products have raised regulatory questions about whether these substances are functioning as drugs and should be regulated as such or whether they should be viewed as new nutrients and allowed in foods, as are vitamin C and iron. At a recent conference, experts in nutritional science concluded that the concept of nutrients should be expanded to include a growing number of desirable food constituents that produce quantifiable health benefits related to disease prevention (Sansalone, 1999). This isolation of new food components and their use in fortifying food products will necessitate a thorough evaluation of safety at the intended level of intake and for the population at large.

Finally, it should be recognized that in most of the world, microbiologic contamination of food represents by far the greatest food-borne risk facing consumers. Thus, while vigilance in assuring the safety of substances added to food under their intended conditions of use is appropriate, we should not lose sight of the major concern of food safety.

Uniqueness of Food Toxicology

The nature of food is responsible for the uniqueness of food toxicology. Food is not only essential to all life but also a major contributor to the quality of life. Food and drink are enjoyed for their appearance, aroma, flavor, and texture. They are significant factors in defining cultures and societies. For example, ethnic foods and gourmet foods have a status that far exceeds their nutritional benefits, but any proposal to ban an ethnic food because new data have raised questions about its safety would be met with strong resistance.

As food occupies a position of central importance in virtually all cultures and because most food cannot be commercially produced in a definable environment under strict quality controls, food generally cannot meet the rigorous standards of chemical identity, purity, and good manufacturing practice met by most consumer products. The fact that food is harvested from the soil, the sea, or inland waters or is derived from land animals, which are subject to the unpredictable forces of nature, makes the constancy of raw food unreliable. Food in general is more complex and variable in composition than are all the other substances to which humans are exposed. However, there is nothing to which humans have greater exposure despite the uncertainty about its chemical identity, consistency, and purity. Experience has supported the safety of commonly consumed foods, and the good agricultural practices under which food is produced mandate the need for quality controls. Nevertheless, it is clear that food is held to a different standard as a practical matter dictated by necessity.

Food also acquires uniqueness from its essential nutrients, which, like vitamin A, may be toxic at levels only 10-fold above those required to prevent deficiencies. The evaluation of food ingredient substances often must rely on reasoning unique to food science in the sense that such substances may be normal constituents of food or modified constituents of food as opposed to the types of substances ordinarily addressed in the fields of occupational, environmental, and medical toxicology. Assessment of the safety of such substances, which are added to food for their technical effects, often focuses on digestion and metabolism occurring in the gastrointestinal (GI) tract. The reason for this focus is that in many cases an ingested substance is not absorbed through the GI tract; only products of its digestion are absorbed, and these products may be identical to those derived from natural food.

Nature and Complexity of Food

Food is an exceedingly complex mixture of nutrient and nonnutrient substances, whether it is consumed in the "natural" (unprocessed) form or as a highly processed ready-to-eat microwaveable meal (Table 30-1). Among the "nutrient" substances, the western diet consists of items of caloric and noncaloric value; that is, carbohydrates supply 47 percent of caloric intake, fats supply 37 percent, and protein supplies 16 percent (all three of which would be considered "macronutrients") (Technical Assessment Systems, Inc., 1992), whereas minerals and vitamins, the "micronutrients," obviously have no caloric value but are no less essential for life.

NUTRIENTS	NONNUTRIENTS
Carbohydrates	Naturally occurring substances
Proteins	Food additives
Lipids	Contaminants
Minerals	Products of food processing
Vitamins	

source: Smith 1991, with permission.

Table 30-1 Food as a Complex Mixture

Nonnutrient substances are often characterized in the popular literature as being contributed by food processing, but nature provides the vast majority of nonnutrient constituents. For instance, in Table 30-2 one can see that even among "natural" (or minimally processed) foods, there are far more nonnutrient than nutrient constituents. Many of these nonnutrient substances are vital for the growth and survival of the plant, including hormones and naturally occurring pesticides (estimated at approximately 10,000 by Gold et al., 1992). Some of these substances may be antinutrient [e.g., goiterogens in *Brassica,* trypsin and/or chymotrypsin inhibitors in soybeans, phytates that may bind minerals (present in soybeans), and antihistamines in fish and plants] or even toxic (e.g., tomatine, cycasin) to humans. An idea of the large number of substances present in food is given in the series edited by Maarse and associates (1993), in which approximately 5500 volatile substances are noted as occurring in one or more of 246 different foods. However, this is only the tip of the iceberg, as the number of unidentified natural chemicals in food vastly exceed the number that have been identified (Miller, 1991).

FOOD	NUMBER OF IDENTIFIED NONNUTRIENT CHEMICALS
Cheddar cheese	160
Orange juice	250
Banana	325
Tomato	350
Wine	475
Coffee	625
Beef (cooked)	625

source: Smith, 1991, with permission.

Table 30-2 Nonnutrient Substances in Food

Nonnutrient substances are also added as a result of processing, and in fact, 21 CFR 170.3(o) lists 32 categories of direct additives, of which there are about 3000 individual substances. Approximately 1800 of the 3000 are flavor ingredients, most of which already occur naturally in food and are nonnutritive. Of the 1800 flavoring ingredients that may be added to food, approximately one-third are used at concentrations below 10 ppm (Hall and Oser, 1968), about the same concentration as is

found naturally.

Importance of the Gastrointestinal Tract

It is essential to appreciate the fact that the gut is a large, complex, and dynamic organ with several layers of organization and a vast absorptive surface that has been estimated to be from 200 to 4500 m^2 (Concon, 1988). The GI transit time provides for adequate exposure of ingesta to a variety of environmental conditions (i.e., variable pH), digestive acids and enzymes (trypsin, chymotrypsin, etc., from the pancreas and carbohydrases, lipases, and proteases from the enterocytes), saponification agents (in bile), and a luxuriant bacterial flora providing a repertoire of metabolic capability not shared by the host (e.g., fermentation of "nondigestible" sugars such as xylitol and sorbitol) (Drasar and Hill, 1974). The enterocytes (intestinal epithelium) possess an extensive capacity for the metabolism of xenobiotics that may be second only to that of the liver, with a full complement of phase (type) I and phase (type) II reactions present. The enteric monooxygenase system is analogous to the liver, as both systems are located in the endoplasmic reticulum of cells, require reduced nicotinamide adenine dinucleotide phosphate (NADPH) and O_2 for maximum activity, are inhibited by SKF-525A and carbon monoxide, and are qualitatively similar in their response to enzyme induction (Hassing et al., 1989). Induction of xenobiotic metabolism by the enteric monooxygenase system has been demonstrated in a number of substances, including commonly eaten foods and their constituents (Table 30-3). Dietary factors may also decrease metabolic activity. For example, in one study, iron restriction and selenium deficiency decreased cytochrome P450 values, but a vitamin A rich diet had the same effect (Kaminsky and Fasco, 1991).

Table 30-3 Induction of Xenobiotic Metabolism in the Rat Intestine

The constituents of food and other ingesta (e.g., drugs, contaminants, inhaled pollutants dissolved in saliva and swallowed) are physicochemically heterogeneous, and because the intestine has evolved into a relatively impermeable membrane, mechanisms of absorption have developed that allow substances to gain access to the body from the intestinal lumen. The four primary mechanisms for absorption are passive or simple diffusion, active transport, facilitated diffusion, and pinocytosis. Each of these mechanisms characteristically transfers a defined group of constituents from the lumen into the body (Table 30-4). As noted in the table, xeno-biotics and other substances may compete for passage into the body.

Table 30-4 Systems Transporting Enteric Constituents

Aiding this absorption is the rich vascularization of the intestine, with a normal rate of blood flow in the portal vein of approximately 1.2 L/h/kg. However, after a meal, there is a 30 percent increase in blood flow through the splanchnic area (Concon, 1988). It follows, then, that substances which affect blood flow also tend to affect the absorption of compounds; an example is alcohol, which tends to increase blood flow to the stomach and thus enhances its own absorption. Few stimuli tend to decrease flow to this area, with the possible exception of energetic muscular activity and hypovolemic shock.

Lymph circulation is important in the transfer of fats, large molecules (such as botulinum toxin), benzo[*a*]pyrene, 3-methylcholanthrene, and *cis*-dimethylaminostilbene (Chhabra and Eastin, 1984). Lymph has a flow rate of about 1 to 2 mL/h/kg in humans, and few factors—with the exception of tripalmitin, which has been shown to double the flow and therefore double the absorption of *p*-aminosalicylic acid and tetracycline—are known to influence its flow (Chhabra and Eastin, 1984). Another factor that lends importance to lymph is the fact that the lymph empties via the thoracic duct into the point of junction of the left internal jugular and subclavian veins, preventing "first-pass" metabolism by the liver, unlike substances transported by the blood.

Many food ingredients are modified proteins, carbohydrates, fats, or components of such substances. Thus, an understanding of the changes these substances undergo in the GI tract, their possible effect on the GI tract, and whether they are absorbed or affect the absorption of other substances is critical to an understanding of food toxicology and safety assessment. Some of the factors that may affect GI absorption and the rate of absorption are listed in Table 30-5.

Table 30-5 Factors Affecting Intestinal Absorption and Rate of Absorption

SAFETY STANDARDS FOR FOODS, FOOD INGREDIENTS, AND CONTAMINANTS

The Food, Drug and Cosmetics Act Provides for a Practicable Approach

The FD&C Act presumes that traditionally consumed foods are safe if they are free of contaminants. For the FDA to ban such foods, it must have clear evidence that death or illness can be traced to consumption of a particular food. The fact that foods contain many natural substances, some of which are toxic at a high concentration, is in itself an insufficient basis under the act for declaring a food as being unfit for human consumption. Examples of this concept include acceptance of generally recognized as safe status and the implementation of tolerances.

The Application of Experience: Generally Recognized as Safe (GRAS) The FD&C Act permits the addition of substances to food to accomplish a specific technical effect if the substance is determined to be GRAS by experts qualified by scientific training and experience to evaluate food safety. The FD&C Act does not require this determination be made by the FDA, though it does not exclude the agency from making such decisions. The act instead requires that scientific experts base a GRAS determination on the adequacy of safety, as shown through scientific procedures or through experience based on common use in food before January 1, 1958, under the intended conditions of use of the substance [FD&C Act, section 201(s)].

In addition to allowing GRAS substances to be added to food, the act provides for a class of substances that are regulated food additives, which are defined as "any substances the intended use of which results in its becoming a component . . . of any food . . . if such substance is not generally recognized . . . to be safe." Hence, a legal distinction is drawn between regulated food additives and GRAS substances. Regulated food additives must be approved and regulated for their intended conditions of use by the FDA under 21 CFR 172–179 before they can be marketed. In section 409 of the act, the requirements for data to support the safe use of a food additive are described in general terms. The requirements or recommended methods for establishing safe conditions of use for an additive are available in the form of a guideline issued by FDA (*Toxicological Principles for the Safety Assessment of Direct Food Additives and Color Additives Used in Food*). These guidelines, referred to as "the Redbook," provide substance and definition to the safety standard applicable to regulated food additives: "reasonable certainty of no harm under conditions of intended use."

Use of Tolerances If a food contains an unavoidable contaminant even with the use of current good manufacturing practices (CGMP), it may be declared unfit as food if the contaminant may render the food injurious to health. Thus, for a food itself to be declared unfit, it must be ordinarily injurious, while an unavoidable contaminant in food need only pose the risk of harm for the food to be found unfit and subject to FDA action. The reason for the dichotomy is practicability. Congress recognized that if authority were granted to ban traditional foods for reasons that go beyond clear evidence of harm to health, the agency would be subject to pressure to ban certain foods.

Foods containing *unavoidable* contaminants are not automatically banned because such foods are subject to the provisions of section 406 of the FD&C Act, which indicates that the quantity of unavoidable contaminants in food may be limited by regulation for the protection of public health and that any quantity of a contaminant exceeding the fixed limit shall be deemed unsafe. This authority has been used by the FDA to set limits on the quantity of unavoidable contaminants in food by regulation (tolerances) or by informal action levels that do not have the force of law. Such action levels have been set for aflatoxin in peanuts, grain, and milk (Table 30-6). Action levels have the advantage of offering greater flexibility than is provided by tolerances established by regulation. Whether tolerances or action levels are applied to unavoidable contaminants of food, the FDA attempts to balance the health risk posed by unavoidable contaminants against the loss of a portion of the food supply. In contrast, contaminants in food that are *avoidable* by CGMP are deemed to be unsafe under section 406 if they are considered poisonous or deleterious. Under such circumstances, the food is typically declared *adulterated* and unfit for human consumption. The extent to which consumers who are already in possession of such food must be alerted depends on the health risk posed by the contaminated food. If there is a reasonable probability that the use of or exposure to such a food will cause serious adverse health consequences or death, the FDA will seek a class I recall which provides the maximum public warning, the greatest depth of recall, and the most follow-up. Classes II and III represent progressively less health risk and require less public warning, less depth of recall, and less follow-up (21 CFR 7.3).

COMMODITY	LEVEL, ng/g
All products, except milk, designated for humans	20
Milk	0.5
Corn for immature animals and dairy cattle	20
Corn for breeding beef cattle, swine, and mature poultry	100
Corn for finishing swine	200
Corn for finishing beef cattle	300
Cottonseed meal (as a feed ingredient)	300
All feedstuffs other than corn	20

Table 30-6 FDA Action Levels for Aflatoxins (Compliance Policy Guides 7120.26, 7106.10, and 7126.33)

Food and Color Additives

An intentionally added ingredient, not considered GRAS, is either a direct food additive or color additive. As with all ingredients intentionally added to food, there must be a specific and justifiable functionality. While a color additive has only one function, a food additive may have any one of 32 functionalities (Table 30-7).

Table 30-7 Direct Food Additives by Functionality

The term *color additive* refers to a dye, pigment, or other substance made by a process of synthesis or extracted and isolated from a vegetable, animal, or mineral source [FD&C Act 201(t)]. Blacks, whites, and intermediate grays are also included in this definition. When such additives are added or applied to a food, drug, or cosmetic or to the human body, they are capable of imparting color. Color additives are not eligible for GRAS status.

Two distinct types of color additives have been approved for food use: those requiring certification by FDA chemists and those exempt from certification. Certification, which is based on chemical analysis, is required for each batch of most organic synthesized colors because they may contain impurities that may vary from batch to batch. Most certified colors approved for food use bear the prefix FD&C. They include FD&C Blue No. 1, FD&C Blue No. 2, FD&C Green No. 3, FD&C Red No. 3, FD&C Red No. 40, FD&C Yellow No. 5, and FD&C Yellow No. 6. Orange B and Citrus Red No. 2 are the only certified food colors that lack the FD&C designation (21 CFR 74 Subpart A).

The basis for the certification of these color additives is the finding that each batch is of suitable purity and can be safely used as prescribed by regulation (FD&C Act, section 721). Certification involves in-depth chemical analysis of major and trace components of each individual batch of color additives by FDA chemists and is required before any batch can be released for commercial use. Such color additives consist of aromatic amines or aromatic azo structures (FD&C Blue No. 1, FD&C Blue No. 2, FD&C Green No. 3, FD&C Red No. 40, FD&C Yellow No. 5, and FD&C Yel-low No. 6) that cannot be synthesized without a variety of impurities.

Although aromatic amines are generally considered relatively toxic substances, the FD&C colors are notably nontoxic. Table 30-8, which is adopted from a publication of the National Academy of Sciences (NAS) (Committee on Food Protection, 1971), shows that certified food colors have a low order of acute toxicity. The principal reason involves sulfonation of the aromatic amine or azo compound that constitutes a color additive. Such sulfonic acid groups are highly polar, which, combined with their high molecular weight, prevents them from being absorbed by the GI tract or entering cells. All the FD&C food colors have been extensively tested in all Concern Level (CL) tests (Table 30-9) and have been found to be remarkably nontoxic.

COLOR	NO ADVERSE EFFECT DIETARY LEVELS IN ANIMAL STUDIES	SAFE LEVEL FOR HUMANS mg/day	ESTIMATED MAXIMUM INGESTION mg/day PER PERSON
FD&C Blue No.1	5.0% rats 2.0% dogs	363	1.23
FD&C Blue No.2	1.0% rats, dogs	181	0.29
FD&C Green No.3	5.0% rats 1.0% dogs 5.0% mice	181	0.87
Orange B	5.0% rats 1.0% dogs 5.0% mice	181	0.11
Citrus Red No.2	0.1% rats	18	Not applicable
FD&C Red No.3	0.5% rats 2.0% dogs 2.0% mice	45	1.88
FD&C Yellow No.5	5.0% rats 2.0% dogs	363	36.3
FD&C Yellow No.6	2.0% rats 2.0% dogs 2.0% mice	363	15.5

Table 30-8 Data on Certified Food Colors Permanently Listed in the United States

CONCERN LEVEL	TESTS REQUIRED
I	Short-term feeding study (at least 28 days in duration)
	Short-term tests for carcinogenic potential that can be used for determining priority for conduct of lifetime carcinogenicity bioassays and are used in the evaluation of results from such bioassays, if conducted
II	Subchronic feeding study (at least 90 days in duration) in a rodent species
	Subchronic feeding study (at least 90 days in duration) in a nonrodent species
	Multigeneration reproduction study (minimum of two generations with a teratology phase) in a rodent species
	Short-term tests for carcinogenic potential
III	Carcinogenicity studies in two rodent species
	A chronic feeding study (at least 1 year in duration in a rodent species; may be combined with a carcinogenicity study)
	Long-term (at least 1 year in duration) feeding study in a nonrodent species
	Multigenerational reproduction study (minimum of two generations) with a teratology phase in a rodent species
	Short-term tests for carcinogenic potential

Table 30-9 Tests for Each Concern Level

Food colors that are exempt from certification typically have not been subjected to such extensive testing requirements. The exempt food colors are derived primarily from natural sources. While synthetic food colors have received the majority of public, scientific, and regulatory attention, natural color agents are also an important class. Currently, 25 color additives have been given exemption from certification in 21 CFR 73. These agents consist of a variety of natural compounds generally obtained by various extraction and treatment technologies. Included in this group of colors are preparations such as dried algae meal, beet powder, grape skin extract, fruit juice, paprika, caramel, carrot oil, cochineal extract, ferrous gluconate, and iron oxide. A problem encountered in attempts to regulate these additives is the lack of a precise chemical definition of many of these preparations. With a few exceptions, such as caramel, which is the most widely used color, the natural colors have not been heavily used. In part, this may be due to economic reasons, but these colors generally do not have the uniformity and intensity characteristic of the synthetic colors, therefore necessitating higher concentrations to obtain a specific color intensity. They also lack the chemical and color stability of the synthetic colors and have a tendency to fade with time.

Intake of color additives varies among individuals. The maximal intake of food colors is estimated to be approximately 53.5 mg/day, whereas the average intake per day is approximately 15 mg (Committee on Food Protection, 1971). Only about 10 percent of the food consumed in the United States contains food colors. The foods that utilize food colors in order of the quantity of color utilized are (1) beverages, (2) candy and confections, (3) dessert powders, (4) bakery goods, (5) sausages (casing only), (6) cereals, (7) ice cream, (8) snack foods, and (9) gravies, jams, jellies, and so forth (Committee on Food Protection, 1971).

Methods Used to Evaluate the Safety of Foods, Ingredients, and Contaminants

Safety Evaluation of Direct Food and Color Additives The philosophy and approach to evaluating the safety of substances added to foods has evolved over the past six decades. The concept that forms the foundation for this evolution is the recognition that the safety of any added substance to food must be established on the basis of specific intended conditions of use or uses in food. Intended conditions of use encompass (1) the foods to which the substance is added, (2) the level of use in such foods, (3) the purpose for which the substance is used, and (4) the population expected to consume the substance.

Exposure: The Estimated Daily Intake Before 1958, the FDA employed the philosophy that additives (and contaminants) should be harmless per se; that is, an additive should not be harmful at *any* level. The impractical nature of this philosophy is illustrated by two examples: A reasonable person would assume that pure, distilled water is harmless, but if enough is ingested to cause electrolyte imbalance, death may result; similarly, sulfuric acid in its concentrated form can dissolve steel, but when used to control pH during the processing of alcoholic beverages or cheeses, it is considered GRAS by the FDA (*Principles,* 1991). Clearly, exposure should be a major criterion for safety evaluation. This philosophy is reflected in the FDA's *Toxicological Principles for the Safety Assessment of Direct Food Additives and Color Additives Used in Food* (U.S. FDA, 1982),[1] in which exposure is a key factor in an algorithm used to determine which types of testing should be carried out on a substance.

Exposure is most often referred to as an estimated daily intake (EDI) and is based on two factors: the daily intake (*i*) of the food in which the substance will be used and the concentration (*C*) of the substance in that food:

$$EDI = C \times I$$

In most cases, an additive is used in several different food categories, but for the sake of simplicity, we can assume that the additive is used only in baked goods. If the additive is used at a level that does not exceed 10 ppm and the mean daily intake of baked goods is 137 g per person per day, the EDI for this substance is 1370 mg per person per day.

Because most additives are used in more than one food, the total exposure (dose) is the sum of the exposures from each of the food categories. The formula for exposure to substance X is

$$EDI_x = (C_x f \times I_f) + (C_x g \times I_g) + (C_x h \times I_h) + (C \ldots)$$

where $C_x f$ and $C_x g$ are the concentration of *X* in food category f and the concentration of *X* in food category g, respectively. I_f and I_g are the daily intake of food

category f, food category g, and so on. Therefore, the EDI is the sum of the individual contributions of X in each of the food categories.

Many of the same principles can be applied to an estimation of the consumption of residue from enzyme preparations [total organic solids (TOS)], residue from secondary direct additives (substances not intended to remain in a food after the technical effect has been accomplished; this includes but is not limited to mold release agents, solvents, defoaming agents, or chemicals used in washing fruits), and contaminants.

These principles give rise to two questions: (1) How does one determine how much is added to each of the food categories? and (2) What are the food categories, and how are they determined? First, the agency will use as the basis for its calculations the highest end of the range of use level for the new substance, but what ensures that these food group maximums will not be exceeded by a food manufacturer? This is also covered by a regulation—CGMPs (21 CFR 110)—in which a manufacturer is bound not to add more of an additive than is reasonably required to achieve its specific technical effect. That is, if the desired red color of strawberry ice cream is achieved with the addition of 1 ppm of red dye and additional dye does not increase the color or the intensity of the color, it is in violation of CGMPs to add an amount greater than 1 ppm. (A discussion of CGMPs may be found in the *Food Chemicals Codex,* 1996.)

In regard to the second question on food categories, one set of 43 food categories is listed in 21 CFR 170.3(n), which grew out of a survey of food additives conducted by the National Academy of Sciences/National Research Council and published in 1972. A sample of those categories is shown in Table 30-10. This survey pioneered the use of food categorization, but changing lifestyles of the population and shifts in food preferences have necessitated the generation of additional, more timely data.

NUMBER	DESIGNATION	DESCRIPTION	EXAMPLES
(70.3(n))			
(1)	Baked goods and baking mixes	Includes all ready-to-eat and ready-to-bake products, flours, and mixes requiring preparation before serving	Doughnuts, bread, croissants, cake mix, cookie dough
(2)	Beverages, alcoholic	Includes malt beverages, wines, distilled liquors, and cocktail mix	Beer, malt liquor, whiskey, liqueurs, wine coolers
(3)	Beverages and beverage bases, nonalcoholic	Includes only special or specialty-use soft drinks, coffee substitutes, and fresh and vegetable-flavored gelatin drinks	Herbal tea mixes containing "teas"), soda pop, chicory
(4)	Breakfast cereals	Includes ready-to-eat and instant and regular hot cereals	Oatmeal (both regular and instant) farina, corn flakes, wheat flakes

Table 30-10 Food Categories

The newer food consumption surveys provide more contemporary data on food intake (Table 30-11). All these databases (and others) have characteristics that serve a particular purpose. For example, one database may be only a 3-day "snapshot" of consumption, another may cover average consumption over 14 days, while yet another provides a detailed breakout of particular subpopulations (e.g., teenagers, the elderly, Hispanics). The majority of these databases are available to the public but may not be particularly "user-friendly," and private industry has made some of them available on a fee basis.

Table 30-11 Databases for Estimating Food Intake

In estimates of consumption and/or exposure, one must also consider other sources of consumption for the proposed intended use of the additive if it already is used in food for another purpose, occurs naturally in foods, or is used in nonfood sources (e.g., drugs, toothpaste, lipstick). Thus, to estimate human consumption of a particular food substance, it is necessary to know (1) the levels of the substance in food, (2) the daily intake of each food containing the substance, (3) the distribution of intakes within the population, and (4) the potential consumption of or exposure to the substance from nonfood sources. (A discussion of chemical intake is covered in Rees and Tennant, 1994.)

Before a food additive is approved, regulatory agencies require evidence that it is safe for its intended use(s) and that its EDI is less than its acceptable daily intake (ADI). If such an estimate exceeds the ADI, regulatory agencies may impose restrictions on approvals for certain uses or restrict future approvals for new categories of use. The ADI is generally based on the results from animal toxicology studies, usually lifetime studies in rodents. These studies are used to determine the no-observed-effect level (NOEL) for the additive. The NOEL is usually divided by 100 to determine the ADI for a food additive, thus providing a 100-fold safety factor to account for species differences and the inter-individual variation among humans. This factor provides a reasonable certainty in estimating safe doses in humans from animal studies (Butchko and Kotsonis, 1996).

Assignment of Concern Level (CL) and Required Testing Structure-activity (SA) relationships are now the basis for developing many therapeutic drugs, pesticides, and food additives. These relationships are put to good use in the *Toxicological Principles for the Safety Assessment of Direct Food Additives and Color Additives Used in Foods* (U.S. FDA, 1982), which describes a qualitative "decision tree" that assigns categories to substances on the basis of the structural and functional groups in the molecule. Additives with functional groups with a high order of toxicity are assigned to category C, those of unknown or intermediate toxicity are assigned to category B, and those with a low potential for toxicity are assigned to category A. For example, a simple saturated hydrocarbon alcohol such as pentanol would be assigned to category A. Similarly, a substance containing an a,b-unsaturated carbonyl function, epoxide, thiazole, or imidazole group would be assigned to category C. Thus, based on structure assignment and calculated exposure, the CLs are assigned (Table 30-12). For example, a substance in structure category B added to food at a level of 0.03 ppm would be assigned to concern level II.

STRUCTURE CATEGORY A	STRUCTURE CATEGORY B	STRUCTURE CATEGORY C	CONCERN LEVEL
<0.05 ppm in the total diet (<0.0012 mg/kg/day)	<0.025 ppm in the total diet (<0.0006 mg/kg/day)	<0.0125 ppm in the total diet (<0.0003 mg/kg/day)	I
or	or	or	
0.05 ppm in the total diet (0.0012 mg/kg/day)	0.025 ppm in the total diet (0.0006 mg/kg/day)	0.0125 ppm in the total diet (0.0003 mg/kg/day)	II
or	or	or	
>1 ppm in the total diet (>0.025 mg/kg/day)	>0.5 ppm in the total diet (>0.0125 mg/kg/day)	>0.25 ppm in the total diet (>0.006 mg/kg/day)	III

Table 30-12 Assignment of Concern Level

Once the CL is established, a specific test battery is prescribed, as shown in Table 30-9. The tests for CL III are the most demanding and provide the greatest breadth for the determination of adverse biological effects, including effects on reproduction. The tests are comprehensive enough to detect nearly all types of observable toxicity, including malignant and benign tumors, preneoplastic lesions, and other forms of chronic toxicity. The tests for CL II are of intermediate breadth. These tests are designed to detect the most toxic phenomena other than late-developing histopathological changes. The short-term (genotoxicity) tests are intended to identify substances for which chronic testing becomes critical. The CL I test battery is the least broad, as is appropriate for the level of hazard which substances in this category may pose. However, if untoward effects are noted, additional assessment becomes necessary. Studies of the absorption, distribution, metabolism, and elimination characteristics of a test substance are recommended before the initiation of toxicity studies longer than 90 days' duration. Of particular importance for many proposed food ingredients is data on their processing and metabolism in the GI tract.

Unique to food additive carcinogenicity testing is the controversial use of protocols that include an in utero phase. Under such protocols, parents of test animals are exposed to the test substance for 4 weeks before mating and throughout mating, gestation, and lactation. Most countries and international bodies do not subscribe to the combining of an in utero phase with a rat carcinogenicity study, as this presents a series of logistic and operational problems and substantially increases the cost of conducting a rat carcinogenicity study. The FDA began requesting in utero studies of the food industry in the early 1970s, when it was discovered from lifetime feeding studies that the artificial sweetener saccharin produced bladder tumors in male rats when in utero exposure was introduced. Subsequently, the FDA required the food, drug, and cosmetic color industries to conduct lifetime carcinogenicity feeding studies of 18 color additives in rats using an in utero exposure phase. This testing has provided the largest database available to date on the performance of in utero testing.

Special note should also be made of genetic toxicity testing. Genetic toxicity tests are performed for two reasons: (1) to test chemicals for potential carcinogenicity and (2) to assess whether a chemical may induce heritable genetic damage. Currently, genetic toxicity assays can be divided into three major groups: (1) forward and reverse mutation assays (e.g., point mutations, deletions), (2) clastogenicity assays detecting structural and numerical changes in chromosomes (e.g., chromosome aberrations, micronuclei), and (3) assays that identify DNA damage (e.g., DNA strand breaks, unscheduled DNA synthesis).

Because the correlation between carcinogens and mutagens has proved to be less than desirable, as has been demonstrated by false-positive and false-negative findings when carcinogens and noncarcinogens have been examined in genetic toxicity tests, it is recommended that several tests be selected from a battery of tests. It should be kept in mind that as the number of tests employed increases, the possibility of false-negative results increases as well. Consequently, the National Toxicology Program (NTP) has advised that only a single gene mutational assay be used (*Salmonella typhimurium*) to optimize the prediction of carcinogenicity (Tennant and Zeiger, 1993).

Safety Determination of Indirect Food Additives Indirect food additives are substances defined as food additives that are not added directly to food but enter food by migrating from surfaces that contact food. These surfaces may be from packaging material (cans, paper, plastic) or the coating of packaging materials or surfaces used in processing, holding, or transporting food.

Essential to demonstrating the safety of an indirect additive are extraction studies with food-simulating solvents. The FDA recommends the use of three food-simulating solvents—8% ethanol, 50% ethanol, and corn oil or a synthetic triglyceride—for aqueous and acidic, alcoholic, and fatty foods, respectively (FDA, 1988). The conditions of extraction depend in part on the intended conditions of use. If the package material is intended to be retorted, the petitioner must conduct extractions for at least 2 hr at 275°F. For all conditions of use, high-temperature extraction (conducted at 275, 250, or 212°F for 2 h) is followed by a minimum of 238 h at 120°F except for refrigerated foods (in which 70°F is used) and frozen food (in which only 120 h of extraction is required).

Extraction studies are used to assess the level or quantity of a substance which might migrate and become a component of food, leading to consumer exposure. The prescribed extraction tests are believed to overestimate the amount of an indirect additive that is likely to migrate to food and thus are unlikely to underestimate consumer exposure. To convert extraction data from packaging material into anticipated consumer exposure, the FDA has determined the fraction of the U.S. diet which comes into contact with different classes of material: glass, metal-coated, metal-uncoated, paper-uncoated, paper-coated, and polymers. For each class, FDA has assigned a "consumption factor" (CF), which is the fraction of the total diet that comes into contact with an individual class of material (Table 30-13).

Package Content	CF	Food-Type Distribution (f_T)			
		Aqueous	Acidic	Alcoholic	Fatty
Glass	0.10	0.08	0.36	0.47	0.09
Metal, polymer-coated	0.17	0.16	0.35	0.40	0.09
Metal, uncoated	0.03	0.54	0.13	0.01	0.30
Paper, polymer-coated	0.20	0.55	0.04	0.01	0.40
Paper, uncoated	0.10	0.57	0.01	0.01	0.41
Polymer	0.40	0.40	0.16	0.10	0.34

[a] To obtain the CF, a maximum CF of 0.05 is used initially for all polymer contacts.
[b] f_T values.

Table 30-13 Exposure Estimate Calculations (Package Type)

The fraction of individual food types (aqueous, acidic, alcoholic, fatty) for which such packaging material is used is referred to as the food-type-distribution factor (f_T). To calculate consumer exposure (EDI), the following equation is used:

$$EDI = CF \times [(f_{T\ aqueous} \times ppm\ in\ 8\%\ ethanol) + (f_{T\ acidic} \times ppm\ in\ 8\%\ ethanol) + (f_{T\ alcohol} \times ppm\ in\ 50\%\ ethanol) + (f_{T\ fatty} \times ppm\ in\ corn\ oil)] \times 3\ kg\ per\ person\ per\ day = mg\ per\ person\ per\ day[2]$$

For additives with virtually no migration (<0.05 ppm), in which the EDIs correspond to 0.15 mg per person per day, acute toxicology data are considered sufficient to provide an assurance of safety for the intended conditions of use of the additive. Migration levels, as determined by extraction studies, that are greater than 0.05 to 1 ppm of exposure generally require subchronic (90-day) feeding studies in rodent and nonrodent (usually the dog) species. Where there is significant migration—that is, more than 1 ppm exposure—carcinogenicity/chronic toxicity testing in rodents, at least a 1 year test in a nonrodent, and multigeneration reproduction testing to a minimum of two generations with a teratology phase in a rodent, are recommended by the FDA. Other studies may be indicated by the data or information available on the substance.

Safety Requirements for GRAS Substances In spite of the fact that the FD&C Act and the relevant regulations (21 CFR 170.3, etc.) scrupulously avoid defining food except in a functional sense—"food means articles used for food or drink for man or other animals . . . [and includes] chewing gum, and . . . articles used for components of any such article"—it regards foods as GRAS when they are added to other food, for example, green beans in vegetable soup (Kokoski et al., 1990). It also regards a number of food ingredients as GRAS, and these ingredients are listed under 21 CFR 182, 184, and 186. However, it is important to note that not all substances regarded as GRAS are listed as such. The language used in 21 CFR 182.1(a) acknowledges that there are substances the FDA considers to be GRAS which are not listed. This accomplishes two things: (1) It leaves the door open for additional nonlisted substances to be affirmed as GRAS by the agency and (2) reinforces the concept that substances can be deemed GRAS whether or not they are listed by the FDA or on a publicly available list. A list of examples of substances regarded as GRAS is given in Table 30-14. It is important to re-emphasize that GRAS substances, though *used* like food additives, are *not* food additives. Although the distinction may seem to be one of semantics, it allows GRAS substances to be exempt from the premarket clearance restrictions enforced by the FDA and exempt from the Delaney clause, because that clause pertains only to food additives.

CFR NUMBER	SUBSTANCE	FUNCTIONALITY
Substances Generally Recognized as Safe 21 CFR 182		
182.2122	Aluminum calcium silicate	Anticaking agent
182.5065	Linoleic acid	Dietary supplement
Direct Food Substances Affirmed as Generally Recognized as Safe 21 CFR 184		
184.1005	Acetic acid	Several
184.1355	Helium	Processing aid
Indirect Food Substances Affirmed as Generally Recognized as Safe 21 CFR 186		
186.1025	Caprylic acid	Antimicrobial
186.1374	Iron oxides	Ingredient of paper and paperboard

Table 30-14 Examples of GRAS Substances and Their Functionality

While the courts have ruled that GRAS substances must be supported by the same quantity and quality of safety data that support food additives, this ruling should not be interpreted to mean that the supporting data must be identical in nature and character to those supporting a food additive. For uses of substances to be eligible for classification as GRAS, there must be common knowledge throughout the scientific community about the safety of substances directly or indirectly added to food (21 CFR 170.30).

The studies relied on for concluding that a given use of a substance is GRAS ordinarily are based on generally available data and information published in the scientific literature. Such data are unlikely to be conducted in accordance with FDA-recommended protocols, as these studies often are conducted for reasons unrelated to FDA approval. GRAS status also can be based on experience with common use in food before January 1, 1958, which further distinguishes GRAS data requirements from those demanded of food additives. Such experience need not be limited to the United States; but if it comes from outside the United States, it must be documented by published or other information that is corroborated by information from an independent source.

Importance of the GRAS Concept

The importance of the GRAS provision is obvious from its many applications. Many substances, for example, that are used in food processing have never received formal FDA approval. The use of these substances in the manufacture of food products is considered appropriate under CGMPs, while the substance itself is considered GRAS for such purposes. Similarly, certain substances are permitted as optional ingredients in standardized foods [foods with standards of identity specified by regulation (21 CFR 130–169)] even though they are not approved food additives and are not on any of the GRAS lists.

The GRAS concept as traditionally applied in the United States also has applicability to certain novel foods which may differ only slightly from traditional foods or which, after careful consideration, can be regarded as raising no issues or questions of safety beyond that raised by the traditional foods they are intended to replace. The GRAS approach may therefore permit the introduction of novel foods that contain less saturated fat and/or cholesterol or more fiber or are in other ways modified.

Transgenic Plant (and New Plant Varieties) Policy Crops have been genetically modified through conventional crop breeding for more than a hundred years to produce new plant varieties. This was usually done by conventional breeding methods. Scientists today can use biotechnology to insert specific genes into a plant to give it new characteristics. For example, approximately 25 percent of the corn crop planted in 1999 in the United States contains a gene from the bacterium *Bacillus thuringiensis* that produces a Bt insecticidal protein (James, 1999). Bt is a protein toxic to certain caterpillar insect pests that destroy corn plants (EPA, 1988; McClintock et al., 1995). By enabling the corn plant to protect itself from this insect pest, the use of this product can reduce the need for and use of conventional insecticides (Gianessi and Carpenter, 1999).

Irrespective of the breeding method used to produce a new plant variety, tests must be done to ensure that the levels of nutrients or toxins in the plants have not changed and that the food is still safe to consume. Clearly, new proteins produced in plant varieties must be nontoxic and not have the characteristics of proteins known to cause allergies. Thus, the proteins produced in genetically modified crops are evaluated for allergenicity (Metcalf et al., 1996). The DNA that is introduced into genetically modified plants to direct the production of such new proteins has been determined to be generally recognized as safe (FDA, 1992). The use of antibiotic resistance marker genes in genetically modified crops has been determined by FDA and other regulatory agencies to be safe (FDA, 1992). Nonetheless, regulatory agencies have advised researchers to avoid using marker genes in crops that encode resistance to clinically important antibiotics.

The safety of new plant varieties (transgenic plants, genetically modified plants) is regulated primarily under the FDA's postmarket authority [section 402(a)(1) of the FD&C Act]. This section, previously applied to occurrences of unsafe levels of toxicants in food, is now applied to new plant varieties whose composition has been altered by an added substance. The new policy has been applied to plants containing substances that are GRAS [*Federal Register* 57(104):22984–23005]. The *Federal Register* notice (May 29, 1992) indicates that "[i]n most cases, the substances expected to become components of food as a result of genetic modification of a plant will be the same as or substantially similar to substances commonly found in food, such as proteins, fats and oils, and carbohydrates." The notice also indicates the responsibility of the FDA to exercise the premarket review process when the "objective characteristics of the substance raise questions of safety." In regard to substances within the new variety that are not similar to substances commonly found in food, a food additive petition may have to be filed.

The *Federal Register* notice offers points of consideration for the safety assessment of new plant varieties (Table 30-15). Accompanying these points of consideration are a decision flowchart and advice that the FDA be consulted on certain findings, for example, transference of allergens from one plant to another, a change in the concentration or bioavailability of nutrients, and the introduction of a new macroingredient.

- Toxicants known to be characteristic of the host and donor species
- The potential that food allergens will be transferred from one food source to another
- The concentration and bioavailability of important nutrients for which a food crop is ordinarily consumed
- The safety and nutritional value of newly introduced proteins
- The identity, composition, and nutritional value of modified carbohydrates or fats and oils

Table 30-15 Points of Consideration in the Safety Assessment of New Plant Varieties

In the United States, new plant varieties are regulated not only by FDA but also by the EPA and USDA. FDA is responsible for the safety and labeling of foods and feeds derived from crops, irrespective of the method used to produce the new plant variety. EPA is responsible for assuring the safety of pesticides; thus in the example cited above whereby a pesticide is produced in a new plant variety, this product would also fall under the EPA's jurisdiction. The USDA's Animal and Plant Health Inspection Service has responsibility for the environmental safety of field-testing and commercial planting of new plant varieties.

Methods for Establishing Safe Conditions of Use for Novel Foods Novel foods, including those derived from new plant varieties and macroingredient substitutes, present new challenges and may require new methods of determining safety. For example, with each new additive, it has been traditional (and rooted in a regulation such as 21 CFR 170.22) to establish an ADI, which is usually based on 1/100 of the NOEL established in animal testing. This works well for additives projected to be consumed at a level of 1.5 g/day or less (which is equal to or less than 25 mg/kg), for this extrapolates at a 100-fold safety factor to consumption by a rat at a level of

2500 mg/kg/day (about 5 percent of the rat's diet). The problem arises when a new food or macroingredient substitute becomes a substantive part of the diet (estimated to constitute as much as 15 to 20 percent). For example, a macroingredient substitute or food projected to be consumed at a level of just 5 percent of the diet (150 g/day) would require the test animal (rat) to consume 250 g/kg/day, or slightly more than the rat's body weight. This is an untenable test requirement, for at those levels, the investigator would establish an effect level only for malnutrition, not for the toxicity of the macroingredient. The converse is true for some essential nutrients, such as vitamins A and D and iron, which at doses 100 times the nutritional use level would be toxic (Kokoski et al., 1990). The answer therefore lies in careful interpretation of toxicological data and the conduct, where appropriate, of special studies to assess drug interactions, nutrient interactions, changes in gut flora, changes in gut activity, and the like (Borzelleca, 1992a,b; Munro, 1990). Also, it may be appropriate to consider what effect, if any, macroingredients may have on individuals with compromised digestive tracts, those dependent on laxatives, and those on high-fiber diets.

The regulatory approval of a new food additive is generally based on traditional toxicology studies. The rationale is that data from such studies will adequately predict adverse effects that could occur in humans. However, such studies, especially for novel foods, may not be adequate. Therefore, although human studies are not generally required for food additives, in the case of novel foods, human studies are likely essential in evaluating their safety (Stargel et al., 1996).

Another useful tool in ensuring the safety of a food additive is monitoring it after its approval, or postmarketing surveillance. With widespread use of a food additive, *monitoring for consumption* can determine whether actual consumption exceeds the EDI and *monitoring for anecdotal complaints* may identify adverse health effects that escaped detection in earlier studies. This could be especially important for novel foods when traditional toxicology studies are not done at large multiples of the EDI (Butchko et al., 1994, 1996). Thus, the combination of traditional toxicity studies, special animal and human studies, and possibly postmarketing surveillance will ensure the safety of consumers and provide evidence to justify a safety factor different from 100.

Dietary Supplements Dietary supplements have a special status within the law and the regulations; supplements are regarded as foods or food-type substances but not food additives and not drugs. Although regarded as foods, they cannot be sold as conventional foods. Unique to dietary supplements (or dietary supplement ingredients) is a lesser standard for safety than is required for food ingredients. That is, while a food ingredient must have *demonstrated safety,* a supplement ingredient must have *no history of unsafe use,* a much easier standard to meet. While this distinction is subtle, it permits the use of a substance as a dietary supplement that cannot be used as a food ingredient (e.g., stevioside). In the example of stevioside, because there is no history of unsafe use, the FDA has not objected to its use as a dietary supplement but feels that the safety data are inadequate to support the use of stevioside as an ingredient added to food. Concomitantly, an unapproved health claim cannot be made for the dietary supplement, as it is then regarded as a "drug" and subject to the rigorous drug application process with demonstrations of safety and effectiveness (Burdock, 2000).

Assessment of Carcinogens

Carcinogenicity as a Special Problem As discussed above, Congress provided the FDA with wide latitude in assessing safety and assuring a safe food supply with—one exception. That exception is a provision of the FD&C Act known as the Delaney clause, which prohibits the approval of regulated food additives "found to induce cancer when ingested by man or animals" [section 409(c)(3)(A)]. The Delaney clause is found in two other sections of the act. The three clauses—sections 409(c)(3)(A), 706(b)(5)(B), and 512(d)(1)(H)—constitute the Delaney clause.

It must be emphasized that the Delaney prohibition applies only to the approval of food additives, color additives, and animal drugs; it does not apply to unavoidable contaminants or GRAS substances or ingredients sanctioned by the FDA or USDA before 1958. The clause also does not apply to carcinogenic constituents that are present in food or color additives or animal drugs as nonfunctional contaminants provided that the level of such contaminants can be demonstrated to be safe and the whole additive, including its contaminants (permitted by specification and regulations), is not found to induce cancer in humans or animals. This interpretation of the Delaney clause was set forth by the FDA in its so-called constituent policy published on April 2, 1982, as an Advanced Notice of Proposed Rulemaking (ANPR). The policy mandates the development and use of animal carcinogenicity data and probabilistic risk assessment to establish a safe level for the contaminant in the additive under its intended conditions of use.

The constituent policy and, as discussed further on, the implementation of the so-called DES (diethylstilbestrol) proviso for animal drugs under the Delaney clause, have forced the FDA to develop a means for establishing safe levels for carcinogenic substances. The DES proviso allows the addition of carcinogenic animal drugs to animal feed if they leave no residue in edible tissue as determined by an approved analytic procedure. To do this, the FDA has turned to the use of probabilistic risk assessment in which tumor data in animals are mathematically extrapolated to an upper-bound risk in humans exposed to particular use levels of the additive. The FDA takes the position that, considering the many conservative assumptions inherent in the procedure, an upper-bound lifetime risk of one cancer in a million individuals is the biological equivalent of zero.

Much controversy surrounds the use of risk-assessment procedures, in part because estimates of risk are highly dependent on the many assumptions that must be made. The tendency is to be "risk-averse" and favor assumptions that exaggerate risk. As these exaggerations are multiplicative, the total overestimation of risk can be several orders of magnitude. Table 30-16 provides some rough estimates of potential ranges of uncertainty that might lead to large overestimates (Flamm and Lorentzen, 1988).

Table 30-16 Uncertainty Parameters and Their Associated Range of Risk Factors

The common practice of testing at a maximum tolerated dose (MTD) (Williams and Weisburger, 1991) raises the question of appropriateness to human exposure. Do high test doses cause physiologic changes unlike those from human exposure? The basic assumption in quantitative risk assessment (QRA) that the dose-response curve is linear beneath the lowest observable effect may result in the calculation of relatively high risks even at doses that are much lower than the lowest dose that produces cancer in experimental animals (Flamm and Lorentzen, 1988). QRA is more a process than a science; many steps in the process are based on assumptions, not proven scientific facts. If only the most conservative assumptions are made throughout the process, many will represent overestimates of human risk by 10- or 100-fold, leading to a combined overestimate of perhaps a millionfold or more.

Risk assessment cannot be used for either food additives or color additives because of the Delaney clause. If these additives are found to induce cancer, they cannot be approved for foods or colors no matter how small the estimated risk. Because of the harsh consequences of finding a food additive to be a carcinogen, the FDA has interpreted this clause as requiring an affirmative finding of a clear and unequivocal demonstration of carcinogenicity upon ingestion. Historically, the FDA has employed a high threshold for establishing that a food or color additive has been found to induce cancer when ingested by humans or animals. Very few substances have been disapproved or banned because of the Delaney clause. Two indirect food additives (Flectol H and mercaptoimidazoline) that migrate from packaging material were banned. Among direct additives, safrole, cinnamyl anthranilate, thiourea, and diethylpyrocarbonate were banned because of the Delaney clause; diethylpyrocarbonate was banned because it forms urethane.

A number of substances [e.g., butylated hydroxyanisole (BHA), xylitol, methylene chloride, sorbitol, trichloroethylene, nitrilotriacetic acid (NTA), diethylhexyl phthalate, melamine, formaldehyde, bentonite] listed in the Code of Federal Regulation as regulated food additives are also listed as carcinogens by National Toxicology Program (NTP), the International Agency for Research on Cancer (IARC), or the state of California (under the Safe Drinking Water and Toxic Enforcement Act of

1986, also known as Proposition 65). How is this possible, and on what basis do these food additive listings continue?

Despite the fact that tests and conditions exist under which each of these substances will produce cancer in animals, the FDA has found it possible to continue listing these substances as food additives. The reasoning applied in almost every case is based on secondary carcinogenesis. The one exception is formaldehyde, which is carcinogenic only on inhalation, and there are compelling reasons to believe that inhalation is not an appropriate test in this case (Flamm and Frankos, 1985). Therefore formaldehyde is not treated as a carcinogen prohibited by the Delaney clause.

For BHA, which induces forestomach cancer, the concept has been advanced that its carcinogenicity is attributable primarily to irritation, restorative hyperplasia, and so on (Clayson et al., 1986). For xylitol, a sugar alcohol, an increase in bladder tumors and adrenal pheochromocytomas is considered secondary to calcium imbalance resulting from the indigestibility of sugar alcohols and their fermentation in the lower GI tract. Sorbitol, another sugar alcohol, behaves in a similar manner. For NTA, the argument is secondary carcinogenesis, and although specific explanations vary, the mechanism involving zinc imbalance has considerable scientific support. The review of diethylhexyl phthalate is ongoing, but the possibility that peroxisome proliferation is involved has been offered, as has the possibility that hepatocellular proliferation is primary to the subsequent development of tumors.

Thus, the FDA has generally interpreted the phrase "found to induce cancer when ingested by man or animals" as excluding cancers that arise through many secondary means. Therefore, to be a carcinogen under the Delaney clause, a food or color additive must be demonstrated to induce cancer by primary means when ingested by humans or animals or to induce cancer by other routes of administration that are found to be appropriate. This is interpreted to mean that the findings of cancer must be clearly reproducible and that the cancers found are not secondary to nutritional, hormonal, or physiologic imbalances. This position allows the agency to argue that changing the level of protein or fat in the diet does not induce cancer but simply modulates tumor incidence (Kritschevsky, 1994). Given the many modulating factors and influences connected with food and diet, the FDA must be careful about what it declares to be a carcinogen under the Delaney clause. Thus, the FDA has always had to look at the mechanistic question and has been doing that for more than 30 years.

Biological versus Statistical Significance Much can be learned about the proper means of assessing carcinogenicity data by studying large databases for substances that have been tested for carcinogenicity many times. The artificial sweetener cyclamate is an example. The existence of more than a dozen studies on cyclamate and the testing of multiple hypotheses at dozens of different organ and tissue sites in all these studies led to the awareness that the overall false-positive error rate (i.e., higher cancer incidence at a specific organ site in treated subjects versus controls as a result of chance) could be inflated if individual findings were viewed out of context (FDA, 1984). Therefore very careful attention must be paid to the totality of the evidence.

The possibility of false-negative error is always of concern because of the need to protect public health. However, it should be recognized that any attempt to prove absolutely that a substance is not carcinogenic is futile. Therefore, an unrelenting effort to minimize false-negative errors can produce an unacceptably high probability of a false positive. Further, demanding certainty (i.e., a zero or implicitly an extremely low probability of false-negative error) has negative consequences for an accurate decision-making process. This is the case because it severely limits the ability to discriminate between carcinogens and noncarcinogens on the basis of bioassays (FDA, 1984).

In addition to the false-positive/false-negative trap, which is a statistical matter, there are many potential biological traps. The appearance of a higher incidence of tumors at a specific organ site in treated animals may not demonstrate by itself a carcinogenic action of the substance employed in the treatment. This is the case because the incidence of tumors at specific organ sites can be influenced and controlled by many biological processes that may affect tumor incidence.

The test substance, typically administered at high MTDs, may affect one or more of the many biological processes known to modulate tumor incidence at a specific organ site without causing an induction of tumors at that or any other site. Nutritional imbalances such as choline deficiency are known to lead to a high incidence of liver cancer in rats and mice. Simple milk sugar (lactose) is known to increase the incidence of Leydig's cell tumors in rats. Caloric intake has been shown to be a significant modifying factor in carcinogenesis. Impairment of immune surveillance by a specific or nonspecific means (stress) affecting immune responsiveness and hormonal imbalance can result in higher incidences of tumors at specific organ sites. Hormonal imbalance, which can be caused by hormonally active agents (e.g., estradiol) or by other substances that act indirectly, such as vitamin D, may result in an increased tumor incidence. Chronic cell injury and restorative hyperplasia resulting from treatment with lemon flavor (*c*-limonene) probably are responsible for renal tumor development in male rats by mechanisms that are of questionable relevance to humans (Flamm and Lehman-McKeeman, 1991).

In these examples, the increases in tumor incidence at specific organ sites probably are secondary to significant changes in normal physiologic balance and homeostasis. Moreover, the increases in tumor incidence, and hence in the risk of cancer, probably would not occur except at toxic doses (Ames and Gold, 1997).

To preserve the ability of a bioassay to discriminate, the possibility of false-positive or false-negative results and of secondary effects must be considered. To be meaningful, evaluations must be based on the weight of evidence, which must be reviewed as carefully as possible. Particular attention must be given to the many factors used in deciding whether tumor incidences are biologically as well as statistically significant. These factors include (1) the historical rate of the tumor in question (is it a rare tumor, or does it occur frequently in the controls?); (2) the survival histories of dosed and test animals (did dosed animals survive long enough to be considered "at risk"? What effect did chemical toxicity and reduced survival have in the interpretation of the data?); (3) the patterns of tumor incidence (was the response dose-related?); (4) the biological meaningfulness of the effect (was it experimentally consistent with the evidence from related studies? Did it occur in a target organ?); (5) the reproducibility of the effect with other doses, sexes, or species; (6) evidence of hyperplasia, metaplasia, or other signs of an ongoing carcinogenic process (is the effect supported by a pattern of related nonneoplastic lesions, particularly at lower doses?); (7) evidence of tumor multiplicity or progression; and (8) the strength of the evidence of an increased tumor incidence (what is the magnitude of the *p* value? for pairwise comparison? for trend?).

A good discussion of the use of these factors by scientists in deciding whether a substance induces cancer in animals is contained in the notice of a final rule permanently listing FD&C Yellow No. 6 (51 FR 41765–41783, 1988). An elevation of tumor incidence in rats was identified at two organ and/or tissue sites: (1) medullary tumors of the adrenal glands in female rats only and (2) renal cortical tumors in female rats only. Scientists at the FDA concluded that the increase in medullary tumors of the adrenal glands in female rats did not suffice to establish that FD&C Yellow No. 6 is a carcinogen. The basis for the decision was (1) a lack of dose response, (2) the likelihood of false positives, (3) the lack of precancerous lesions, (4) morphologic similarity of adrenal medullary lesions in treated and control rats, (5) an unaffected latency period, (6) a lack of effect in male rats, and (7) a comparison with other studies in which there was no association between exposure to FD&C Yellow No. 6 and the occurrence of adrenal medullary tumors.

A similar judgment was made with respect to the cortical renal lesions in female rats, which were not found to provide a basis for concluding that FD&C Yellow No. 6 can induce cancer of the kidneys. The main reasons leading to this conclusion were (1) the relatively common occurrence of proliferative renal lesions in aged male control rats (28 months or older), (2) the lack of renal tumors in treated males despite their usually greater sensitivity to renal carcinogens, (3) the lack of malignant tumors indicating no progression of adenomas to a malignant state, (4) the lack of a decreased latency period compared with controls, (5) the coincidence of renal proliferative lesions and chronic renal disease, (6) the lack of genotoxicity, and (7) a lack of corroborative evidence from other studies that suggests a treatment-related carcinogenic effect of FD&C Yellow No. 6 on the kidney. Both of these examples emphasize the importance of considering all the evidence in attempting to decide the significance of any subset of data.

As essential elements, vitamins, sugars, and calories per se can increase tumor incidence in test animals; the mechanism by which tumors arise as the result of exposure to food or food ingredients is critically important to assessing the relevance of the finding to the safety of the substance under its intended conditions of use in food. McClain (1994) provides an excellent discussion of mechanistic considerations in the regulation and classification of chemical carcinogens.

Carcinogenic Contaminants The Delaney clause, which prohibits the addition of carcinogens to food, could ban many food additives and color additives if it were strictly interpreted to include carcinogenic contaminants of additives within its definition. Clearly, this was not Congress's intent, and just as clearly, the FDA needed to develop a commonsense policy for addressing the problem that all substances, including food and color additives, may contain carcinogenic contaminants at some trace level.

Toward this end, the agency argued (FDA, 1982) that banning food and color additives simply because they have been found or are known to contain a trace level of a known carcinogen does not make sense because all substances may contain carcinogenic contaminants. The agency asserted in its constituent policy that the mere fact an additive contains a contaminant known to be carcinogenic should not automatically lead the agency to ban that food additive under the Delaney clause but should instead cause the agency to consider the health risks it poses based on its level of contamination and the conditions of its use. The agency stated that by using highly conservative scientific assumptions and a highly conservative methodology for extrapolating cancer risk from high dose to low and from animals to humans, one could estimate such risks in a manner that would assure that the actual risks posed to humans would not be underestimated. This reaffirmed the

agency's position taken in the proposal on the addition of carcinogens to the feed of food-producing animals (FDA, 1977).

SAFETY OF FOOD

Adverse Reactions to Food or Food Ingredients

In a survey of Americans, 30 percent indicated that they or someone in their immediate families had a food sensitivity. Although this number is likely too high, as much as 7.5 percent of the population may be allergic to some food or component thereof (Taylor et al., 1989). Lactose intolerance (a deficiency of the disaccharide enzyme lactase) is very high among some groups; for example, there is an incidence of 27 percent in black children age 12 to 24 months, which may increase to 33 percent by age 6 years (Juambeltz et al., 1993). The percentage of young (northern European) children allegedly intolerant to food additives ranges from 0.03 to 0.23 percent (Wuthrich, 1993) to 1 to 2 percent (Fuglsang et al., 1993). Further, there are certain drug-food incompatibilities about which physicians and pharmacists are obligated to warn patients, such as monoamine oxidase (MAO) inhibitors and tyramine in cheese or benzodiazapenes and naringenin in grapefruit juice. People who are prescribed tetracycline also must be alerted not to take milk with this antibiotic. By any standard, there are large numbers of real and perceived adverse reactions to or incompatibilities with food (Thomas and Tschanz, 1994). The first step in understanding these reactions is to define the nomenclature, a task undertaken by the American Academy of Allergy and Immunology (Committee on Adverse Reactions to Foods) and the National Institute of Allergy and Infectious Diseases (Anderson and Sogn, 1984). An adaptation of their attempt at definition and classification is represented in Table 30-17. In the table, the definitions proceed from general to most specific. Obviously, there is little to distinguish the terms *adverse reaction* and *sensitivity* to a food or a food *intolerance* except perhaps in the lexicon of the individual, colored by his or her own experience. That is, an "adverse reaction" may indicate something as simple as an unpleasing esthetic or hedonic quality such as an unpleasant taste, which may in fact have a genetic basis, as in the ability to taste phenyl-thiocarbamide (Guyton, 1971), or may indicate a fatal outcome resulting from an immune or toxic reaction.

Table 30-17 Adverse Reaction to Food: Definition of Terms

Clinical descriptions of adverse reactions to food are not new. Hippocrates (460–370 B.C.) first recorded adverse reactions to cow's milk that caused gastric upset and urticaria, and Galen (A.D. 131–210) described allergic symptoms to goat milk. However, the immunologic basis of many adverse reactions to food was not established until the passive transfer of sensitivity to fish was described in the early 1960s (Frankland, 1987; Taylor et al., 1989). This test, which evolved into the (skin) prick test and later the radioallergosorbent (RAST) test, allowed a distinction to be made between immunologically based adverse reactions (true allergies) and adverse reactions with other causation.

Food Allergy *Description* Food hypersensitivity (allergy) refers to a reaction involving an immune-mediated response. Such a response is generally IgE-mediated, although IgG_4- and cell-mediated immunity also may play a role in some instances (Fukutomi et al., 1994). What generally distinguishes food allergy from other reactions is the involvement of immunoglobulins, basophils, or mast cells (the latter being a source of mediating substances including histamine and bradykinin for immediate reactions and prostaglandins and leukotrienes for slower-developing reactions) and a need for a prior exposure to the allergen or a cross-reactive allergen. An allergic reaction may be manifest by one or more of the symptoms listed in Table 30-18. The list of foods known to provoke allergies is long and is probably limited only by what people are willing to eat. Although cutaneous reactions and anaphylaxis are the most common symptoms associated with food allergy, the body is replete with a repertoire of responses that are rarely confined to only a few foods.

Cutaneous	Urticaria (hives), eczema, dermatitis, pruritus, rash
Gastrointestinal	Nausea, vomiting, diarrhea, abdominal cramps
Respiratory	Asthma, wheezing, rhinitis, bronchospasm
Other	Anaphylactic shock, hypotension, palatal itching, swelling including tongue and larynx, methemoglobinemia[a]

[a] An unusual manifestation of allergy reported to occur in response to soy or cow milk protein intolerance in infants (Murray and Christie, 1993).

Table 30-18 Symptoms of IgE-Mediated Food Allergies

A curious type of food allergy, the so-called exercise-induced food allergy, is apparently provoked by exercise that has been immediately preceded or followed by the ingestion of certain foods (Kivity et al., 1994), including shellfish, peach, wheat, celery, and "solid" food (Taylor et al., 1989). The exact mechanism is unknown, but it may involve enhanced mast-cell responsiveness to physical stimuli and/or diminished metabolism of histamine similar to red wine allergy (Taylor et al., 1989). On the other hand, food intolerance in patients with chronic fatigue may have less to do with allergic response and has been shown to be a somatization trait of patients with depressive symptoms and anxiety disorders (Manu et al., 1993).

Chemistry of Food Allergens Most allergens (antigens) in food are protein in nature, and although almost all foods contain one or more proteins, a few foods are associated more with allergic reactions than are others. For example, anaphylaxis to peanuts is more common than is anaphylaxis to other legumes (e.g., peas, soybeans). Similarly, although allergies may occur from bony fishes, there is no basis for cross-reactivity to other types of seafood (e.g., mollusks and crustaceans), although dual (and independent) sensitivities may exist (Anderson and Sogn, 1984). Interestingly, patients who are allergic to milk can usually tolerate beef and inhaled cattle dander, and patients allergic to eggs can usually tolerate ingestion of chicken and feather-derived particles (Anderson and Sogn, 1984)—although in the "bird-egg" syndrome, patients can be allergic to bird feathers, egg yolk, egg white, or any combination of the three (DeBlay et al., 1994; Szepfalusi et al., 1994). Some of the allergenic components of common food allergens are listed in Table 30-19.

Table 30-19 Known Allergenic Food Proteins

Although food avoidance is usually the best means of protection, it is not always possible because (1) the content of some prepared foods may be unknown (e.g., the presence of eggs or cottonseed oil), (2) there is the possibility of contamination of food from unsuspected sources [e.g., *Penicillium* in cheeses or meat, *Candida albicans* (Dayan, 1993; Dorion et al., 1994), and cow's milk antigens in the breast milk of mothers who have consumed cow's milk (Halken, et al., 1993)], (3) an allergen may be present in a previously unknown place [the insertion of Brazil nut DNA into soybeans and subsequent appearance of the allergic 2S protein in soybean products (Nordlee et al., 1996)], and (4) there is a lack of knowledge about the phylogenetic relationships between food sources (legumes include peas, soybeans, and peanuts; some Americans are not aware that ham is a pork product). While avoidance is not always possible, promising research in the area of probiotics (i.e., promotion of the growth of beneficial intestinal bacteria including lactobacilli or bifidobacteria) may help in management of food allergy (Kirjavainen et al., 1999; Arunachalam, 1999).

Demographics of Food Allergy Although children appear to be the most susceptible to food allergy, with adverse reactions occurring in 4 to 6 percent of infants, the incidence appears to taper off with maturation of the digestive tract, with only 1 to 2 percent of young children (4 to 15 years) susceptible (Fuglsang et al., 1993). The increase in the number of adults exhibiting food allergy may be due in part to an expanded food universe—that is, an increased willingness to try different foods. In one study, allergies among young children were most commonly to milk and eggs, while allergies that developed later in life tended to be to fruit and vegetables (Kivity et al., 1994).

Familial relationships also play a role. Schrander and colleagues (1993) noted that among infants intolerant of cow's milk protein, 65 percent had a positive family history (first- or second-degree relatives) for atopy compared with 35 percent of healthy controls.

Food Toxicity (Poisoning) See "Substances for which Tolerances May Not Be Set" below.

Food Idiosyncrasy Food idiosyncrasies are generally defined as *quantitatively* abnormal responses to a food substance or additive; this reaction differs from the physiologic effect, and although it may resemble hypersensitivity, it does not involve immune mechanisms. Food idiosyncratic reactions include those that occur in specific groups of individuals who may be genetically predisposed. Examples of such reactions and the foods that are probably responsible are given in Table 30-20.

Table 30-20 Idiosyncratic Reactions to Foods

Probably the most common idiosyncratic reaction is lactose intolerance, a deficiency of the lactase enzyme needed for the metabolism of the lactose in cow's milk. A lack of this enzyme results in fermentation of lactose to lactic acid and an osmotic effect in the bowel, with resultant symptoms of malabsorption and diarrhea. Lactose intolerance is lowest in northern Europe at 3 to 8 percent of the population; it reaches 70 percent in southern Italy and Turkey and nearly 100 percent in southeast Asia (Gudmand-Hoyer, 1994; Anderson and Sogn, 1984).

Anaphylactoid Reactions Anaphylactoid reactions are historically thought of as reactions mimicking anaphylaxis (and other "allergic-type" responses, including though not limited to itching, chronic urticaria, angioedema, exacerbation of atopic eczema, rhinitis, bronchial obstruction, asthma, diarrhea and other intestinal disturbances, and vasomotor headaches) through direct application of the primary mediator of anaphylactic reactions: histamine. Ingestion of scombroid fish (e.g., tuna, mackerel, bonito) as well as some nonscombroid fish (mahimahi and bluefish) that have been acted upon by microorganisms (most commonly *Proteus morganii, Proteus vulgaris, Clostridium* spp., *Escherichia coli, Salmonella* spp., and *Shigella* spp.) to produce histamine may result in an anaphylactoid reaction also called *scombrotoxicosis* (Table 30-21) (Clark et al., 1999). The condition was reported to be mimicked by the direct ingestion of 90 mg of histamine in unspoiled fish (van Geldern et al., 1992), but according to Taylor (1986), the effect of simply ingesting histamine does not produce the equivalent effect. Instead, Taylor stated that histamine ingested with spoiled fish appears to be much more toxic than is histamine ingested in an aqueous solution, as a result of the presence of histamine potentiators in fish flesh. These potentiators included putrefactive amines (putrescine and cadaverine) and pharmacologic potentiators such as aminoguanidine and isoniazid (histaminase inhibitors). The mechanism of potentiation involves the inhibition of intestinal histamine-metabolizing enzymes (diamine oxidase), which causes increased histamine uptake. Scombrotoxicosis in the absence of high histamine levels (less than the U.S. FDA action level for tuna of 50 mg histamine/100 g fish) was reported by Gessner et al., 1996. Melnik et al., (1997) proposed that anaphylactoid responses may be the sum of several mechanisms: (1) an increased intake of biogenic amines (including histamine) with food, (2) an increased synthesis by the intestinal flora, (3) a diminished catabolism of biogenic amines by the intestinal mucosa, and (4) an increased release of endogenous histamine from mast cells and basophils by histamine-releasing food. Further, improvement was observed in 50 percent of patients with histamine intolerance and atopic eczema who maintained a histamine-depleted diet. Ijomah and coworkers (1991) claimed that dietary histamine is not a major determinant of scombrotoxicosis, since potency is not positively correlated with the dose and volunteers tend to fall into susceptible and nonsusceptible subgroups. Ijomah and coworkers (1991) suggested that endogenous histamine released by mast cells plays a significant role in the etiology of scombrotoxicosis, whereas the role of dietary histamine is minor. An exception to this endogenous histamine theory was described by Morrow and colleagues (1991), who found the expected increase in urinary histamine in scombroid-poisoned individuals but did not find an increase in urinary 9a,11b-dhydroxy-15-oxo-2,3,18,19-tetranorprost-5-ene-1,20-dioic acid, the principal metabolite of prostaglandin D$_2$, a mast cell secretory product; thus, no mast-cell involvement was indicated. Rittweger et al. (1994) have reported an increase in urinary immunoreaction angiotensin I and angiotensin II following oral provocation tests to patients with a history of anaphylactoid reactions to drugs, foods, and food additives, but unfortunately there are no reports describing urinary angiotensin levels following oral histamine administration.

Table 30-21 Anaphylactoid Reactions to Food

[Smith (1991)](#) described sulfite-induced bronchospasm (sometimes leading to asthma), which was first noticed as an acute sensitivity to metabisulfites sprayed on restaurant salads (and salad bars) and in wine. Sulfite is normally detoxicated rapidly to inorganic sulfate by the enzyme sulfite oxidase. In sensitive individuals, there is apparently a deficiency in this enzyme, making them supersensitive to sulfites. (The FDA has taken the position that the addition of sulfite to food is safe only when properly disclosed on the food label.)

Pharmacologic Food Reactions Also referred to as "false food allergies" ([Moneret-Vautrin, 1987](#)), these adverse reactions are characterized by exaggerated responses to pharmacologic agents in food ([Table 30-22](#)). These reactions are distinguished from other classifications because they are not associated with a specific anomaly of metabolism (e.g., lactose intolerance or favism) but may be a receptor anomaly instead. These, then, are common pharmacologic agents acting in a very predictable manner, but at exceptionally low levels.

Table 30-22 Pharmacologic Reactions to Food

Metabolic Food Reactions Metabolic food reactions are distinct from other categories of adverse reactions in that the foods are more or less commonly eaten and demonstrate toxic effects only when eaten to excess or improperly processed ([Table 30-23](#)). The susceptible population exists as a result of its own behavior—that is, the "voluntary" consumption of food as a result of a limited food supply or an abnormal craving for a specific food. Such an abnormal craving was reported by [Bannister and associates (1977)](#), who noted hypokalemia leading to cardiac arrest in a 58-year-old woman who had been eating about 1.8 kg of licorice per week. In "glycyrrhizism," or licorice intoxication, glycyrrhizic acid is the active component, with an effect resembling that of aldosterone, which suppresses the renin-angiotensin-aldosterone axis, resulting in the loss of potassium. Clinically, hypokalemia with alkalosis, cardiac arrhythmias, and muscular symptoms, together with sodium retention, edema, and severe hypertension are observed. The syndrome may develop at a level of 100 g licorice per day but gradually abates upon withdrawal of the licorice ([Tonnesen, 1979](#)).

Table 30-23 Metabolic Food Reactions

This category also includes the ingestion of improperly prepared food such as cassava or cycad, which, if prepared properly will result in a toxin-free food. For example, cycad (*Cacaos circinalis*) is a particularly hardy tree in tropical to subtropical habitats around the world. Cycads often survive when other crops have been destroyed (e.g., a natural disaster such as a typhoon or drought) and therefore may serve as an alternative source of food. Among people who have used cycads for food, the method of detoxification is remarkably similar despite the wide range of this plant: the seeds and stems are cut into small pieces and soaked in water for several days; they are then dried and ground into flour. The effectiveness of leaching the toxin (cycasin) from the bits of flesh is most directly dependent on the size of the pieces, the duration of soaking, and the number of water changes. Shortcuts in processing may have grave consequences ([Matsumoto, 1985](#)).

Importance of Labeling

Food labeling allows susceptible individuals to avoid foods containing ingredients that may be harmful to them, such as allergens or substances they may be intolerant of, such as lactose. Thus, if a food contained an allergy-causing protein, this would have to be indicated on the label. The FDA has indicated that, at this time, they are not aware of any information that foods developed through genetic engineering differ as a class in any attribute from foods developed through conventional means, and that such foods would therefore not warrant a special label ([Thompson, 2000](#)). FDA allows companies to include on the label of a product any statement as long as the statement is truthful and not misleading.

TOLERANCE SETTING FOR SUBSTANCES IN FOODS

Pesticide Residues

A pesticide is defined under the FD&C Act as any substance used as a pesticide, within the meaning of the Federal Insecticide, Fungicide and Rodenticide Act (FIFRA), in the production, storage, or transportation of raw agricultural commodities (food in its raw or natural state) [section 201(q)]. The Pesticide amendments of 1956 to the FD&C Act (section 408) were the first amendments to the FD&C Act requiring premarket clearance evaluations of the safety of chemicals added to food.

Currently, the U.S. Environmental Protection Agency (EPA) is responsible for evaluating the safety of pesticides before issuing tolerances.

The regulation of pesticides and their safety is accomplished under both FIFRA and the FD&C Act. FIFRA governs the registration of pesticides. Registration addresses specific uses of a pesticide, and without such registration a pesticide cannot be lawfully sold for such use in the United States. A major part of the registration process involves tolerance setting. Pesticides intended for use on food crops must be granted tolerances or exempted from tolerances under the FD&C Act.

Tolerances for raw agriculture commodities (RAC's) were established under section 408 of the FD&C Act. If the pesticide chemical was found to concentrate in any of the processed fractions from the processing studies on the food crops (usually at least 1.5 or 2.0× of the residue concentration in the RAC), the residues in the processed fraction(s) were considered to be intentional food additives and were required to be assigned "Food Additive Tolerances" under Section 409 of the act. If the pesticide chemical in question had been classified by the EPA as a human or animal carcinogen, the Delaney clause would then be invoked, and the section 409 food additive tolerance(s) could be denied on that basis.

Under the new Food Quality Protection Act (FQPA) of 1996, section 201(s) of the FD&C Act excludes pesticides from the definition of *food additive*—even in the case of concentration of residues in processed fractions. Consequently, the Delaney clause is no longer applicable *for pesticides.* The Delaney clause has *not* been repealed from section 409 and continues to apply to intentional food additives *other than pesticides.* In the case of concentration of pesticide residues in a processed fraction above the section 408 tolerances established for the RAC, an additional tolerance for that processed fraction is still established, but now under section 408 rather than section 409.

The FQPA requires that an additional tenfold safety factor "shall be applied for infants and children to take into account potential pre- and post-natal toxicity and completeness of the data with respect to exposure and toxicity to infants and children." Therefore the "default" assumption is that the additional 10× safety factor will be applied to the chemical safety assessment resulting in a total safety factor of 1000×. It further states, however, that "the Administrator may use a different margin of safety for the pesticide chemical residue only if, on the basis of reliable data, such margin will be safe for infants and children." Therefore, the additional 10× safety factor may be reduced depending on such things as adequacy of exposure assessment, adequacy of the toxicologic data-base, and the nature and severity of any adverse effects observed in these studies, the most important being the adequacy of the toxicologic data base.

Drugs Used in Food-Producing Animals

An animal drug "means any drug intended for use for animals other than man" [section 201(w) of the FD&C Act]. Animal drugs, which typically are used for growth promotion and increased food production, present a complex problem in the safety assessment of animal drug residues in human food. Determination of the potential human health hazards associated with animal drug residues is complicated by the metabolism of an animal drug, which results in residues of many potential metabolites. The sensitivity of modern analytic methodologies designed to quantitate small amounts of drugs and their various metabolites has made evaluation more complex.

The primary factors that must be considered in the evaluation of animal drugs are (1) consumption and absorption by the target animal, (2) metabolism of the drug by the target food animal, (3) excretion and tissue distribution of the drug and its metabolites in food animal products and tissues, (4) consumption of food animal products and tissues by humans, (5) potential absorption of the drug and its metabolites by humans, (6) potential metabolism of the drug and its metabolites by humans, and (7) potential excretion and tissue distribution in humans of the drug, its metabolites, and the secondary human metabolites derived from the drug and its metabolites. Thus, the pharmacokinetic and biotransformation characteristics of both the animal and the human must be considered in an assessment of the potential human health hazard of an animal drug.

When an animal drug is considered GRAS, the safety assessment of the drug is handled as described under the section on GRAS, above. With respect to new animal drugs, safety assessment is concerned primarily with residues that occur in animal food products (milk, cheese, etc.) and edible tissues (muscle, liver, etc.). Toxicity studies in the target species (chicken, cow, pig, etc.) should provide data on metabolism and the nature of metabolites along with information on the drug's pharmacokinetics. If this information is not available, these studies must be performed using the animal species that is likely to be exposed to the drug. During this phase, the parent drug and its metabolites are evaluated both qualitatively and quantitatively in the animal products of concern (eggs, milk, meat, etc.). This may involve the development of sophisticated analytic methodologies. Once these data are obtained, it is necessary to undertake an assessment to determine potential human exposure to these compounds from the diet and other sources. If adequate toxicity data are available, it is possible to undertake a safety assessment pursuant to the establishment of a tolerance.

To comply with the congressional intent regarding the use of animal drugs in food-producing animals as required in the "no residue" provision of the Delaney clause, the FDA began to build a system for conducting risk assessment of carcinogens in the early 1970s (FDA, 1977). In the course of developing a policy and/or regulatory definition for "no residue," the FDA was compelled to address the issue of residues of metabolites of animal drugs known to induce cancer in humans or animals. As the number of metabolites may range into the hundreds, it became apparent that, as a practical matter, not every metabolite could be tested with the same thoroughness as the parent animal drug. This forced the FDA to consider threshold assessment for the first time. Threshold assessment combines information on the structure and in vitro biological activity of a metabolite for the purpose of determining whether carcinogenicity testing is necessary (Flamm et al., 1994). If testing is necessary and the substance is found to induce cancer, the FDA's definition states that a lifetime risk of one in a million as determined by a specified methodology is equivalent to the meaning of "no residue" as intended by Congress.

Unavoidable Contaminants

Certain substances—such as polychlorinated biphenyls (PCB's) or heavy metals—are unavoidable in food because their widespread industrial applications or their presence in the earth's crust have resulted in their becoming a persistent and ubiquitous contaminant in the environment. As a result, foods and animal feeds, principally those of animal and marine origin, contain unavoidable contaminants at some level. Tolerances for residues of unavoidable contaminants are established for foods and food ingredients to ensure that they are safe under expected or intended conditions of use.

Heavy Metals There are 92 natural elements; approximately 22 are known to be essential nutrients of the mammalian body and are referred to as *micronutrients* (Concon, 1988). Among the micronutrients are iron, zinc, copper, manganese, molybdenum, selenium, iodine, cobalt, and even aluminum and arsenic. However, among the 92 elements, lead, mercury, and cadmium are familiar as contaminants or at least have more specifications setting their limits in food ingredients (e.g., Food Chemicals Codex, 1996). The prevalence of these elements as contaminants is due to their ubiquity in nature but also to their use by humans.

Lead Although the toxicity of lead is well known, lead may be an essential trace mineral. A lead deficiency induced by feeding rats <50 ppb (versus 1000 ppb in controls) over one or more generations produced effects on the hematopoietic system, decreased iron stores in the liver and spleen, and caused decreased growth (Kirchgessner and Reichmayer-Lais, 1981), but apparently not as a result of an effect on iron absorption (Reichmayer-Lais and Kirchgessner, 1985). Although the toxic effects of lead are discussed elsewhere in this text, it is important to note that the effects are profound (especially in children) and appear to be long-lasting, since mechanisms for excretion appear to be inadequate in comparison to those for uptake (Linder, 1991).

Over the years, recognition of the serious nature of lead poisoning in children has caused the World Health Organization (WHO) and FDA to adjust the recommended tolerable total lead intake from all sources of not more than 100 mg/day for infants up to 6 months of age and not more than 150 mg/day for children from 6 months to 2 years of age to the considerably lower range of 6 to 18 mg/day as a provisional tolerable range for lead intake in a 10-kg child.

Initiatives to reduce the level of lead in foods, such as the move to eliminate lead-soldered seams in soldered food cans that was begun in the 1970s and efforts to eliminate leachable lead from ceramic glazes, have resulted in a steady decline in dietary lead intake. Although food and water still contribute lead to the diet, data from the FDA's Total Diet Study indicated a reduction in mean dietary lead intake for adult males from 95 mg/day in 1978 to 9 mg/day in the period 1986–1988 (Shank and Carson, 1992).

Some lead sources are difficult to curtail, as lead often survives food processing; for example, lead in wheat remains in the finished flour (Linder, 1991). Therefore, reducing the contribution from dietary sources remains a challenge, but elimination of lead-soldered cans, lead-soldered plumbing, and especially the removal of tetraethyl lead as a gasoline additive have produced substantial reductions in lead ingestion. What is needed now is continued vigilance of largely imported lead-based ceramic ware, lead-containing calcium supplements, and lead leaching into groundwater (Shank and Carson, 1992).

Arsenic Arsenic is a ubiquitous element in the environment; it ranks 20th in relative abundance among the elements of the earth's crust and 12th in the human body (Concon, 1988). (Since arsenic is discussed in detail elsewhere in this text, the discussion here is limited to its relationship to foods.) There is some competition for arsenic absorption with selenium, which is known to reduce arsenic toxicity; arsenic is also known to antagonize iodine metabolism and inhibit various metabolic processes, as a result affecting a number of organ systems. There are a number of sources of arsenic, including drinking water, air, and pesticides (Newberne, 1987), but arsenic consumed via food is largely in proportion to the amount of seafood eaten (74 percent of the arsenic in a market basket survey came from the meat-poultry-fish group, of which seafood consistently has the highest concentration) (Johnson et al., 1981). Although arsenic is used as an animal feed additive, this source does not contribute much to the body burden, as 0.1% arsanilic acid or docecylamine- *p*-chlorophenylarsonate fed to turkeys resulted in tissue residues of only 0.31 and 0.24 ppm in fresh muscle (Underwood, 1973).

Acute poisoning with arsenic often results from mistaking arsenic for sugar, baking powder, and soda and adding it to food. The time between exposure and symptoms is 10 min to several days, and the symptoms include burning of the mouth or throat, a metallic taste, vomiting, diarrhea (watery and bloody), borborigmi (rumbling of the bowles caused by movement of gas in the GI tract), painful tenesmus (spasm of the anal or vesical sphincter), hematuria, dehydration, jaundice, oliguria, collapse, and shock. Headache, vertigo, muscle spasm, stupor, and delirium may occur (Bryan, 1984).

Cadmium Cadmium is a relatively rare commodity in nature and is usually associated with shale and sedimentary deposits. It is often found in association with zinc ores and in lesser amounts in fossil fuel. Although rare in nature, it is a nearly ubiquitous element in American society because of its industrial uses in plating, paint pigments, plastics, and textiles. Exposure of humans often occurs through secondary routes as a result of dumping at smelters and refining plants, disintegration of automobile tires (which contain rubber-laden cadmium), subsequent seepage into the soil and groundwater, and inhalation of combustion of cadmium-containing materials. The estimated yearly release of cadmium from automobile tires ranges from 5.2 to 6.0 metric tons (Davis, 1970; Lagerwerff and Specht, 1971).

Although, like mercury, cadmium can form alkyl compounds, unlike mercury, the alkyl derivatives are relatively unstable and consumption almost always involves the inorganic salt. Of two historical incidents of cadmium poisoning, one involved the use of cadmium-plated containers to hold acidic fruit slushes before freezing. Up to 13 to 15 ppm cadmium was found in the frozen confection, 300 ppm in lemonade, and 450 in raspberry gelatin. Several deaths resulted. A more recent incident of a chronic poisoning involved the dumping of mining wastes into rice paddies in Japan. Middle-aged women who were deficient in calcium and had had multiple pregnancies seemed to be the most susceptible. Symptoms included hypercalciuria; extreme bone pain from osteomalacia; lumbago; pain in the back, shoulders, and joints; a waddling gait; frequent fractures; proteinuria; and glycosuria. The disease was called *itai ita.* ("ouch-ouch disease") as a result of the pain with walking. The victims had a reported intake of 1000 mg/day, approximately 200 times the normal intake in unexposed populations (Yamagata and Shigematsu, 1970). Cadmium exposure also has been associated with cancer of the breast, lung, large intestine, and urinary bladder (Newberne, 1987).

Chlorinated Organics Chlorinated organics have been with us for some time, and given their stability in water and resistance to oxidation, ultraviolet light, microbial degradation, and other sources of natural destruction, chlorinated organics will continue to reside in the environment for some time to come, albeit in minute amounts. However, with the introduction of chlorinated hydrocarbons as pesticides in the 1930s, diseases associated with an insect vector such as malaria were nearly eliminated. In the industrialized world, chlorinated organics brought the promise of nearly universal solvents, and their extraordinary resistance to degradation made them suitable for use as heat transfer agents, carbonless copy paper, and fire retardants (Table 30-24).

Table 30-24 Examples of Levels of Chlorinated Hydrocarbons in British Food

As persistent as these substances are in the environment and despite the degree of toxicity that might be implied, the possible hazard from chlorinated substances is relatively low. Ames et al. (1987) described a method for interpreting the differing potencies of carcinogens and human exposures: the percentage HERP (human exposure dose/rodent potency dose). Using this method, they demonstrated that the hazard from trichloroethylene-contaminated water in Silicon Valley or Woburn, Massachusetts, or the daily dietary intake from DDT (or its product, DDE) at a HERP of 0.0003 to 0.004 percent is considerably less than the hazard presented by the consumption of symphytine in a single cup of comfrey herb tea (0.03 percent) or the hazard presented by aflatoxin in a peanut butter sandwich (0.03 percent). The FDA's authority to set tolerances has been used only once in establishing levels for polychlorinated biphenyls (21 CFR 109.15 and 109.30).

Although the possibility always exists, there have been only a few incidents of mass poisonings via food, two of which involved contaminated cooking oil. The first became known as *yusho,* or rice oil disease, from rice oil contamination by polychlorinated biphenyls (PCBs). The most vulnerable individuals were newborn infants of poisoned mothers. The liver and skin were the most severely affected. Symptoms included dark brown pigmentation of nails; acne-like eruptions; increased eye discharge; visual disturbances; pigmentation of the skin, lips, and gingiva; swelling of the upper eyelids; hyperemia of the conjunctiva; enlargement and elevation of hair follicles; itching; increased sweating of the palms; hyperkeratotic plaques on the soles and palms; and generalized malaise. Recovery requires several years (Anderson and Sogn, 1984). The second incident has become known as *Spanish toxic oil syndrome,* and although details are still not fully known, it occurred after aniline-contaminated rapeseed oil was distributed as cooking oil in Spain in 1981. Approximately 20,000 people were affected and there were several deaths. Because symptoms were unique—including respiratory effects, eosinophilia, and muscle wasting—but not typical of aniline poisoning, the exact etiologic agent is still unknown. Because the source of the aniline may have been improperly cleaned tank trucks that had imported industrial chemicals, three hypotheses have been offered: the etiologic agent may have been (1) a contaminant in the aniline, (2) a contaminant introduced during transportation, or (3) a reaction product of normal oil components and the potential contaminants (the fraction of the oil most commonly associated with toxicity contained $C_{18:3}$ anilide, also called oleyl anilide and "fatty acid anilide") (Borda et al., 1998; Posada de la Paz et al., 1996; Wood et al., 1994).

Nitrosamines, Nitrosamides, and *N*-Nitroso Substances Nitrogenous compounds such as amines, amides, guanidines, and ureas can react with oxides of nitrogen (NO_x) to form *N*-nitroso compounds (NOCs) (Hotchkiss et al., 1992). The NOCs may be divided into two classes: the nitrosamines, which are *N*-nitroso derivatives of secondary amines, and nitrosamides, which are *N*-nitroso derivatives of substituted ureas, amides, carbamates, guanidines, and similar compounds (Mirvish, 1975).

Nitrosamines are stable compounds, while many nitrosamides have half-lives on the order of minutes, particularly at pH >6.5. Both classes have members that are potent carcinogens, but by different mechanisms. In general, the biological activity of an NOC is thought to be related to alkylation of genetic macromolecules. *N*-nitrosamines are metabolically activated by hydroxylation at an a-carbon. The resulting hydroxyalkyl moiety is eliminated as an aldehyde, and an unstable primary nitrosamine is formed. The nitrosamine tautomerizes to a diazonium hydroxide and ultimately to a carbonium ion. Nitrosamides spontaneously decompose to a carbonium ion at physiologic pH by a similar mechanism (Hotchkiss et al., 1992). This is consistent with in vitro laboratory findings because nitrosamines require S9 for activity and nitrosamides are mutagenic de novo.

NOCs originate from two sources: environmental formation and endogenous formation (Table 30-25). Environmental sources have declined over the last several years but still include foods (e.g., nitrate-cured meats) and beverages (e.g., malt beverages), cosmetics, occupational exposure, and rubber products (Hotchkiss, 1989). NOCs formed in vivo may actually constitute the greatest exposure and are formed from nitrosation of amines and amides in several areas, including the stomach, where the most favorable conditions exist (pH 2 to 4), although consumption of H_2-receptor blockers or antacids decreases the formation of NOCs.

Table 30-25 Sources of Dietary NOCs

Environmentally, nitrite is formed from nitrate or ammonium ions by certain microorganisms in soil, water, and sewage. In vivo, nitrite is formed from nitrate by microorganisms in the mouth and stomach, followed by nitrosation of secondary amines and amides in the diet. Sources of nitrate and nitrite in the diet are given in Table 30-26. Many sources of nitrate are also sources of vitamin C. Another possibly significant source of nitrate is well water; although the levels are generally in the range of 21 mM, average levels of 1600 mM (100 mg/L) have been reported (Hotchkiss et al., 1992). However, on the average, western diets contain 1 to 2 mmol nitrate per person per day (Hotchkiss et al., 1992). Nitrosation reactions can be inhibited by preferential, competitive neutralization of nitrite with naturally occurring and synthetic materials such as vitamin C, vitamin E, sulfamate, and antioxidants such as BHT, BHA, gallic acid, and even amino acids or proteins (Hotchkiss, 1989; Hotchkiss et al., 1992).

Table 30-26 Nitrate and Nitrite Content of Food

N-nitrosoproline is the most common nitrosoamine present in humans and is excreted virtually unchanged in the urine. The basal rate of urinary excretion of nitrosoproline, which is claimed to be noncarcinogenic, is 2 to 7 mg/day in subjects on a low-nitrate diet (Oshima and Bartsch, 1981). Epidemiologic studies have not provided evidence of a causal association between nitrate exposure and human cancer, nor has a causal link been shown between N-nitroso compounds preformed in the diet or endogenously synthesized and the incidence of human cancer (Gangolli 1999).

Food-Borne Molds and Mycotoxins Molds have served humans for centuries in the production of foods (e.g., ripening of cheese) and have provided various fungal metabolites with important medicinal uses; they also may produce metabolites with the potential to produce severe adverse health effects. Mycotoxins represent a diverse group of chemicals that can occur in a variety of plant foods. They also can occur in animal products derived from animals that consume contaminated feeds. The current interest in mycotoxicoses was generated by a series of reports in 1960–1963 that associated the death of turkeys in England (so-called turkey X disease) and ducklings in Uganda with the consumption of peanut meal feeds containing mold products produced by *Aspergillus flavus* (Stoloff, 1977). The additional discovery of aflatoxin metabolites (for example, aflatoxin M$_1$) led to more intensive studies of mycotoxins and to the identification of a variety of these compounds associated with adverse human health effects, both retrospectively and prospectively.

Moldy foods are consumed throughout the world during times of famine, as a matter of taste, and through ignorance of their adverse health effects. Epidemiologic studies designed to ascertain the acute or chronic effects of such consumption are few. Data from animal studies indicate that the consumption of food contaminated with mycotoxins has a high potential to produce a variety of human diseases (Miller, 1991).

With some exceptions, molds can be divided into two main groups: "field fungi" and "storage fungi." The former group contains species that proliferate in and under field conditions and do not multiply once grain is in storage. Field fungi are in fact superseded and overrun by storage fungi if conditions of moisture and oxygen allow. Thus, for instance, *Fusarium* spp., a field fungus commonly found on crops, is seldom found after about 6 weeks of storage, its place being taken by *Aspergillus* and *Penicillium,* both of which represent several species of storage fungi (Harrison, 1971). However, the presence of mold does not guarantee the presence of mycotoxin, which is elaborated only under certain conditions. Further, more than one mold can produce the same mycotoxin (e.g., both *Aspergillus* and *Penicillium* may produce the mycotoxin cyclopiazonic acid) (Truckness et al., 1987; El-Banna et al., 1987). Also, more than one mycotoxin may be present in an intoxication; that is, as in the outbreak of turkey X disease, there is evidence that aflatoxin and cyclopiazonic acid both exerted an effect, but the profound effects of aflatoxin overshadowed those of cyclopiazonic acid (Miller, 1989). Although there are many different mycotoxins and subgroups (Table 30-27), this discussion is confined largely to two of the more toxicologically and economically important ones: the aflatoxins and trichothecenes.

Table 30-27 Selected Mycotoxins Produced by Various Molds

Aflatoxins Among the various mycotoxins, the aflatoxins have been the subject of the most intensive research because of the extremely potent hepatocarcinogenicity and toxicity of aflatoxin B$_1$ in rats. Epidemiologic studies conducted in Africa and Asia suggest that it is a human hepatocarcinogen, and various other reports have implicated the aflatoxins in incidences of human toxicity (Krishnamachari et al., 1975; Peers et al., 1976).

Generally, aflatoxins occur in susceptible crops as mixtures of aflatoxins B$_1$, B$_2$, G$_1$, and G$_2$, with only aflatoxins B$_1$ and G$_1$ demonstrating carcinogenicity. A carcinogenic hydroxylated metabolite of aflatoxin B$_1$ (termed aflatoxin M$_1$) can occur in the milk from dairy cows that consume contaminated feed. Aflatoxins may occur

in a number of susceptible commodities and products derived from them, including edible nuts (peanuts, pistachios, almonds, walnuts, pecans, Brazil nuts), oil seeds (cottonseed, copra), and grains (corn, grain sorghum, millet) (Stoloff, 1977). In tropical regions, aflatoxin can be produced in unrefrigerated prepared foods. The two major sources of aflatoxin contamination of commodities are field contamination, especially during times of drought and other stresses, which allow insect damage that opens the plant to mold attack, and inadequate storage conditions. Since the discovery of their potential threat to human health, progress has been made in decreasing the level of aflatoxin in specific commodities. Control measures include ensuring adequate storage conditions and careful monitoring of susceptible commodities for aflatoxin level and the banning of lots that exceed the action level for aflatoxin B$_1$.

Aflatoxin B$_1$ is acutely toxic in all species studied, with an LD$_{5c}$ ranging from 0.5 mg/kg for the duckling to 60 mg/kg for the mouse (Wogan, 1973). Death typically results from hepatotoxicity. This aflatoxin is also highly mutagenic, hepatocarcinogenic, and possibly teratogenic. A problem in extrapolating animal data to humans is the extremely wide range of species susceptibility to aflatoxin B$_1$. For instance, whereas aflatoxin B$_1$ appears to be the most hepatocarcinogenic compound known for the rat, the adult mouse is essentially totally resistant to its hepatocarcinogenicity.

Aflatoxin B$_1$ is an extremely reactive compound biologically, altering a number of biochemical systems. The hepatocarcinogenicity of aflatoxin B$_1$ is associated with its biotransformation to a highly reactive electrophilic epoxide that forms covalent adducts with DNA, RNA, and protein. Damage to DNA is thought to be the initial biochemical lesion resulting in the expression of the pathologic tumor growth (Miller, 1978). Species differences in the response to aflatoxin may be due in part to differences in biotransformation and susceptibility to the initial biochemical lesion (Campbell and Hayes, 1976; Monroe and Eaton, 1987).

Although the aflatoxins have received the greatest attention among the various mycotoxins because of their hepatocarcinogenicity in certain species, there is no compelling evidence that they have the greatest potential to produce adverse human health effects.

Trichothecenes Trichothecenes represent a group of toxic substances of which it is likely that several forms may be consumed concomitantly. They represent many different chemical entities all containing the trichothecene nucleus, and are produced by a number of commonly occurring molds, including *Fusarium, Myrothecium, Trichoderma,* and *Cephalosporium.* The trichothecenes were first discovered during attempts to isolate antibiotics, and although some show antibiotic activity, their toxicity has precluded their pharmacologic use. Trichothecenes most often occur in moldy cereal grains. There have been many reported cases of trichothecene toxicity in farm animals and a few in humans. One of the more famous cases of presumed trichothecene toxicity associated with the consumption of trichothecenes occurred in Russia during 1944 around Orenburg, Siberia. The disruption of agriculture caused by World War II led to the overwintering of millet, wheat, and barley in the field. Consumption of these grains resulted in vomiting, skin inflammation, diarrhea, and multiple hemorrhages, among other symptoms. This exposure was fatal to over 10 percent of the affected individuals (Ueno, 1977). The extent of toxicity associated with the trichothecenes in humans and farm animals is currently unknown owing to the number of entities in this group and the difficulty of assaying for these compounds. The acute LD$_{50}$s of the trichothecenes range from 0.5 to 70 mg/kg, and though there have been reports of possible chronic toxicity associated with certain members of this group, more research will be needed before the magnitude of their potential to produce adverse human health effects is understood (Sato and Ueno, 1977).

Fumonisins Fumonisins are recently discovered mycotoxins produced by *Fusarium moniliforme* and several other *Fusarium* species. Corn products contaminated with *Fusarium moniliforme* are responsible for several agriculturally important diseases in horses and swine (Norred, 1993) and are being actively evaluated to determine how great a threat they pose to public health. Initial evidence of the involvement of *F. moniliforme* produced toxins in human disease was reported by Marasas et al. (1988). They found that an increased incidence of esophageal cancer was associated with the consumption of contaminated corn (maize) by humans in a region in South Africa. Corn borer insect pests cause damage to the developing grain, which enables spores of the toxin-producing *Fusarium* fungi to germinate. The fungus then proliferates, which leads to ear and kernel rot and the production of potentially hazardous levels of fumonisins. Corn varieties that express the Bt insecticidal protein have recently been shown to contain significantly reduced levels of fumonisin because the Bt protein significantly reduces corn borer–induced tissue damage in corn products (Munkvold et al., 1997; 1999; Masoero et al., 1999).

Zearalenone Another mycotoxin produced by *Fusarium* is zearalenone. It was first discovered during attempts to isolate an agent from feeds that produced a hyperestrogenic syndrome in swine, characterized by a swollen and edematous vulva and actual vaginal prolapse in severe cases (Stob et al., 1962). Zearalenone can occur in corn, barley, wheat, hay, and oats as well as other agricultural commodities (Mirocha et al., 1977). Zearalenone consumption can decrease the reproductive potential of farm animals, especially swine.

SUBSTANCES FOR WHICH TOLERANCES MAY NOT BE SET

All of the contaminants of food described to this point are those associated with synthesis, growth, production, or storage and are regarded by the FDA as *unavoidable.* Because they are unavoidable, the FDA sets limits rather than banning them, as described earlier. The substances in this section are regarded as (1) *avoidable* or of such hazard that a safe level cannot be set, therefore the FDA has determined that food containing such substances is banned; or (2) beyond the control of the FDA and cannot be regulated (for example, substances produced in the home).

Toxins in Fish, Shellfish, and Turtles

There are a number of seafood toxins (to be distinguished from marine venoms), many of which are not confined to a single species (over 400 species have been incriminated in ciguatera toxicity) and are therefore most likely to be influenced by the environment. However, some seafood toxins are specific to a single species or genus. A complicating factor in the study of seafood toxins is the sporadic frequency and nonpredictability of the presence of the toxin.

Seafood toxins generally can be classified according to the location of the poison. For example: (1) ichthyosarcotoxin is concentrated in the muscles, skin, liver, or intestines or is otherwise not associated with the reproductive system or circulatory system, (2) ichthyootoxin is associated with reproductive tissue, (3) ichthyohemotoxin is confined to the circulatory system, and (4) ichthyohepatotoxin is confined to the liver. In general, seafood toxins under FDA policy have a zero tolerance, with any detectable level considered cause for regulatory action.

Dinoflagellate Poisoning (Paralytic Shellfish Poisoning or PSP; Saxitoxin) The etiologic agent in this type of poisoning is saxitoxin or related compounds and is found in mussels, cockles, clams, soft-shell clams, butter clams, scallops, and shellfish broth. Bivalve mussels are the most common vehicles. Saxitoxin, originally isolated from toxic Alaskan butter clams (*Saxidomus giganticus*) is actually a family of neurotoxins and includes neosaxitin and gonyautoxins 1 through 4. All block neural transmission at the neuromuscular junction by binding to the surface of the sodium channels and interrupting the flow of Na$^+$ ions; atrioventricular nodal conduction may be suppressed, and there may be direct suppression of the respiratory center and progressive reduction of peripheral nerve excitability. The toxin produces paresthesias and neuromuscular weakness without hypotension and lacks the emetic and hypothermic action of tetrodotoxin. Moderate symptoms are produced by 120 to 180 mg per person and are reversible within hours or days, while 80 mg of purified toxin per 100 g of tissue (0.5 to 2 mg per person) may be lethal, due to asphyxiation, usually within 12 h of ingestion. The toxin is an alkaloid and relatively heat stable. The toxin is produced by several genera of plankton [*Gonyaulax* (now known as *Alexandrium*) *catenella, Gonyaulax acatenella, Gonyaulax tamarensis, Pyrodinium* spp., *Ptychodiscus brevis, Gymnodinium catenaturm,* and others]; and during red tides, blooms of these plankton may reach 20 to 40 million per milliliter. Toxic materials are stored in various parts of the body of shellfish. Digestive organs, liver, gills, and siphons contain the greatest concentrations of poison during the warmer months. Distribution is worldwide (Bryan, 1984; Clark et al., 1999; Liston, 2000).

Amnesic Shellfish Poisoning (Domoic Acid) Consumption of mussels harvested from the area off Prince Edward Island in 1987 resulted in gastroenteritis, and many of the older individuals affected or those with underlying chronic diseases experienced neurologic symptoms including memory loss. Despite treatment, three patients (71 to 84 years old) died within 11 to 24 days. The poisoning was attributed to domoic acid produced by the diatom *Nitzschia pungens* f. *multiseries,* which had been ingested by the mussels during the normal course of feeding. Occurrence of domoic acid has also been reported in California shellfish, produced by *Nitzschia pseudodelicatissima,* and in anchovies (resulting in pelican deaths), produced by *Nitzschia pseudoseriata* (now called *Pseudonitzchia australis*). Domoic acid has been reported in shellfish in other provinces of Canada, Alaska, Washington, and Oregon; it may be as frequent as PSP toxins. Domoic acid has also been reported in seaweed. Domoic acid was reported in Japan in 1958 and was isolated from the red algae *Chondria armata.*

In the Canadian outbreak, mice injected with extracts (as in the PSP assay) died within 3.5 h. The mice exhibited a scratching syndrome uniquely characteristic of domoic acid, followed by increasingly uncoordinated movements and seizures until the mice fell on their sides, rolled over, and died. Levels of domoic acid >40 mg/g wet weight of mussel meat caused the mouse symptoms (Canadian authorities require cessation of harvesting when levels approach 20 mg/g). Mice and rats can generally tolerate 30 to 50 mg/kg (mouse NOEL via intraperitoneal injection is 24 mg/kg). Domoic acid is dose-responsive in humans, with no effect at 0.2 to 0.3 mg/kg, mild (gastrointestinal) symptoms at 0.9 to 1.9 mg/kg, and the most serious symptoms at 1.9 to 4.2 mg/kg. Although rodents may appear to be more tolerant, the fatalities in humans were associated with underlying illness. Domoic acid is an analog of glutamine, a neurotransmitter, and of kainic acid; the toxicity of all three is

similar as they are excitatory and act on three types of receptors in the central nervous system, with the hippocampus being the most sensitive. Domoic acid may be a more potent activator of kannic acid receptors than kannic acid itself. The stimulatory action may lead to extensive damage of the hippocampus but less severe injury to the thalamic and forebrain regions (Clark et al., 1999; Todd, 1993).

Ciguatera Poisoning The *cigua* in *ciguatera* is derived from the Spanish name for the sea snail *Turbo pica,* in which the symptoms were first reported. Ciguatera and related toxins (scaritoxin and maitotoxin) are ichthyosarcotoxic neurotoxins (anticholinesterase) and are found in 11 orders, 57 families, and over 400 species of fish as well as in oysters and clams. The penultimate toxin (gambiertoxin) is produced by the dinoflagellate *Gambierdiscus toxicus,* commonly isolated from microalgae growing on or near coral reefs that have ingested the dinoflagellate. The pretoxin appears to pass through the food chain and is biotransformed upon transfer to or by the ingesting fish to the active form, which is consumed by mammals. Other toxins, including palytoxin and okadaic acid, unrelated to gambiertoxin, may be present in ciguarteric fish and may not contribute to toxicity. The asymptomatic period is 3 to 5 h after consumption but may last up to 24 h. The onset of illness is sudden, and symptoms may include abdominal pain, nausea, vomiting, and watery diarrhea; muscular aches; tingling and numbness of the lips, tongue, and throat; a metallic taste; temporary blindness; and paralysis. Deaths have occurred. Recovery usually occurs within 24 h, but tingling may continue for a week or more. The intraperitoneal LD_{50} of maitotoxin in mice is 50 ng/kg (Bryan, 1984; Liston, 2000).

Puffer Fish Poisoning (Tetrodotoxin) Tetrodon or puffer fish poisoning may be caused by the improper preparation and consumption of any of about 90 species of puffer fish (fugu, blowfish, globefish, porcupine fish, molas, burrfish, balloonfish, toadfish, etc.) and has been found in newts, frogs, octopus, starfish, flatworms, various crabs, and gastropods. The toxin (tetrodotoxin) is located in nearly all the tissues, but the ovaries, roe, liver, intestines, and skin are the most toxic. Toxicity is highest during the spawning period, although a species may be toxic in one location but not another. Tetrodotoxin is associated with the presence of several bacteria on and in fish and shellfish and gives the fish an evolutionary advantage in providing protection against predators (i.e., they are *endosymbiotic* bacteria). A total of 21 species can produce tetrodotoxins including *Vibrio, Pseudomonas, E. coli,* and at least two strains of red algae.

Tetrodotoxin is a neurotoxin and causes paralysis of the central nervous system and peripheral nerves by blocking the movement of all monovalent cations. The toxin is water-soluble and is stable to boiling except in an alkaline solution. A fatal dose may be as little as 1 to 4 mg per person. The victim is asymptomatic for 10 to 45 min but may have a reprieve for as long as 3 h or more. Toxicity is manifest as a tingling or prickly sensation of the fingers and toes; malaise; dizziness; pallor; numbness of the lips, tongue, and extremities; ataxia; nausea, vomiting, and diarrhea; epigastric pain; dryness of the skin; subcutaneous hemorrhage and desquamation; respiratory distress; muscular twitching, tremor, incoordination, and muscular paralysis; and intense cyanosis. Fatality rates are high (Bryan, 1984; Liston, 2000).

Moray Eel Poisoning Although the moray eel (*Gymnothorax javanicus*) and other carnivorous fish may accumulate ciguatoxin as the result of eating other contaminated fish, the Indo-Pacific moray eel (*Lycodontis nudivomer*) has been shown to posses a mucous skin secretion with hemolytic, toxic, and hemagglutinating properties. The hemolytic properties can be separated from the hemagglutinating properties. The hemolytic property is lost upon treatment with trypsin and is unstable in the presence of heat or acidic or alkaline media (Randall et al., 1981). The skin mucus of other species of eels, the common European eel (*Anguilla anguilla*) and pike eel (*Muraenesox cinereus*), was found to have proteinaceous toxins immunologically similar to that of the skin mucous toxin from the Japanese eel (*Anguilla japonica*) (Shiomi et al., 1994).

Fish Liver Poisoning This type of poisoning involves an ichthyohepatotoxin and may be related to or cause hypervitaminosis A. It occurs after the consumption of the liver of *sawara* (Japanese mackerel) and *ishinagi* (sea bass, sandfish, and porgy). After an asymptomatic period of 30 min to 12 h, the victim experiences nausea, vomiting, fever, headache, mild diarrhea, rash, loss of hair, dermatitis, desquamation, bleeding from the lips, and joint pain (Bryan, 1984).

Fish Roe Poisoning This type of poisoning involves a group of ichthyootoxins found in the roe and ovaries of carp, barbel, pike, sturgeons, gar, catfish, tench, bream, minnows, salmon, whitefish, trout, blenny, cabezon, and other freshwater and saltwater fish. Poisonings have been reported in Europe, Asia, and North America. Within this group of ichthyootoxins are heat-stable toxins and lipoprotein toxins. The asymptomatic period is 1 to 6 h, followed by a bitter taste, dryness of the mouth, intense thirst, headache, fever, vertigo, nausea, vomiting, abdominal cramps, diarrhea, dizziness, cold sweats, chills, and cyanosis. Paralysis, convulsions, and death may occur in severe cases (Bryan, 1984; Furman, 1974).

Abalone Poisoning (Pyropheophorbide) Abalone poisoning is caused by abalone viscera poison (located in the liver and digestive gland) and is unusual in that it causes photosensitization. The toxin, pyropheophorbide a, is stable to boiling, freezing, and salting. It is found in Japanese abalone, *Haliotis discus* and *Haliotis sieboldi.* The development of symptoms is contingent on exposure to sunlight. The symptoms are of sudden onset and include a burning and stinging sensation over the entire body, a prickling sensation, itching, erythema, edema, and skin ulceration on parts of the body exposed to sunlight (Bryan, 1984; Shiomi, 1999). Paralytic shellfish toxin (PST) have been detected in abalone, probably through consumption of the mossworm, a plankton feeder that also clings to seaweed, and some shellfish (Takatani et al., 1997).

Sea Urchin Poisoning The etiologic agent forms during the reproductive season and is confined to the gonads. The sea urchins involved include *Paracentrotus lividus, Tripneustes ventricosus,* and *Centrechinus antillarum.* The symptoms include abdominal pain, nausea, vomiting, diarrhea, and migraine-like attacks (Bryan, 1984). The toxin has been shown to interfere with calcium uptake in nerve preparations (Zhang et al., 1998).

Sea Turtle Poisoning (Chelonitoxin) The etiologic agent here is chelonitoxin, which is found in the liver (greatest concentration) but also in the flesh, fat, viscera, and blood. Toxicity is described as sporadic or even seasonal, indicating that the poison may be derived from toxic marine algae. Most outbreaks occur in the Indo-Pacific region. The turtles involved include the green sea turtle as well as the hawksbill and leatherback turtles. Local custom in Sri Lanka is to first offer the liver to crows, and if the birds eat it, the flesh is regarded as safe. However, because the symptoms appear over a few hours to several days, this bioassay requires patience. Symptoms of intoxication in humans include vomiting; diarrhea; sore lips, tongue, and throat; foul breath; difficulty in swallowing; a white coating on the tongue, which may become covered with pin-sized, pustular papules; tightness of the chest; coma; and death. The toxin has been reported transferred to nursing infants from intoxicated mothers. Postmortem examinations reveal congestion of internal organs, interstitial pulmonary edema, and necrosis of myocardial fibers. Fatality rates of 7 and 25 percent have been reported (Ariyananda and Fernando, 1987; Bryan, 1984; Champetier De Ribes et al., 1997; Chandrasiri et al., 1988).

Haff Disease Haff disease is a syndrome of unknown etiology that occurs following consumption of certain types of fish. The syndrome consists of rhabdomyolysis with a release of muscle cell contents into the blood. Patients are often rigid, sensitive to touch, and unable to move; their urine may have a dark brown color. Symptoms appear 18 h (with a range of 6 to 21 h) after consumption; they resolve within 2 to 3 days, and the fatality rate is approximately 1 percent. "Haff disease" was first reported in the 1920s along the Koenigsberg Haff, a brackish inlet on the Baltic Sea, although outbreaks have been reported in Sweden, the former Soviet Union, and in the United States beginning in 1984. U.S. poisonings have been associated with buffalo fish (*Ictiobus cyprnellus*) caught in California, Missouri (St. Louis), and Louisiana. No etiologic agent has been identified (Anonymous, 1998).

Microbiologic Agents—Preformed Bacterial Toxins

Although the United States likely has the safest and cleanest food supply in the world, most U.S. food-related illness results from microbial contamination. If all the food-borne health concerns could be divided into two large categories— *poisonings* and *infections*—the former would include chemical poisonings (e.g., contaminants such as chlorinated hydrocarbons) and intoxications, which may have a plant, animal, or microbial origin. In the infections category, food acts as a vector for organisms that exhibit their pathogenicity once they have multiplied inside the body. Infections include the two subcategories enterotoxigenic infections (with the release of toxins following colonization of the GI tract) and invasive infections, in which the GI tract is penetrated and the body is invaded by organisms.

Food-borne disease outbreaks are tracked by the Centers for Disease Control and Prevention (CDC), which reports that there are approximately 400 outbreaks of food-borne disease per year, involving 10,000 to 20,000 people. However, the actual frequency may be as much as 10 to 200 times as high because (1) an outbreak is classified as such only when the source can be identified as affecting two or more people and (2) most home poisonings are mild or have a long incubation time; they are therefore not connected to the ingested food and go unreported. Naturally, because of differences in virulence and opportunity, some species are more likely than others to cause outbreaks.

There are a number of food toxins of microbial origin; however, discussion in this chapter is limited to preformed bacterial toxins—that is, those toxins elaborated by bacteria concomitant to their residence and growth in or on the food *prior* to ingestion. There are a number of different types of toxins. An *enterotoxin* is a toxin having action on the *enteric* cells of the intestine and an *endotoxin* is generally a lipopolysaccharide membrane constituent released from a dead or dying gram-negative becteria. These toxins are nonspecific and stimulate inflammatory responses from macrophages, including but not limited to prostaglandins, thromboxans, interleukins, and other mediators of immunity. *Exotoxins* are synthesized and released (usually by gram-positive bacteria) and are not an integral part of the organism;

however, they may enhance its virulence. Some bacteria, such as *Shigella, Staphylococcus aureus,* and *E. coli* (which releases the shiga-like Vero toxin), can elaborate both endotoxin and exotoxin.

Clostridium botulinum and **Clostridium butyricum** Food botulism, although now relatively rare, still occurs and is important because of its potency. All organisms of the *Clostridium* genus are gram-positive, spore-forming anaerobes. Botulism is due to the toxins A, B, E, and F, which may be produced by one or more strains of *C. botulinum* and *C. butyricum* (type E only); toxins C and D cause botulism in animals. Type G has not caused any human cases. *C. botulinum* organisms are categorized as group I to IV on the basis of toxin produced; additionally, group I is proteolytic in culture (liquefying egg white, gelatin, and other solid proteins). The toxin is elaborated in foods, wounds, and infant gut and is neurotoxic, interfering with acetylcholine at peripheral nerve endings. Although the spores are among the most heat-resistant, the toxins are heat-labile (the toxin may be rendered harmless at 80 to 100°C for 5 to 10 min). Botulinum toxins are large zinc-metalloproteins of ~150,000 Da, composed of two parts: a 50,000-Da piece, the catalytic subunit, and the 100,000-Da piece, containing an N-terminal translocation domain and a C-terminal binding domain. The structural features are similar to those of tetanus toxin. For types B, D, F, and G (and tetanus toxin), the target protein is VAMP/synaptobrevin, a protein associated with the synaptic vesicle. Types A and E cleave a protein associated with the presynaptic membrane, ANAP25. Botulinum toxin C cleaves SNAP25 and syntaxin, another protein involved in exocytosis. Although intracellular mechanisms of botulinum and tetanus toxins are similar, symptoms are different because different populations of neurons are targeted. The symptoms may include respiratory distress and respiratory paralysis that may persist for 6 to 8 months. The case fatality rate is 35 to 65 percent, and the poison is fatal in 3 to 10 days; a lethal dose is approximately 1 ng. Sources and reservoirs include soil, mud, water, and the intestinal tracts of animals. Foods associated with botulinum toxin include improperly canned low-acid foods (green beans, corn, beets, asparagus, chili peppers, mushrooms, spinach, figs, baked potato, cheese sauce, beef stew, olives, and tuna). The toxin also may occur in smoked fish, fermented food (seal flippers, salmon eggs) and improperly home-cured hams. An increasing source of poisonings is from the use of flavored oils or oil infusion, most typically in garlic-in-oil preparations; in 1993, FDA required acidification of such preparations to prevent the growth of *Clostridium*. While a proteolytic strain of *C. botulinum* (group I) may cause the food to appear and smell "spoiled" (by-products include isobutyric acid, isovaleric acid, and phenylpropionic acid), this is not the case with nonproteolytic strains, many of which can flourish and elaborate toxin at temperatures as low as 3°C (Belitz and Grosch, 1999; Bryan, 1984; Crane, 1999; Hobbs, 1976; Loving, 1998; Lund and Peck, 2000).

The successful use of nitrates in meat to prevent spoilage by *C. botulinum* resulted in the petitioning of FDA by the USDA to have sodium and potassium nitrate approved for addition by "prior sanction" (21 CFR 181.33). The mechanism of nitrates is believed to be due to an inactivation by nitric oxide of iron-sulfur proteins such as ferrodoxin and pyruvate oxidoreductase within the germinated cells. The activity is dependent on the pH and is proportional to the level of free HNO_2; 100 mg nitrate/kg of meat is necessary for the antimicrobial effect, although this effect can be enhanced with ascorbates and chelating agents. Other antibacterials that prevent *C. botulinum* include nisin (used in cheese spreads), parabens, phenolic antioxidants, polyphosphates and carbon dioxide (Belitz and Grosch, 1999; Lund and Peck, 2000).

Clostridium perfringens The primary reservoir for *C. perfringens,* unlike *C. botulinum,* is the intestinal tract of warm-blooded animals (including humans). Most incidences of *C. perfringens* food poisoning are associated with the consumption of roasted meat that has been contaminated with intestinal contents at slaughter, followed by roasting and inadequate storage, allowing *C. perfringens* growth and enterotoxin (CPE) to be elaborated (although some CPE may actually be released during a "second sporulation" process in the stomach of the victim). Virtually all food poisoning is produced by type A strain, although a particularly severe form (called "pig-bel") is produced by type C strain and is only seen among natives of the New Guinea highlands. CPE is enterotoxic and follows an ordered series of events, first causing cellular ion permeability, followed by macromolecular (DNA, RNA) synthesis inhibition, morphologic alteration, cell lysis, villus tip desquamation, and severe fluid loss. This is manifest by abdominal cramping diarrhea occurring within 8 to 16 h, although symptoms are of short duration—1 day or less. Foods associated with *C. perfringens* poisoning include cooked meat or poultry, gravy, stew, and meat pies. The curious form called pig-bel follows feasting on pork by New Guinea highlanders, in whom low levels of proteases are inadequate to hydrolyze the toxins, which are subsequently absorbed. *C. perfringens* is also associated with the production of other 11 other toxins, including those associated with gas gangrene (Bryan, 1984; Crane, 1999; Duncan, 1976; Hauschild, 1971; Hobbs, 1979; Hobbs et al., 1953; Labbe, 2000; Walker, 1975).

Bacillus cereus B. cereus is also a gram-positive, spore-forming rod, but it is an aerobe. *B. cereus* is a causative agent of emetic or diarrheagenic exo- and enterotoxins elaborated in food. The emetic thermostable toxin (surviving 259°F for 90 min) is called *cerulide* (a small cyclic peptide, of 1.2 kDa that acts on 5-HT_3 receptors, stimulating the vagus afferent nerve) and is produced by serotypes 1, 3, and 8. The diarrheagenic thermolabile toxin (133°F for 20 min) is produced by serotypes 1, 2, 6, 8, 10, and 19 and may also be produced in situ in the lower intestine of the host. The diarrheal form may actually consist of three toxins, one of which is hemolytic. Reservoirs are soil and dust. Foods associated with this organism and its toxic properties include boiled and fried rice (principally the emetic form), while the diarrheal form has a wider occurrence and may be found in meats, stews, pudding, sauces, dairy products, vegetable dishes, soups, and meat loaf (Bryan, 1984; Crane, 1999; Gilbert, 1979; Goepfert et al., 1972; Granum and Lund, 1997).

Evidence is accumulating that other species of *Bacillus* may elaborate food toxins, including *Bacillus thuringiensis, Bacillus subtilis, Bacillus licheniformis* and *Bacillus pumilis* (Crane, 1999; Granum and Baird-Parker, 2000).

Staphylococcus aureus Staphylococcal intoxication includes staphlyoenterotoxicosis and staphylococcal food poisoning. *S. aureus* produces a wide variety of exoproteins, including toxic shock syndrome toxin-1 (TSST-1), the exfoliative toxins ETA and ETB, leukociden, and the staphylococcal enterotoxins (SEA, SEB, SECn, SED, SEE, SEG, SHE and SEI). TSST-1 and the staphylococcal enterotoxins (SE) are also known as pyrogenic toxin superantigens (PTSAgs) on the basis of their biological characteristics. Although enterotoxemia develops only from the ingestion of large amounts of SE, emesis is produced as the result of stimulation of the putative SE receptors in the abdominal viscera, following which there is a cascade of inflammatory mediator release. All the SE toxins share a number of properties: an ability to cause emesis and gastroenteritis in primates, superantigenicity, intermediate resistance to heat and pepsin digestion, and tertiary structural similarity, including an intramolecular disulfide bond. Sources of *Staphylococcus* include nose and throat discharges, hands and skin, infected cuts, wounds, burns, boils, pimples, acne, and feces. The anterior nares of humans are the primary reservoirs. Other reservoirs include mastitic udders of cows and ewes (responsible for contamination of unpasteurized milk) and arthritic and bruised tissues of poultry. Foods are usually contaminated after cooking by persons cutting, slicing, chopping, or otherwise handling them and then keeping the foods at room temperature for several hours or storing them in large containers. Foods associated with staphylococcal poisoning include cooked ham; meat products, including poultry and dressing; sauces and gravy; cream-filled pastry; potatoes; ham, poultry, and fish salads; milk; cheese; bread pudding; and generally high-protein leftover foods (Bryan, 1976, 1984; Bergdoll, 1979; Cohen, 1972; Crane, 1999; Dinges et al., 2000; Minor and Marth, 1976).

Escherichia coli Although *E. coli* does not produce a preformed toxin, it deserves mention because of the overwhelming publicity the emergent strain O157:H7 has received (H and O refer to flagellar antigens and virulence markers). There are four categories of *E. coli* associated with diarrheal disease: enteropathogenic (EPEC), enterotoxigenic (ETEC), enteroinvasive (EIEC), and Vero cytotoxin–producing *E. coli* (VTEC). The classification VTEC also includes "shiga-like toxin"–producing *E. coli* (or SLTEC) and "shiga toxin"–producing *E. coli* (STEC). *Enterohemorrhagic E. coli* (EHEC) refers to those strains producing bloody diarrhea, which are a subset of VTEC. The reference to shiga toxin is the result of the clinical similarity of the bloody diarrhea caused by EHEC to that caused by *Shigella*. Each of the diseases presented by the four categories is also associated with one or more toxins (Willshaw et al., 2000).

Because cattle are a significant reservoir of *E. coli,* it is logical that most outbreaks in the United States have been associated with hamburgers and other beef products, although raw vegetables (often fertilized with manure) and unpasteurized apple cider and juice have been reported as souces of outbreaks. Outbreaks in Europe are more often associated with contamination of recreational waters (swimming pools, lakes, etc.). Other sources of contamination include person-to-person contact (especially among institutionalized persons and in families) and contact with farm animals, especially following educational farm visits (Karch et al., 1999).

The subject of organic food has increasingly captured the public interest. Within this issue is a debate concerning the use in organic and conventional farming of organic fertilizers (e.g., cow manure) that may contain *E. coli* O157:H7 (Stephenson, 1997). Data reported to the U.S. Centers for Disease Control and Prevention (CDC) in 1996 and tabulated in a CDC document entitled "Clusters/Outbreaks of *E. coli* O157:H7 reported to CDC in 1996" show that approximately 10 percent of all *E. coli* O157:H7 infections reported that year were from organically grown lettuce, although organic foods apparently account for less than 1 percent of the total food supply. This information, although much too preliminary for any meaningful conclusions, nonetheless suggests the need for careful evaluation of the use of manure in conventional and organic farming.

At the basis of the potential problem is the use of inadequately treated manure for fertilizer. Human cases of *E. coli* O157:H7 infection have been reported from consumption of contaminated lettuce, potatoes, radish sprouts, alfalfa sprouts, cantaloupe, and unpasteurized apple cider and juice (Karch et al., 1999). Adequate treating of manure requires composting the manure for a minimum of 3 months, during which the heap must reach a temperature of 60°C; although this may be adequate to kill vegetative pathogens, it will not destroy spore formers such as *Clostridium perfringens* or *Clostridium botulinum*. Survival of viruses and protozoa during composting is not known (Anonymous, 1999).

Bovine Spongiform Encephalopathy

Bovine spongiform encephalopathy (BSE) was first indentified in Great Britain in 1986. BSE is a neurologic disease classified as a transmissible spongiform encephalopathy (TSE) and is similar to TSEs in other species, including scrapie (sheep and goats), transmissible mink encephalopathy (ranch-bred mink), chronic wasting disease (mule deer and elk), exotic ungulate encephalopathy (captive exotic bovoids such as bison, oryx, and kudu), and feline spongiform encephalopathy (domestic cats, zoo Felidae). TSEs among humans include kuru, Creutzfeldt-Jakob disease (CJD) and "new variant" CJD (nvCJD).

Clinically, these diseases all present neurologic deterioration and wasting, with the incubation period and interval from clinical onset to inexorable death determined by the dose of infective agent, its virulence, and the genetic makeup of the victim. The incubation of BSE in cattle is generally 4 to 5 years (range of 20 months to 18 years) and an interval of 1 to 12 months from presentation of clinical signs to death. Characteristic histologic lesions in the brain and spinal cord are vacuolation and "spongiform" changes. BSE fibrils (long strands of host glycoprotein called *prion protein* or PrP) in spinal cord preparations may be seen with electron microscopy following detergent extraction and proteinase K digestion. Scrapie tissues with highest infectivity are brain and spinal cord, followed by spleen, tonsil lymph nodes, distal ileum, and proximal colon. The infective agent can be transferred using preparations of neural tissue from infected animals across species barriers. The most effective method of transfer is direct injection into the brain or spinal cord, but transfer has been reported with intraperitoneal injection and oral dosing. Vertical transfer (mother to offspring) has been reported among domestic cattle, and lateral transfer through biting or injury (especially among mink) has also been reported. It is generally agreed that the infective agent is likely a variant of scrapie (endemic to sheep) and was transferred to cattle from rendered sheep via inadequately processed meat and bone meal protein supplement. Disputes have arisen about other details of BSE, its relationship to other TSEs, and its effects in humans because of an expectation of conformation by BSE to historical principles of disease.

There is mainstream agreement that the infective agents is a prion, a proteinaceous infective particle that does not possess nucleic acid. It is resistant to heat, animicrobials, ultraviolet rays, and ionizing radiation and is not consistently inactivated with alcohol, formaldehyde, glutaraldehyde, or sodium hydroxide. Phenol and sodium hypochlorite disinfection have had variable success.

PrP protein is not the infectious agent, but rather the product of a TSE infection which has switched on the *PrF* gene. While the infectious agent has not been elucidated, investigators have concluded that the agent in nvCJD and BSE is the same strain and that the same agent is also linked to feline spongiform encephalopathy and exotic ungulate encephalopathy. While this information might indicate a simple mode of transmission, workers with the highest potential incidence of exposure to BSE or TSE (sheep farmers, butchers, veterinarians, cooks, and abattoir workers) do not have an unusually high incidence of nvCJD (Collee, 2000; Prusiner, 1991). Likewise, hemophilic patients have not reflected an increased incidence of nvCJD, although CJD transmission has been documented as the result of injections of human growth hormone or gonadotrophin (derived from human pituitary gland), implantation of dura mater and corneas, and even infected EEG electrodes and neurosurgical instruments (Collee, 2000; Lee et al., 1998; Prusiner, 1994).

The final chapter on BSE and other TSEs will not be written for at least 15 to 20 years, the probable conclusion of the incubation period for those exposed to BSE in the late 1980s and early 1990s.

Substances Produced by Cooking

Tolerances cannot be set for contaminants produced as a result of an action taken by the consumer. An example of this type of contaminant is heterocyclic amines, which are generated during cooking. Heterocyclic amines (HCAs) were discovered serendipitously by Japanese investigators who, while examining the mutagenicity of smoke generated by charred foods, found that the extracts of the charred surfaces of the meat and fish were quantitatively more mutagenic than could be accounted for by the presence of polycyclic aromatic hydrocarbons (Sugimura et al., 1989). Collectively, there are more than 20 HCAs. They are formed as a result of high-temperature cooking of proteins (especially those containing high levels of creatinine) and carbohydrates. Normally, as a result of such heating, desirable flavor components are formed, for example, pyrazines, pyridines, and thiazoles. Intermediates in the formation of these substances are dihydropyrizines and dihydropyridines, which in the presence of oxygen form the flavor components; however, in the presence of creatinine, HCAs are formed (Table 30-28) (Chen and Chiu, 1998; Schut and Snyderwine, 1999).

	Amount in Cooked Food, ng/g				
SAMPLE	IQ	MeIQ	4,8-DiMeIQx	Trp-P-1	Trp-P-2
Broiled beef	0.19	2.11		0.21	0.25
Fried ground beef	0.70	0.64	0.12	0.19	0.21
Broiled chicken		2.33	0.81	0.12	0.18
Broiled mutton		1.01	0.67		0.15
Food-grade beef extract		3.11

Table 30-28 Amounts of Heterocyclic Amines in Cooked Foods

These substances are rapidly absorbed by the GI tract, are distributed to all organs, and decline to undetectable levels within 72 h. HCAs behave as electrophilic carcinogens (Table 30-29). They are activated through *N*-hydroxylation by cytochrome P450 or P448, depending on the specific HCA. The *N*-hydroxy forms require further activation by *O*-acetylation or *O*-sulfonation to react with DNA. DNA adducts are formed with guanosine in various organs, including the liver, heart, kidney, colon, small intestine, forestomach, pancreas, and lung. Unreacted substances are subject to phase II detoxication reactions and are excreted via the urine and feces. In vitro, HCAs require metabolic activation, with some requiring *O*-acetyltransferase and others not requiring it. Although much of the mutagenicity testing has been carried out in TA98 and TA100, these substances are mutagenic in mammalian cells both in vitro and in vivo, *Drosophila,* and other strains of *Salmonella* (Skog et al., 1998; Sugimura and Wakahayashi, 1999)

Table 30-29 Mutagenicity and Carcinogenicity of Heterocyclic Amines

Miscellaneous Contaminants in Food

Sometimes the items under the "miscellaneous" heading are the most interesting. For example, Rodricks and Pohland (1981) pointed out an interesting historical case

of the possible transfer of a toxic botanic chemical from an animal to humans which was first identified by Hall (1979). It is found in the Bible, Book of Numbers, 11:31–33, which describes hungry Israelites inundated with quail blown in from the sea; those who ate the quail quickly died. Hall speculated that the quail had consumed various poisonous berries, including hemlock, while they overwintered in Africa. The hemlock berry contains coniine, a neurotoxic alkaloid to which quail are resistant and that can accumulate in their tissue. Humans are not resistant to coniine, and consumption of large quantities of quail tissue containing the neurotoxin could result in death as described in the biblical text.

Mountain laurel, rhododendron, and azaleas all possess andromedotoxin (now called acetylandromedol) and grayanotoxins (I, II, and II) in their shoots, leaves, twigs, and flowers. Honey made from flowers of these plants is toxic to humans, and after an asymptomatic period of 4 to 6 h, salivation, malaise, vomiting, diarrhea, tingling of the skin, muscular weakness, headache, visual difficulties, coma, and convulsions occur. Life-threatening bradycardia and arterial hypotension may ensue. Needless to say, beekeepers maintain apiaries well away from these species of plants. A similar poisoning occurs with oleander (*Nerium oleander* and *Nerium indicum*), where honey made from the flowers, meat roasted on oleander sticks, or milk from a cow that eats the foliage can produce prostrating symptoms. The oleander toxin consists of a series of cardiac glycosides: thevetin, convallarin, steroidal, helleborein, ouabain, and digitoxin. Sympathetic nerves are paralyzed; the cardiotoxin stimulates the heart muscles much as digitalis does, and gastric distress ensues (Anderson and Sogn, 1984; VonMalottki and Weichmann, 1996).

Other contaminations include contamination of milk with pyrrolizidine and other alkaloids after a cow has fed on tansy ragwort (*Senecio jacobaea*) and tremetol contamination of milk from white snakeroot (*Eupatorium rugusum*).

CONCLUSIONS

Food toxicology differs in many respects from other subspecialties of toxicology largely because of the nature and chemical complexity of food. Food consists of hundreds of thousands of chemical substances in addition to the macro- and micronutrients that are essential to life. The federal law defining food safety in the United States, the FD&C Act, provides a workable scheme for establishing the safety of foods, food ingredients, and contaminants. While the act does not specify how the safety of food and its components and ingredients is to be demonstrated, it emphasizes the need for reasonable approaches in both the application of tests and their interpretation. The specific examples of reasonable approaches and interpretations of safety data discussed in this chapter illustrate both the means and the necessity for reasonableness. New policies, consistent with the safety provisions of the act, are being developed to provide guidance for determination of the safety-in-use of novel foods and those foods derived from new plant varieties.

Contaminants found in food may be divided into two large classes: those that are unavoidable by current good manufacturing practice and those that are not. The former class is represented by substances such as certain chlorinated organic compounds, heavy metals, and mycotoxins that have been determined to be unavoidable by current food manufacturing practice and for which tolerances or action levels may be established. Additionally, pesticide residues and residues of drugs used in food-producing animals may have tolerances established when necessary to protect public health. For an avoidable class of contaminants, tolerances are not set either because public health concerns dictates that the mere presence of the substance or agent demands immediate regulatory action or because contamination results from food preparation in the home, which is beyond FDA control.

It is important to emphasize that the vast majority of food-borne illnesses in developed countries are attributable to microbiologic contamination of food arising from the pathogenicity and/or toxigenicity of the contaminating organism. Thus, the overwhelming concern for food safety in the United States remains directed toward preserving the microbiologic integrity of food.

---

[1]At the time of this writing, *Redbook II* remains in draft form and may undergo significant revision before finalizing. For this reason, the original (1982) version is used in this chapter except where noted.
[2]The 3 kg is the FDA's value for daily food consumption which, when multiplied by mg/kg (ppm) and the weighting factors, reduces to milligrams of the additive per day.

ANALYTIC/FORENSIC TOXICOLOGY

Alphonse Poklis

It is impossible to consider the topic of forensic toxicology without discussing analytic toxicology in detail. However, analytic toxicology has its roots in forensic applications. Therefore, it is logical to discuss these mutually dependent areas together. Analytic toxicology involves the application of the tools of analytic chemistry to the qualitative and/or quantitative estimation of chemicals that may exert adverse effects on living organisms. Generally, the chemical that is to be measured (the analyte) is a xenobiotic that may have been altered or transformed by metabolic actions of the organism. Frequently, the specimen that is to be analyzed presents a matrix consisting of body fluids or solid tissues from the organism. Both the identity of the analyte and the nature of the matrix present formidable problems to an analytic toxicologist.

Forensic toxicology involves the use of toxicology for the purposes of the law (Cravey and Baselt, 1981). Although this broad definition includes a wide range of applications, such as regulatory toxicology and urine testing to detect drug use, by far the most common application is to identify any chemical that may serve as a causative agent in inflicting death or injury on humans or in causing damage to property. Frequently, as a result of such unfortunate incidents, charges of liability or criminal intent are brought that must be resolved by the judicial system. At times, indirect or circumstantial evidence is presented in an attempt to prove cause and effect. However, there is no substitute for an unequivocal identification of a specific chemical substance that is demonstrated to be present in tissues from the victim at a sufficient concentration to explain the injury with a reasonable degree of scientific probability or certainty. For this reason, forensic toxicology and analytic toxicology have long shared a mutually supportive partnership.

Some forensic toxicologic activities have been deemed so important by society that a great effort is expended to initiate and implement analytic procedures in a forensically credible manner as an aid in deciding whether adverse effects have been produced by certain chemicals. Attempts to control drivers whose driving ability may be impaired by ethanol or certain drugs are evidenced by laws prescribing punishment to individuals who are so impaired. The measurement of ethanol in blood or breath at specific concentrations is generally required to prove impairment by this agent (Fisher et al., 1968). Similarly, the decade of the 1980s saw a growing response by society to the threat of drug abuse. Attempts to identify drug users by testing urine for the presence of drugs or their metabolites, using methods and safeguards developed by forensic toxicologists, have become required by law (Department of Health and Human Services, 1988).

The diagnosis and treatment of health problems induced by chemical substances (Blanke and Decker, 1986) and the closely allied field of therapeutic drug monitoring (Moyer et al., 1986) also rely greatly on analytic toxicology. Although the analytes are present in matrices similar to those seen in forensic toxicology, the results must be reported rapidly to be of use to clinicians in treating patients. This requirement of a rapid turnaround time limits the number of chemicals that can be measured because methods, equipment, and personnel must all be available for an instant response to toxicologic emergencies.

Occupational toxicology (Chap. 33) and regulatory toxicology (Chap. 34) require analytic procedures for their implementation or monitoring. In occupational toxicology, the analytic methods used to monitor threshold limit values (TLVs) and other means of estimating the exposure of workers to toxic hazards may utilize simple, nonspecific, but economical screening devices. However, to determine the actual exposure of a worker, it is necessary to analyze blood, urine, breath, or another specimen by employing methods similar to those used in clinical or forensic toxicology. For regulatory purposes, a variety of matrices (food, water, air, etc.) must be examined for extremely small quantities of analytes. Frequently, this requires the use of sophisticated methodology with extreme sensitivity. Both of these applications of analytic toxicology impinge on forensic toxicology because an injury or occupational disease in a worker can result in a legal proceeding, just as a violation of a regulatory law may.

Other applications of analytic toxicology occur frequently during the course of experimental studies. Confirmation of the concentration of dosing solutions and monitoring of their stability often can be accomplished with the use of simple analytic techniques. The bioavailability of a dose may vary with the route of administration and the vehicle used. Blood concentrations can be monitored as a means of establishing this important parameter. In addition, an important feature in the study of any toxic substance is the characterization of its metabolites as well as the distribution of the parent drug, together with its metabolites, to various tissues. This requires sensitive, specific, and valid analytic procedures. Similar analytic studies can be conducted within a temporal framework to gain an understanding of the dynamics of the absorption, distribution, metabolism, and excretion of toxic chemicals.

It is evident that analytic toxicology is intimately involved in many aspects of experimental and applied toxicology. Because toxic substances include all chemical types and because the measurement of toxic chemicals may require the examination of biological or nonbiological matrices, the scope of analytic toxicology is broad. Nevertheless, a systematic approach and a reliance on the practical experience of generations of forensic toxicologists can be used in conjunction with the sophisticated tools of analytic chemistry to provide the data needed to understand the hazards of toxic substances more completely. These concepts are described in detail in the rest of this chapter.

ANALYTIC TOXICOLOGY

In light of the statement by Paracelsus five centuries ago, "All substances are poisons: there is none which is not a poison" (Klaassen et al., 1986), analytic toxicology potentially encompasses all chemical substances. Forensic toxicologists learned long ago that when the nature of a suspected poison is unknown, a systematic, standardized approach must be used to identify the presence of most common toxic substances. An approach that has stood the test of time was first suggested by Chapuis in 1873 in *Elements de Toxicologie.* It is based on the origin or nature of the toxic agent (Peterson et al., 1923). Such a system can be characterized as follows:

1. Gases
2. Volatile substances
3. Corrosive agents
4. Metals
5. Anions and nonmetals
6. Nonvolatile organic substances
7. Miscellaneous

Closely related to this descriptive classification is the method for separating a toxic agent from the matrix in which it is embedded. The matrix is generally a biological specimen such as a body fluid or a solid tissue. The agent of interest may exist in the matrix in a simple solution or may be bound to protein and other cellular constituents. The challenge is to separate the toxic agent in sufficient purity and quantity to permit it to be characterized and quantified. At times, the parent compound is no longer present in large enough amounts to be separated. In this case, known metabolites may indirectly provide a measure of the parent substance

([Hawks and Chiang, 1986](#)). With other substances, interaction of the poison with tissue components may require the isolation or characterization of a protein adduct ([SanGeorge and Hoberman, 1986](#)). Methods for separation have long provided a great challenge to analytic toxicologists. Only recently have methods become available that permit direct measurement of some analytes without prior separation from the matrix.

Gases are most simply measured by means of gas chromatography. Some gases are extremely labile, and the specimen must be collected and preserved at temperatures as low as that of liquid nitrogen. Generally, the gas is carefully liberated by incubating the specimen at a predetermined temperature in a closed container. The gas, freed from the matrix, collects over the specimen's "headspace," where it can be sampled and injected into the gas chromatograph. Other gases, such as carbon monoxide, interact with proteins. These gases can be carefully released from the protein, or the adduct can be measured independently, as in the case of carboxyhemoglobin.

Volatile substances are generally liquids of a variety of chemical types. The temperature at which they boil is sufficiently low that older methods of separation utilized microdistillation or diffusion techniques. Gas-liquid chromatography is the simplest approach for simultaneous separation and quantitation in favorable cases. The simple alcohols can be measured by injecting a diluted body fluid directly onto the column of the chromatograph. A more common approach is to use the headspace technique, as is done for gases, after incubating the specimen at an elevated temperature.

Corrosives include mineral acids and bases. Many corrosives consist of ions that are normal tissue constituents. Clinical chemical techniques can be applied to detect these ions when they are in great excess over normal concentrations. Because these ions are normal constituents, the corrosive effects at the site of contact of the chemical, together with other changes in blood chemistry values, can confirm the ingestion of a corrosive substance.

Metals are encountered frequently as occupational and environmental hazards. Elegant analytic methods are available for most metals even when they are present at extremely low concentrations. Classic separation procedures involve destruction of the organic matrix by chemical or thermal oxidation. This leaves the metal to be identified and quantified in the inorganic residue. Unfortunately, this prevents a determination of the metal in the oxidation state or in combination with other elements, as it existed when the metal compound was absorbed. For example, the toxic effects of metallic mercury, mercurous ion, mercuric ion, and dimethylmercury are all different. Analytic methods must be selected that determine the relative amount of each form present to yield optimal analytic results. The analytic difficulty in doing this has lent support to the unfortunate practice of discussing the toxicity of metals as if each metal existed as a single entity.

Toxic anions and nonmetals are a difficult group for analysis. Some anions can be trapped in combination with a stable cation, after which the organic matrix can be destroyed, as with metals. Others can be separated from the bulk of the matrix by dialysis, after which they are detected by colorimetric or chromatographic procedures. Still others are detected and measured by ion-specific electrodes. There are no standard approaches for this group, and other than phosphorus, they are rarely encountered in an uncombined form.

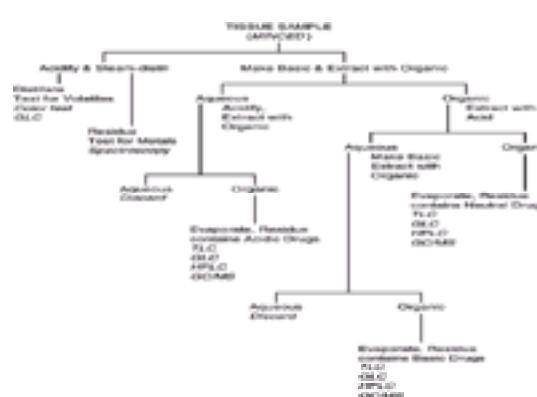
The *nonvolatile organic substances* constitute the largest group of substances that must be considered by analytic toxicologists. This group includes drugs, both prescribed and illegal, pesticides, natural products, pollutants, and industrial compounds. These substances are solids or liquids with high boiling points. Thus, separation procedures generally rely on differential extractions of tissue specimens ([Fig. 31-1](#)). These extractions often are not efficient, and recovery of the toxic substance from the matrix may be poor. When the nature of the toxic substance is known, immunoassay procedures are useful because they allow a toxicologist to avoid using separation procedures. These compounds can be classified as


Figure 31-1. A scheme of separation for poisons from tissues by steam distillation and differential solvent extraction.

Abbreviations: GC/MS, gas chromatography/mass spectrometry; GLC, gas-liquid chromatography; HPLC, high-pressure liquid chromatography; TLC, thin-layer chromatography.

Organic strong acids
Organic weak acids
Organic bases
Organic neutral compounds
Organic amphoteric compounds

Separation generally is achieved by adjusting the acidity of the aqueous matrix and extracting with a water-immiscible solvent or a solid-phase absorbent material. Finally, a *miscellaneous* category must be included to cover the large number of toxic agents that cannot be detected by the routine application of the methods described above. Venoms and other toxic mixtures of proteins or uncharacterized constituents fall into this class. Frequently, if antibodies can be grown against the active constituent, immunoassay may be the most practical means of detecting and measuring these highly potent and difficult to isolate substances. Unfortunately, unless highly specific monoclonal antibodies are used, the analytic procedure may not be acceptable for forensic purposes. Most frequently, specific analytic procedures must be developed for each analyte of this type. At times, biological endpoints are utilized to semiquantify the concentration of the isolated product.

After this brief description of the scope of analytic toxicology, we shall now show how it is applied to a variety of aspects of toxicology.

ANALYTIC ROLE IN GENERAL TOXICOLOGY

In almost all experimental studies in toxicology, an agent, generally a single chemical substance, is administered in known amounts to an organism. It is universally acknowledged that the chemical under study must be pure or the nature of any contaminants must be known to interpret the experimental results with validity. However, it is common practice to proceed with the experimental study without verifying the purity of the compound. Not only does this practice lead to errors in establishing an accurate dose, but, depending on the nature of the study, other erroneous conclusions may be drawn. For example, the presence of related compounds in the dosage form of a tricyclic antidepressant led to erroneous conclusions about the metabolic products of the drug when it was administered together with the unidentified contaminants ([Saady et al., 1981](#)). An even greater error may result when a small amount of a contaminant may be supertoxic. A well-publicized example of this error involved the presence of dioxin in mixtures of the defoliants 2,4-D and 2,4,5-T ([Panel on Herbicides, 1971](#)) used during the Vietnam war as Agent Orange. Some of the adverse effects of Agent Orange may have been due to the low concentration of dioxin in those mixtures. Other researchers have reported that the toxicity of mixtures of polybrominated biphenyls may be due to the high toxicity of specific components, while other brominated biphenyls are relatively nontoxic ([Mills et al., 1985](#)).

A related application of analytic toxicology is in monitoring dosage forms or solutions for stability throughout the course of an experimental study. Chemicals may degrade in contact with air, by exposure to ultraviolet or other radiation, by interaction with constituents of the vehicle or dosing solution, and by other means. Developing an analytic procedure by which these changes can be recognized and corrected is essential in achieving consistent results throughout a study ([Blanke, 1989](#)).

Finally, analytic methods are important in establishing the bioavailability of a compound that is under study. Some substances with low water solubility are difficult to

introduce into an animal, and a variety of vehicles may be tried. However, measuring blood concentrations of the compound under study provides a simple means of comparing the effectiveness of vehicles. Introducing a compound to the stomach in an oil vehicle may not be the most effective means of enhancing the absorption of that compound (Granger et al., 1987). Rather than observing dose–effect relationships, it may be more accurate to describe blood (serum) concentration–effect relationships.

ANALYTIC ROLE IN FORENSIC TOXICOLOGY

The duties of a forensic toxicologist in postmortem investigations include the qualitative and quantitative analysis of drugs or poisons in biological specimens collected at autopsy and the interpretation of the analytic findings in regard to the physiologic and behavioral effects of the detected chemicals on the deceased at the time of death.

The complete investigation of the cause or causes of sudden death is an important civic responsibility. Establishing the cause of death rests with the medical examiner, coroner, or pathologist, but success in arriving at the correct conclusion often depends on the combined efforts of the pathologist and the toxicologist. The cause of death in cases of poisoning cannot be proved beyond contention without a toxicologic analysis that establishes the presence of the toxicant in the tissues and body fluids of the deceased.

Many drugs or poisons do not produce characteristic pathologic lesions; their presence in the body can be demonstrated only by chemical methods of isolation and identification. If toxicologic analyses are avoided, deaths resulting from poisoning may be erroneously ascribed to an entirely different cause or poisoning may be designated as the cause of death without definite proof. Such erroneous diagnoses may have significant legal and social consequences.

Additionally, a toxicologist can furnish valuable evidence concerning the circumstances surrounding a death. Such cases commonly involve demonstrating the presence of intoxicating concentrations of ethanol in victims of automotive or industrial accidents or such concentrations of carbon monoxide in fire victims. The degree of carbon monoxide saturation of the blood may indicate whether the deceased died as a result of the fire or was dead before the fire started. Arson is commonly used to conceal homicide. Also, licit or illicit psychoactive drugs often play a significant role in the circumstances associated with sudden and violent death. The behavioral toxicity of many illicit drugs may explain the bizarre or "risk-taking" behavior of the deceased that led to his or her demise. At times, a negative toxicologic finding is of particular importance in assessing the cause of death. For example, toxicology studies may demonstrate that a person with a seizure disorder was not taking the prescribed medication and that this contributed to the fatal event.

Additionally, the results of postmortem toxicologic testing provide valuable epidemiologic and statistical data. Forensic toxicologists are often among the first to alert the medical community to new epidemics of substance abuse (Poklis, 1982) and the dangers of abusing over-the-counter drugs (Garriott et al., 1985). Similarly, they often determine the chemical identity and toxicity of novel analogues of psychoactive agents that are subject to abuse, including "designer drugs" such as "china white" (methylfentanyl) (Henderson, 1988) and "ecstasy" (methylenedioxymethamphetamine) (Dowling et al., 1987).

Today there are numerous specialized areas of study in the field of toxicology; however, it is the forensic toxicologist who is obliged to assist in the determination of the cause of death for a court of law who has been historically recognized by the title "toxicologist."

Until the nineteenth century, physicians, lawyers, and law enforcement officials harbored extremely faulty notions about the signs and symptoms of poisoning (Thorwald, 1965). Unless a poisoner was literally caught in the act, there was no way to establish the fact that the victim died from poison. In the early eighteenth century, a Dutch physician, Hermann Boerhoave, theorized that various poisons in a hot, vaporous condition yield characteristic odors. He placed substances suspected of containing poisons on hot coals and tested their smells. While Boerhoave was not successful in applying his method, he was the first to suggest a chemical method for proving the presence of poison.

White arsenic (arsenic trioxide) has been widely used with murderous intent for over a thousand years. Therefore it is not surprising that the first milestones in the chemical isolation and identification of a poison in body tissues and fluids centered on arsenic. In 1775, Karl Wilhelm Scheele, a Swedish chemist, discovered that white arsenic is converted to arsenous acid by chlorine water. The addition of metallic zinc reduced the arsenous acid to poisonous arsine gas. If gently heated, the evolving gas would deposit metallic arsenic on the surface of a cold vessel. In 1821, Serullas utilized the decomposition of arsine for the detection of small quantities of arsenic in stomach contents and urine in poisoning cases. In 1836, James M. Marsh, a chemist at the Royal British Arsenal in Woolwich, applied Serullas's observations in developing the first reliable method to determine the presence of an absorbed poison in body tissues and fluids such as liver, kidney, and blood. After acid digestion of the tissues, Marsh generated arsine gas, which was drawn through a heated capillary tube. The arsine decomposed, leaving a dark deposit of metallic arsenic. Quantitative measures were performed by comparing the length of the deposit from known concentrations of arsenic with those of the test specimens.

The 1800s witnessed the development of forensic toxicology as a scientific discipline. In 1814, Mathieiv J. B. Orfila (1787–1853), the "father of toxicology," published *Traité des Poisons,* the first systematic approach to the study of the chemical and physiological nature of poisons (Gettler, 1977). Orfila's role as an expert witness in many famous murder trails, particularly his application of the Marsh test for arsenic in the trial of the poisoner Marie Lafarge, aroused both popular and scholarly interest in the new science. As dean of the medical faculty at the University of Paris, Orfila trained numerous students in forensic toxicology.

The first successful isolation of an alkaloidal poison was done in 1850 by Jean Servials Stas, a Belgian chemist, using a solution of acetic acid in warm ethanol to extract nicotine from the tissues of the murdered Gustave Fougnie. As modified by the German chemist Fredrick Otto, the Stas-Otto method was quickly applied to the isolation of numerous alkaloidal poisons, including colchicine, coniine, morphine, narcotine, and strychnine. In the latter half of the nineteenth century, European toxicologists were in the forefront of the development and application of forensic sciences, providing valuable evidence of poisoning. A number of these trials became "causes célèbres" and the testimony of forensic toxicologists captured the imagination of the public and increased awareness of the development and application of toxicology. Murderers could no longer poison with impunity.

In the United States, Rudolph A. Witthaus, professor of chemistry at Cornell University Medical School, made many contributions to toxicology and called attention to the new science by performing analyses for the city of New York in several famous morphine poisoning cases, including the murder of Helen Potts by Carlyle Harris and that of Annie Sutherland by Dr. Robert W. Buchanan. In 1911, Witthaus and Tracy C. Becker edited a four-volume work on medical jurisprudence, forensic medicine, and toxicology, the first standard forensic textbook published in the United States. In 1918, the city of New York established a medical examiner's system, and the appointment of Dr. Alexander O. Gettler as toxicologist marked the beginning of modern forensic toxicology in this country. Although Dr. Gettler made numerous contributions to the science, perhaps his greatest was the training and direction he gave to future leaders in forensic toxicology. Many of his associates went on to direct laboratories within coroners' and medical examiners' systems in major urban centers throughout the country.

In 1949, the American Academy of Forensic Sciences was established to support and further the practice of all phases of legal medicine in the United States. The members of the toxicology section represent the vast majority of forensic toxicologists working in coroners' or medical examiners' offices. Several other international, national, and local forensic science organizations, such as the Society of Forensic Toxicologists and the California Association of Toxicologists, offer a forum for the exchange of scientific data pertaining to analytic techniques and case reports involving new or infrequently used drugs and poisons. The International Association of Forensic Toxicologists, founded in 1963, with over 750 members in 45 countries, permits worldwide cooperation in resolving the technical problems confronting toxicology.

In 1975, the American Board of Forensic Toxicology (ABFT) was created to examine and certify forensic toxicologists. One of the stated objectives of the board is "to make available to the judicial system, and other publics, a practical and equitable system for readily identifying those persons professing to be specialists in forensic toxicology who possess the requisite qualifications and competence." Those certified as diplomats of the board must have a doctor of philosophy or doctor of science degree, have at least 3 years of full-time professional experience, and pass a written examination. In 2000, the board began certifying "forensic toxicology specialists." Specialists must have a master's or bachelor's degree and 3 years of full-time professional experience and must pass a written examination. At present, there are approximately 225 diplomats and 20 specialists certified by the board. In 1998, the board began an accreditation program for forensic toxicology laboratories. ABFT accredited laboratories must meet standards of qualified experienced personnel and forensically sound procedures for the handling of evidence, analysis of specimens, and reporting of results. Laboratories must pass periodic on-site inspections involving a review of laboratory procedures and previous casework since the last inspection in order to maintain their continuous accreditation.

TOXICOLOGIC INVESTIGATION OF A POISON DEATH

The toxicologic investigation of a poison death may be divided into three steps: (1) obtaining the case history and suitable specimens, (2) the toxicologic analyses,

and (3) the interpretation of the analytic findings.

Case History and Specimens

Today, thousands of compounds are readily available that are lethal if ingested, injected, or inhaled. Usually a limited amount of specimen is available on which to perform analyses; therefore it is imperative that, before the analyses are initiated, as much information as possible concerning the facts of the case be collected. The age, sex, weight, medical history, and occupation of the decedent as well as any treatment administered before death; the gross autopsy findings; the drugs available to the decedent; and the interval between the onset of symptoms and death should be noted. In a typical year, a postmortem toxicology laboratory will perform analyses for such diverse poisons as prescription drugs (analgesics, antidepressants, hypnotics, tranquilizers), drugs of abuse (hallucinogens, narcotics, stimulants), commercial products (antifreeze, aerosol products, insecticides, rodenticides, rubbing compound, weed killers), and gases (carbon monoxide, cyanide). Obviously, thorough investigation of the death scene including a tentative identification of the administered poison is helpful prior to beginning the analysis (Ernst et al., 1982).

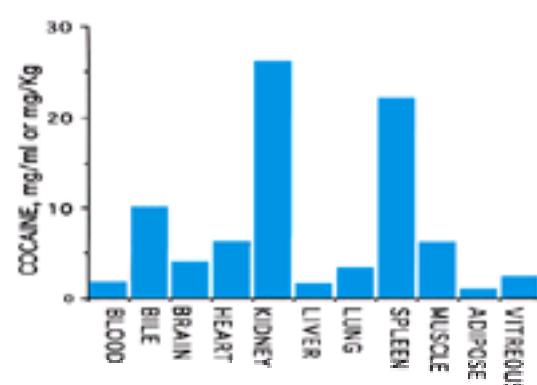
The pathologist at autopsy usually performs the collection of postmortem specimens for analysis. Specimens of many different body fluids and organs are necessary, as drugs and poisons display varying affinities for body tissues (Fig. 31-2). Therefore, detection of a poison is more likely in a tissue in which it accumulates. A large quantity of each specimen is needed for thorough toxicologic analysis because a procedure that extracts and identifies one compound or class of compounds may be ineffective in extracting and identifying others (Table 31-1).


Figure 31-2. Cocaine tissue distribution in a fatal poisoning. (Data drawn from Poklis A, Mackell MA, Graham M: Disposition of cocaine in a fatal poisoning in man. J Anal Toxicol 9:227–229, 1985.)

SPECIMEN	QUANTITY
Brain	100 g
Liver	100 g
Kidney	50 g
Heart blood	25 g
Peripheral blood	10 g
Vitreous humor	All available
Bile	All available
Urine	All available
Gastric contents	All available

Table 31-1 Suggested List of Specimens and Amounts to Be Collected at Autopsy

In collecting the specimens, the pathologist labels each container with the date and time of autopsy, the name of the decedent, the identity of the sample, an appropriate case identification number, and his or her signature or initials. It is paramount that the handling of all specimens, their analysis, and the resultant reports be authenticated and documented. A form developed at the collection site that identifies each specimen is submitted to the laboratory with the specimens. The form is signed and dated by the pathologist and subsequently by any individual handling, transfering, or transporting the specimens from one individual or place to another. In legal terms, this form constitutes a "chain of custody" of specimens, documenting by time, date, name, and signature all persons transferring or receiving the specimens. The chain of custody enables a toxicologist to introduce his or her results into legal proceedings, having established that the specimens analyzed came from the decedent.

Specimens should be collected before embalming, as this process may destroy or dilute the poisons present, rendering their detection impossible. Conversely, methyl or ethyl alcohol may be a constituent of embalming fluid, giving a false indication of the decedent's drinking before death.

On occasion, toxicologic analysis is requested for cases of burned, exhumed, and skeletal remains. In such instances, it is necessary to analyze unusual specimens such as bone marrow, hair, skeletal muscle, vitreous humor, and even maggots (Inoue, 1992). Numerous drugs have been successfully identified in bone marrow and bone washings from skeletal remains even after decomposition and burial (Benko, 1985). Similarly, the vitreous humor of the eye is isolated and sequestered from putrefaction, charring, and trauma; thus, it is a useful specimen for the detection of most drugs, anions, and even volatile poisons such as alcohols, ketones, and glycols (Coe, 1993). Hair analysis is a rapidly growing technique in forensic toxicology. Recently, numerous therapeutic agents such as antibiotics and antipsychotic drugs as well as drugs subject to abuse (morphine, phencyclidine, and cocaine) have been identified in hair (Tagliro, 1993). Limited data are available to support a direct correlation between hair values and drug doses or between physiologic and behavioral effects; however, qualitative results have been accepted as indicators of drug use. In severely decomposed bodies, the absence of blood and/or the scarcity of solid tissues suitable for analysis have led to the collection and testing of maggots (fly larvae) feeding on the body (Pounder, 1991). The fundamental premise underlying maggot analysis is that if drugs or intoxicants are detected, they could only have originated from the decedents' tissues on which the larvae were feeding. Surprisingly, analysis of maggots is rather straightforward, requiring no special methodology beyond that routinely applied in toxicology laboratories. Case reports have documented the detection of numerous drugs and intoxicants in maggots collected from decomposed bodies. The compounds detected include barbiturates, benzodiazepines, phenothiazines, morphine, and malathion. Controlled studies in which maggots were allowed to feed on tissues to which drugs had been added have demonstrated the accumulation of propoxphene and amitriptyline in the larvae (Goff et al., 1993).

Toxicologic Analysis

Before the analysis begins, several factors must be considered: the amount of specimen available, the nature of the poison sought, and the possible biotransformation of the poison. In cases involving oral administration of the poison, the gastrointestinal (GI) contents are analyzed first, because large amounts of residual unabsorbed poison may be present. The urine may be analyzed next, as the kidney is the major organ of excretion for most poisons and high concentrations of toxicants and/or their metabolites often are present in urine. After absorption from the GI tract, drugs or poisons are carried to the liver before entering the general systemic circulation; therefore, the first analysis of an internal organ is conducted on the liver. If a specific poison is suspected to have caused or contributed to a death, the toxicologist may first analyze the tissues and fluids in which the poison concentrates.

A knowledge of drug biotransformation is often essential before an analysis is performed. The parent compound and any major physiologically active metabolites should be isolated and identified. In some instances, the metabolites provide the only evidence that a drug or poison has been administered. Many screening tests, such as immunoassays, are specifically designed to detect not the parent drug but its major urinary metabolite. An example of the relationship of pharmacokinetic and analytic factors is provided by cocaine. The major metabolites of cocaine biotransformation are benzoylecgonine and ecgonine methylester (Fig. 31-3). The ingestion of alcohol combined with the administration of cocaine results in the hepatic transesterification of cocaine to form cocaethylene (Hime et al., 1991) (Fig. 31-3). The

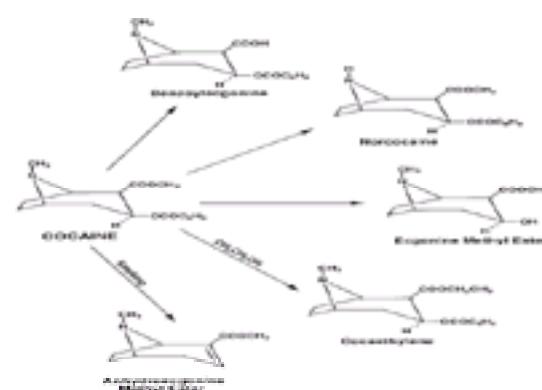
disposition of these compounds in various body fluids and hair is shown in Fig. 31-4. Thus, the initial testing of urine to determine cocaine use is performed with immunoassays specifically designed to detect the presence of benzoylecgonine, the major urinary metabolite. If saliva or hair is tested, parent cocaine is the analyte sought. To determine a cocaine profile of each compound present in a specimen, chromatographic procedures such as gas chromatography/mass spectrometry (GC/MS), that allow the simultaneous separation and quantification of each compound, are used.


Figure 31-3. Biotransformation and pyrolysis products of cocaine.
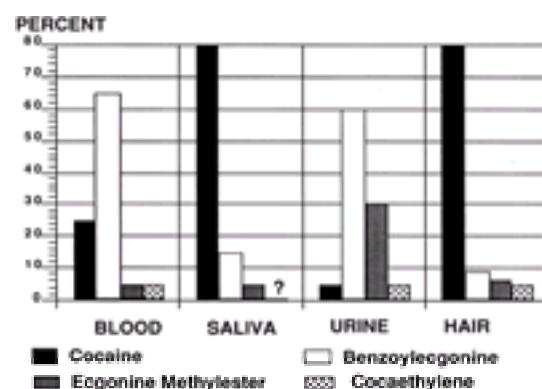

Figure 31-4. Disposition of cocaine and cocaine metabolites in human fluids and hair. (Data redrawn from Spiehler V: Society of Forensic Toxicology Conference on Drug Testing in Hair, Tampa, FL, October 29, 1994.)

The analysis may be complicated by the normal chemical changes that occur during the decomposition of a cadaver. The autopsy and toxicologic analysis should be started as soon after death as possible. The natural enzymatic and nonenzymatic processes of decomposition and microbial metabolism may destroy a poison that was present at death or produce substances or compounds with chemical and physical properties similar to those of commonly encountered poisons. As early as the 1870s, so-called cadaveric alkaloids isolated from the organs of putrefied bodies were known to produce color test reactions similar to those produced by morphine and other drugs. These cadaveric alkaloids resulted from the bacterial decarboxylation of the amino acids ornithine and lysine, producing putrescine and cadaverine, respectively (Evans, 1963). Similarly, during decomposition, phenylalanine is converted to phenylethylamine, which has chemical and physical properties very similar to those of amphetamine. The hydrolysis, oxidation, or reduction of proteins, nucleic acids, and lipids may generate numerous compounds, such as hydroxylated aliphatic and aromatic carboxylic acids, pyridine and piperidine derivatives, and aromatic heterocyclics such as tryptamine and norharmane (Kaempe, 1969). All these substances may interfere with the isolation and identification of the toxicants being sought. The concentration of cyanide and ethyl alcohol and the carbon monoxide saturation of the blood may be decreased or increased, depending on the degree of putrefaction and microbial activity. However, many poisons—such as arsenic, barbiturates, mercury, and strychnine—are extremely stable and may be detectable many years after death.

Before analysis, the purity of all chemicals should be established. The primary reference material used to prepare calibrators and controls should be checked for purity, and the salt form or degree of hydration should be determined (Blanke, 1989). All reagents and solvents should be of the highest grade possible and should be free of contaminants that may interfere with or distort analytic findings. For example, the chloroform contaminants phosgene and ethyl chloroformate may react with primary or secondary amine drugs to form carbamyl chloride and ethyl carbamate derivatives (Cone et al., 1982). Specimen containers, lids, and stoppers should be free of contaminants such as plasticizers, which often interfere with chromatographic or GC/MS determinations. Care should be exercised to ensure a clean laboratory environment. This is of particular concern in the analysis of metals, as aluminum, arsenic, lead, and mercury are ubiquitous environmental and reagent contaminants.

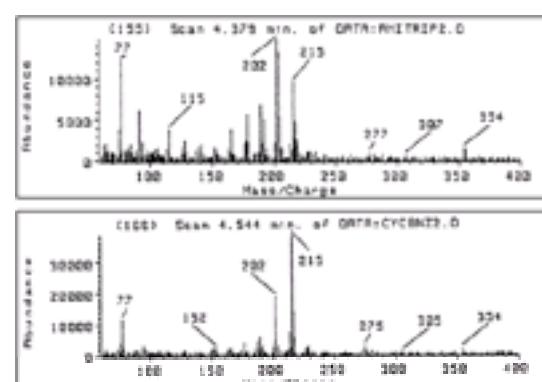
Forensic toxicology laboratories analyze specimens by using a variety of analytic procedures. Initially, nonspecific tests designed to determine the presence or absence of a class or group of analytes may be performed directly on the specimens. Examples of tests used to rapidly screen urine are the FPN (ferric chloride, perchloric, and nitric acid) color test for phenothiazine drugs and immunoassays for the detection of amphetamines, benzodiazepines, and opiate derivatives. Positive results obtained with these tests must be confirmed by a second analytic procedure that identifies the particular drug. The detection limit of the confirmatory test should be lower than that of the initial nonspecific test. Some analytic procedures identify specific compounds. Even in such instances, a second test should be performed to identify the analyte. The second test should be based on a chemical or physical principle different from that of the first test. Such additional testing is performed to establish an unequivocal identification of the drugs or poisons present. Whenever possible, the most specific test for the compound of interest should be performed. Today, GC/MS or high-performance liquid chromatography (HPLC)/MS is the most widely applied methodology in toxicology and is generally accepted as unequivocal identification for most drugs. Analyte identification is based upon the retention time in the chromatographic system coupled with the ion fragmentation spectrum in the mass spectrometer. The analyte mass spectrum is the pattern of mass to charge ion fragments and their relative abundance. Even drugs such as amitriptyline and cyclobenzaprine that display similar chromatographic behavior and differ in their chemical structure by only a double bond may be readily identified by GC/MS (Fig. 31-5).


Figure 31-5. Electron impact mass spectra of amitriptyline and cyclobenzaprine, scanning ion mass from 60 to 400 m/e. (From Poklis A: Cyclobenzaprine in emergency toxicology. Clin Chem CC96-3:43–57, 1996. American Society of Clinical Pathologists, with permission.)

The lower limit of detection, the smallest concentration of analyte reliably identified by the assay, and the specificity of all qualitative methods should be well documented. The laboratory must demonstrate that the assay response to blank or negative calibrators does not overlap with the response of the lowest positive calibrator. In certain instances, qualitative identification of a poison or drug is sufficient to resolve forensic toxicology issues. However, most cases require reliable

estimates of poison concentrations for forensic interpretation. For quantitative analysis, the linearity, precision, and specificity of the procedure must be established. Linearity should be determined by using at least a drug free and three drug added calibrators whose concentrations bracket the anticipated concentrations in the specimen. Precision, which statistically demonstrates the variance in the value obtained, is determined by replicate analyses of a specimen of a known concentration. For a variety of reasons, a quantitative result occasionally will deviate spuriously from the true value. Therefore, replicate quantitative determinations should be performed on all specimens, at least in duplicate (Blanke, 1987).

When unusual samples such as bone marrow, hair, and maggots are analyzed, the extraction efficiency of a procedure may vary greatly, depending on the nature of the specimens. Therefore, all calibrators and controls should be prepared in the same matrix as the specimens and analyzed concurrently with the specimens. Often the matrix is "unique" or impossible to match, such as decomposed or embalmed tissue. In these instances, the method of "standard additions" may be used. Known amounts of the drug or poison of interest are added to specimen aliquots and these are analyzed. The concentration of poison in the test specimen is determined by comparing the proportional response of the "poison added" specimens to that of the test specimens. When comparable results are obtained from analysis of specimens by both direct extraction methods and "standard addition," not only is the efficacy of the extraction method validated, but also the accuracy of the results is assured (Poklis et al. 1998).

Interpretation of Analytic Results

Once the analysis of the specimens is complete, the toxicologist must interpret his or her findings in regard to the physiologic or behavioral effects of the toxicants on the decedent at the concentrations found. Specific questions may be answered, such as the route of administration, the dose administered, and whether the concentration of the toxicant present was sufficient to cause death or alter the decedent's actions enough to cause his or her death. Assessing the physiologic or behavioral meanings of analytic results is often the most difficult problem faced by the forensic toxicologist.

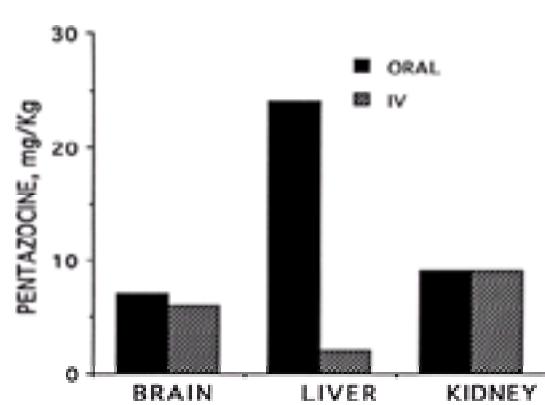
In determining the route of administration, the toxicologist notes the results of the analysis of the various specimens. As a general rule, the highest concentrations of a poison are found at the site of administration. Therefore, the presence of large amounts of drugs and/or poisons in the GI tract and liver indicates oral ingestion, while higher concentrations in the lungs than in other visceral organs can indicate inhalation or intravenous injection. The ratio or relative distribution of drugs in different tissues may also differentiate oral from parenteral administration (Fig. 31-6). Drugs may also be detected in the tissue surrounding an injection site following intramuscular or intravenous injection. Smoking is a popular route of administration for abusers of controlled substances such as cocaine, heroin, and phencyclidine. Pyrolysis of these drugs leads to the inhalation not only of the parent drug but also of characteristic breakdown products of combustion. For example, a major pyrolysis product of "crack" cocaine smoking is anhydroecgonine methylester (Martin et al., 1989) (Fig. 31-3). Thus, identification of relatively high concentrations of this compound along with cocaine or cocaine metabolites in urine or other body fluids or tissues indicates smoking as the route of cocaine administration (Jacob et al., 1990).


Figure 31-6. Comparison of pentazocine distribution in fatal poisonings due to intravenous injection and oral administration. (Data from Baselt RC: Disposition of Toxic Drugs and Chemicals in Man, 2d ed. Davis, CA: Biomedical Publications, 1982, pp 603–606, and Poklis A, MacKell MA: Toxicological findings in deaths due to pentazocine: A report of two cases. Forensic Sci Int 20:89–95, 1982.)

The presence of a toxic material in the GI tract, regardless of the quantity, does not provide sufficient evidence to establish that agent as the cause of death. It is necessary to demonstrate that absorption of the toxicant has occurred and that it has been transported by the general circulation to the target organ in order to exert its lethal effect. This is established by blood and tissue analysis. An exception to the rule is provided by strong corrosive chemicals such as sulfuric acid, lye, and phenol, which exert their deleterious effects by directly digesting tissue, causing hemorrhage and shock. The results of urinalysis are often of little benefit in determining the physiologic effects of a toxic agent. Urine results establish only that the poison was present in the body at some time before death. Correlation of urine values with physiologic effects is poor because of various factors that influence the rate of excretion of specific compounds and the urine volume.

The physiologic effects of most drugs and poisons are correlated with their concentrations in blood or blood fractions such as plasma and serum. Indeed, in living persons, this association is the basis of therapeutic drug monitoring. However, postmortem blood has been described as a fluid resembling blood that is obtained from the vasculature after death. Therefore interpretation of postmortem blood results requires careful consideration of the case history, the site of collection, and postmortem changes. The survival time between the administration of a poison and death may be sufficiently long to permit biotransformation and excretion of the agent. Blood values may appear to be nontoxic or consistent with therapeutic administration. Death from hepatic failure after an acetaminophen overdose usually occurs at least 3 to 4 days after ingestion. Postmortem acetaminophen concentrations in blood may be consistent with the ingestion of therapeutic doses. Therefore, fatal acetaminophen overdose is established by case history, central lobular necrosis of the liver, and, if available, analysis of serum specimens collected from the decedent when he or she was admitted to the emergency department (Price et al., 1991). Emergency medical treatment—such as the administration of fluids, plasma extenders, diuretics, and blood transfusions—may dilute or remove toxic agents. Similarly, prolonged survival on a mechanical respirator, hemodialysis, or hemoperfusion may significantly reduce initially lethal blood concentrations of poisons.

Until recently, it was generally assumed that postmortem blood drug concentrations were more or less uniform throughout the body. However, in the 1970s, several investigators noted that postmortem concentrations of digoxin in heart blood greatly exceeded those in simultaneously collected femoral blood. They also observed that postmortem blood concentrations, particularly in heart blood, exceeded the expected values at the time of death (Vorpahl and Coe, 1978; Aderjan et al., 1979). This postmortem increase in blood digoxin concentrations was apparently due to release of the drug from tissue stores, particularly the myocardium. Recently, other researchers have demonstrated that for many drugs, blood concentrations in the same body vary greatly depending on the site from which the specimen is collected: subclavian vein, thoracic aorta, inferior vena cava, femoral vein, and so forth. For example, in a case of fatal multiple drug ingestion, analysis of postmortem blood collected from 10 different sites demonstrated imipramine concentrations that differed by as much as 760 percent (2.1 to 16.0 mg/L) (Jones and Pounder, 1987). In an extensive investigation, Prouty and Anderson (1990) demonstrated that postmortem blood drug concentrations were not only site-dependent but increased greatly over the interval between death and specimen collection, particularly in heart blood. This increase over the postmortem interval was most pronounced for basic drugs with large apparent volumes of distribution, such as tricyclic antidepressants.

In an overt drug overdose, postmortem blood concentrations are elevated sufficiently to render an unmistakable interpretation of fatal intoxication. However, in many cases, the postmortem redistribution of drugs may significantly affect the interpretation of analytic findings. For drugs whose volume of distribution, plasma half-life, and renal clearance vary widely from person to person or that undergo postmortem redistribution, tissue concentrations readily distinguish therapeutic administration from drug overdose (Apple, 1989). Therefore, to provide a foundation of reasonable medical certainty in regard to the role of a drug in the death of an individual, it is recommended that, in addition to heart blood, a peripheral blood specimen and tissues be analyzed.

The analysis of tissue specimens is important for the estimation of a "minimal administered dose" or body burden of a drug or poison. In order to calculate a minimum body burden, it is necessary to analyze as many different body tissues and fluids as possible to determine the concentrations of the drug present. The concentration of drug in each separate specimen is then multiplied by the total weight or volume of that particular tissue or fluid. In this manner, the total amount of drug in each different tissue or fluid is determined. The amounts of drug in each separate tissue and fluid are then added together to give the total body burden or minimal administered dose. This simple approach has often proven extremely effective in resolving legal medical issues. For example, lidocaine is commonly administered in 50- to 100-mg bolus injections as an antiarrythmic agent for ventricular arrhythmia during resuscitation efforts. Because of poor circulation and tissue perfusion during arrhythmias, lidocaine is not well distributed in the body of the victim of a fatal heart attack. Postmortem bloods often exceed 50 mg/L in such cases, while values for

effective antiarrythmic prophylaxis do not exceed 5 mg/L. Therefore, a blood lidocaine value of 50 mg/L may be an artifact of resuscitation efforts or might represent a fatal overdose. Tissue distribution studies have resolved this issue in both accidental and homicidal poisoning with lidocaine (Poklis et al., 1984).

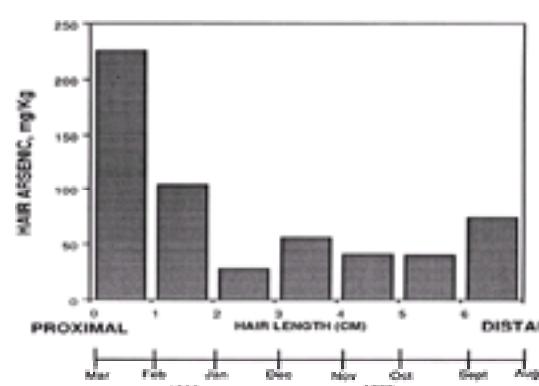
Postmortem toxicology results are often used to corroborate investigative findings. For example, the analysis of sequential sections of hair provides a reliable correlation with the pattern of arsenic exposure. Significant increases in the arsenic content of the root and the first 5 mm of the hair occur within hours after the ingestion of arsenic (Smith, 1964). The germinal cells are in relativity close equilibrium with circulating arsenic; thus, as arsenic concentrations in blood rise or fall, so does arsenic deposition in growing hair. Normal arsenic content in hair varies with nutritional, environmental, and physiologic factors; however, the maximum upper limit of normal with a 99 percent confidence limit in persons not exposed to arsenic is 5 mg/kg (Shapiro, 1967). Hair grows at a rate of approximately 12.5 mm (in.) per month. Therefore, analysis of 1.0-cm segments provides a monthly pattern of exposure (Fig. 31-7). Such analyses are often performed in cases of homicidal poisoning to demonstrate that increases in arsenic deposition in the victim's hair correlate with times when a poisoner had an opportunity to administer the poison. Continuously elevated hair arsenic values indicate chronic rather than acute poisoning as the cause of death.


Figure 31-7. Results of neutron activation analysis for arsenic in sequential sections of hair, demonstrating chronic arsenic poisoning. Increased exposure in the first two sections is consistent with fatal events. Lower values in section 3 are consistent with 2 weeks of hospitalization. (Data from Poklis A, Saady JJ: Arsenic poisoning: Acute or chronic? Suicide or murder? Am J Forensic Med Pathol 11:226–232, 1990.)

A new extension of forensic toxicology is the analysis of impurities of illicit drug synthesis in biological specimens. Many drugs of abuse are illicitly manufactured in clandestine laboratories, particularly methamphetamine. There are several popular methods of methamphetamine synthesis; when these are applied in clandestine laboratories, side reactions or incomplete conversion of the reactants yield an impure mixture of methamphetamine and synthetic impurities. These impurities can be characteristic of a particular synthetic method and their detection in biological specimens can indicate use of an illicitly produced drug that is not a legal pharmaceutical product; suggest the synthetic method that was used to produce the drug; point to a possible common source of illicit production; and provide a link between manufacturers, dealers, and users. A recent example of impurity analysis was the detection of metabolites of a-benzyl- Λ-methylphenethylamine (BNMPA) in the urine of abusers of methamphetamine (Moore et al., 1996) and in a case of fatal drug overdose involving methamphetamine (Moore et al., 1996). BNMPA is an impurity arising from the synthesis of methamphetamine via the Leukart reaction using phenyl-2-propanone (P2P) synthesized from phenylacetic acid. Clandestine laboratories often must synthesize the P2P starting material, as its sale and distribution is regulated by the federal Drug Enforcement Agency.

CRIMINAL POISONING OF THE LIVING

Over the past few decades, forensic toxicologists have become more and more involved in the analysis of specimens obtained from living victims of criminal poisonings. Generally, this increase in testing has arisen from two types of cases: (1) administration of drugs to incapacitate victims of kidnapping, robbery, or sexual assault and (2) poisoning as a form of child abuse.

For centuries those severely intoxicated from alcohol often became victims of kidnapping, robbery, or sexual assault. In the days of sail, the kidnapping of drunks in seaports was a common way of obtaining sailors for long commercial voyages such as those involved in whaling. Late in the nineteenth century, the mixing of the powerful hypnotic chloral hydrate with alcohol produced the legendary "Mickey Finn." While alcohol is still often a primary factor in cases of alleged sexual assault, common drugs of abuse or other psychoactive drugs are often involved (Table 31-2). Of particular concern are the many potent inductive agents medically administered prior to general anesthesia. Many of these drugs, such as benzodiazepines and phenothiazines, are available today through illicit sources or legal purchase in foreign countries. When administered surreptitiously, they cause sedation and incapacitate the victim while also producing amnesia in the victim as to the events while drugged without causing severe central nervous system depression. These cases often present a difficult analytic challenge to the toxicologist. Usually the victim does not bring forth an allegation of assault until 24 h to several days after the attack. Thus, the intoxicating drug may have been largely eliminated or extensively metabolized such that extremely low concentrations of drug or metabolites are present in the victim's blood, urine, and/or hair specimens. Sophisticated, highly sensitive analytic methods such as GC/MS or HPLC/MS may be required to accurately identify drugs in such specimens. To provide guidance in the choice of analytic approaches to such cases, recommendations for the toxicologic investigation of sexual assaults have recently been formulated by the Toxicology Section of the American Academy of Forensic Sciences (LeBeau et al., 1999).

Table 31-2 Distribution of Drugs of Abuse Encountered Urine Specimens in 578 Cases of Alleged Sexual Assault

Poisoning as a form of child abuse involves the deliberate administration of toxic or injurious substances to a child, usually by a parent or other caregiver. The victims of such poisonings range in age from a few months to the teens. Common agents used to intentionally poison children have included syrup of ipecac, table salt, laxatives, diuretics, antidepressants, sedative-hypnotics, and narcotics (Dine and McGovern, 1982). The motivation for such heinous behavior is in the province of psychiatry, not toxicology. However, toxicologists must have some understanding of the nature of these poisonings to aid in the investigation of such cases. In some instances, it is a form of child battering committed by persons with low tolerance to the child's upsetting behaviors. The poison may be given to an infant to stop its crying or be force-fed to older children as a form of punishment. Such behavior is characteristic of persons with a cultural background where violence toward children is common or who have severe personality disorders or other mental illnesses. "Munchausen syndrome by proxy" is to another form of child poisoning (Murray, 1997). The *term Munchausen syndrome* (MS) is used to describe patients who seek admission to hospitals with apparent illness along with plausible, dramatic, albeit fictitious medical histories. Such people seek medical treatment solely to assume the role of a patient and receive the attention derived from this deception. "MS by proxy" refers to the situation in which an individual, usually a parent, presents not him- or herself but a child with a fictitious illness often induced by physical or chemical means. The purpose of the poisoning is not to kill the child but to induce signs and symptoms of illness that will assure medical attention. Thereby, the parent as caregiver gains the craved attention. Given a fictitious case history and the obvious illness of the child, these cases are almost always and understandably misdiagnosed. Often the child may be chronically poisoned at home and in the hospital for as long as a year before suspicion leads to the collection of specimens for extensive toxicologic testing. Although the parent may not have intended such an outcome, some children have died from fatal poisoning in these situations. As in the

case of sexual assault, sophisticated GC/MS testing methods may be required to detect such agents as emetine and cephaeline, the emetic alkaloids in syrup of ipecac. Testing in these cases is best preformed in a laboratory with forensic experience, as positive drug findings will usually result in some form of legal proceeding.

FORENSIC URINE DRUG TESTING

Concerns about the potentially adverse consequences of substance abuse both for the individual and for society have led to widespread urine analysis for the detection of controlled or illicit drugs (Gust and Walsh, 1989). Currently, such testing is conducted routinely by the military services, regulated transportation and nuclear industries, many federal and state agencies, public utilities, federal and state criminal justice systems, and numerous private businesses and industries. Significant ethical and legal ramifications are associated with such testing. Those having positive test results may not receive employment, be dismissed from a job, be court-martialed, or suffer a loss of reputation.

To assure the integrity of workplace urine testing, two certification programs currently accredit forensic urine-testing laboratories. Laboratories conducting testing of federal employees are required to be certified under the Department of Health and Human Services Mandatory Guidelines for Workplace Drug Testing as published in the April 11, 1988, *Federal Register* (Department of Health and Human Services, 1988). The College of American Pathologists (CAP) also conducts a certification program for urine-testing laboratories. The federal program regulates a specific program from specimen collection through testing to the reporting of results, whereas the CAP program allows flexibility in the construction of programs servicing a broad range of clients. Both programs involve periodic on-site inspection of laboratories and proficiency testing.

Forensic urine drug testing (FUDT) differs from other areas of forensic toxicology in that urine is the only specimen analyzed and testing is performed for a limited number of drugs. At present, under the federal certification program, analyses are performed for only five drug classes or drugs of abuse (Table 31-3). While FUDT laboratories typically analyze 100 to 1000 urine specimens daily, only a relatively small number of those specimens are positive for drugs. To handle this large workload, initial testing is performed by immunoassays on high-speed, large-throughput analyzers. A confirmation analysis in FUDT-certified laboratories is performed by GC/MS.

Table 31-3 Forensic Urine Drug-Testing Analytes and Cutoff Concentrations

Proper FUDT is a challenge to good laboratory management. As with all forensic activities, every aspect of the laboratory operation must be thoroughly documented: specimen collection, chain of custody, quality control, procedures, testing, qualifications of personnel, and the reporting of results. The facility must be constructed and operated to assure total security of specimens and documents. Confidentiality of all testing results is paramount; only specifically authorized persons should receive the results. The presence of a controlled or illicit drug in a single random urine specimen is generally accepted as proof of recent or past substance abuse. However, positive urine drug findings are only evidence that, at some time before the collection of the sample, the individual was administered the drug, self-administered it, or was exposed to it. Positive urine tests do not prove impairment from the drug, abuse, or addiction.

FUDT results are reported only as positive or negative for the drugs sought. Cutoff values are established for both the initial and confirmation assays (Table 31-2). The cutoff value is a concentration at or above which the assay is considered positive. Below the cutoff value, the assay is negative. Obviously, drugs may be present below the cutoff concentration. However, the use of cutoff values allows uniformity in the drug testing and reporting of results. All test reports indicate the drug tested and its cutoff value. FUDT laboratories must be thoroughly familiar with all regulatory and analytic issues related to urine testing and devise strategies to resolve uncertainties. Many individuals who are subject to regulated urine testing have devised techniques to mask their drug use either by physiologic means such as the ingestion of diuretics or by attempting to adulterate the specimen directly with bleach, vinegar, or other products that interfere with the initial immunoassay tests (Warren, 1989). Thus, specimens are routinely tested for adulteration by checking urinary pH, creatinine, and specific gravity and noting any unusual color or smell. Recently a mini-industry has developed to sell various products that are alleged to "fool drug testers." These products often have colorful trade names such as UrinAid, Instant Clean ADD-IT-ive, and Klear. They contain chemicals that, when added to a urine specimen, interfere with either the initial or confirmatory drug test. For example, several of these products contain glutaraldehyde, which will react with the nitrogen atoms of the antibody proteins of the immunoassay screening test, thereby cross-linking the antibodies and inactivating the assay. However, this distruction of the test is so complete that the immunoassay analyzer records almost no signal, thus indicating possible adulteration of the specimen. Another adulterant, for the marijuana metabolite urine test, contains sodium nitrite. In acidic urine, the nitrite salt is converted to nitrous acid, which then converts the marijuana metabolites to nitroso derivatives, rendering them undetectable by routine GC/MS analysis (Lewis et al., 1999). Often the pH of the urine is insufficiently acidic for complete nitroso conversion of the tetrahydrocannabinol (THC) metabolite, THC–carboxylic acid. Thus the urine will screen positive by the initial immunoassay. When urine is acidified to extract the THC acid metabolite for MS confirmation testing, the metabolite is completely oxidized and undetectable. However, the deuterated THC–carboxylic acid added to the sample as the internal standard of the confirmation test is also completely destroyed. Failure to detect the internal standard readily alerts the analyst that an oxidant adulterant had been added to the urine. In such cases, a quantitative test for nitrite is performed. Nitrite may be present in urine from numerous internal and external sources such as foods, drugs, pathologic conditions, and infection from nitrate-reducing microorganisms. However, none of these sources produces urinary nitrite concentrations that even begin to approach those obtained by the addition of adulterant amounts of potassium nitrite, >1000 mg/L (Urey et al., 1998). Most chemical adulterants can be detected in urine by specific colorimetric tests that can be readily adapted to high-volume auto-analyzers (Table 31-4). Thus, FUDT laboratories now routinely test not only for drugs of abuse but also for a wide variety of chemical adulterants. In most instances, a positive test result for adulteration has as serious a consequence as a positive drug test.

Table 31-4 Urine Adulterants Detected by Chemical Test

There may be valid reasons other than substance abuse for positive drug findings, such as therapeutic use of controlled substances, inadvertent intake of drugs via food, and passive inhalation. For example, the seed of *Papaver somniferum,* poppy seed, is a common ingredient in many pastries and breads. Depending on their

botanical source, poppy seeds may contain significant amounts of morphine. Several studies have demonstrated that the ingestion of certain poppy-seed foods results in the urinary excretion of readily detectable concentrations of morphine (ElSohly and Jones, 1989). Morphine is a major urinary metabolite of heroin. Therefore, to readily differentiate heroin abuse from poppy seed ingestion, analysis may be performed for 6-monoacetylmorphine, a unique heroin metabolite (Fehn and Megges, 1985).

Even over-the-counter medications may present potential problems for laboratories conducting urine drug testing. Methamphetamine may occur as a racemic mixture of *d* and *l* optical isomers. *c*-Methamphetamine, a Schedule II controlled substance, is a potent central nervous system stimulant subject to illicit drug abuse, while *l*-methamphetamine (*l*-desoxyephedrine) is an alpha-adrenergic stimulant available in over-the-counter Vicks inhalers as a nasal decongestant. Cross-reactivity of *l*-desoxyephedrine with the initial immunoassay screening test may occur after excessive use of the Vicks inhaler (Poklis and Moore, 1995). Additionally, the most popular confirmational GC/MS products for amphetamines are achiral. Therefore, if such analyses are performed, a "false-positive" result for *c*-methamphetamine may be reported. This dilemma is easily resolved if confirmational testing is done with a *chiral* GC/MS procedure, which can readily resolve the stereoisomers of methamphetamine (Fitzgerald et al., 1988).

HUMAN PERFORMANCE TESTING

Forensic toxicology activities also include the determination of the presence of ethanol and other drugs and chemicals in blood, breath, or other specimens and the evaluation of their role in modifying human performance and behavior. The most common application of human performance testing is to determine driving under the influence of ethanol (DUI) or drugs (DUID). While operation of a motor vehicle is a common experience to most people, few appreciate the complexity of mental and physical functioning involved. A driver must simultaneously coordinate fine motor skills in tracking the road course and applying pressure to accelerator or brake—with visual attention immediately in front, to the horizon, and to the periphery of the vehicle—while continuously judging distance, speed, and appropriateness of response to signals, traffic, and unexpected events. The threshold blood ethanol concentration (BAC) for diminished driving performance of these complex functions in many individuals is as low as 0.04 g/dL, the equivalent of ingestion of two beers within an hour's time. The statutory definition of DUI in the United States is a BAC of either 0.08 or 0.10 g/dL, depending on the particular state law. These concentrations are consistent with diminished performance of complex driving skills in the vast majority of individuals. Over the past half century, an enormous amount of data has been developed correlating blood ethanol concentrations with intellectual and physiologic impairment, particularly of the skills associated with the proper operation of motor vehicles. Numerous studies have demonstrated a direct relationship between an increased BAC in drivers and an increased risk of involvement in road accidents (Council on Scientific Affairs, 1986). Alcohol-impaired drivers are responsible for 25 to 35 percent of all crashes causing serious injury in single-vehicle accidents, and 55 to 65 percent of fatally injured drivers have a BAC of 0.10 g/dL or greater.

During the past decade, there has been growing concern about the deleterious effects of drugs other than ethanol on driving performance. Several studies have demonstrated a relatively high occurrence of drugs in impaired or fatally injured drivers (White et al., 1981; Mason and McBay, 1984). These studies tend to report that the highest drug-use accident rates are associated with the use of such illicit or controlled drugs as cocaine, benzodiazepines, marijuana, and phencyclidine. However, most studies test for only a few drugs or drug classes, and the repeated reporting of the same drugs may be a function of limited testing. Before "driving under the influence of drugs" testing is as readily accepted by the courts as ethanol testing, many legal and scientific problems concerning drug concentrations and driving impairment must be resolved (Consensus Report, 1985). The ability of analytic methodology to routinely measure minute concentrations of drug in blood must be established. Also, drug-induced driving impairment at specific blood concentrations in controlled tests and/or actual highway experience must be demonstrated.

COURTROOM TESTIMONY

The forensic toxicologist often is called upon to testify in legal proceedings. As a general rule of evidence, a witness may testify only to facts known to him or her. The witness may offer opinions solely on the basis of what he or she has observed (Moenssens et al., 1973). Such a witness is called a "lay witness." However, the toxicologist is referred to as an "expert witness." A court recognizes a witness as an expert if that witness possesses knowledge or experience in a subject that is beyond the range of ordinary or common knowledge or observation. An expert witness may provide two types of testimony: objective testimony and "opinion." Objective testimony by a toxicologist usually involves a description of his or her analytic methods and findings. When a toxicologist testifies as to the interpretation of his or her analytic results or those of others, that toxicologist is offering an "opinion." Lay witnesses cannot offer such opinion testimony, as it exceeds their ordinary experience.

Before a court permits opinion testimony, the witness must be "qualified" as an expert in his or her particular field. In qualifying someone as an expert witness, the court considers the witness's education, on-the-job training, work experience, teaching or academic appointments, and professional memberships and publications as well as the acceptance of the witness as an expert by other courts. Qualification of a witness takes place in front of the jury members, who consider the expert's qualifications in determining how much weight to give his or her opinions during their deliberations.

Whether a toxicologist appears in criminal or civil court, workers' compensation or parole hearings, the procedure for testifying is the same: direct examination, cross-examination, and re-direct examination. The attorney who has summoned the witness to testify conducts direct examination. Testimony is presented in a question-and-answer format. The witness is asked a series of questions that allow him or her to present all facts or opinions relevant to the successful presentation of the attorney's case. During direct examination, an expert witness has the opportunity to explain to the jury the scientific bases of his or her opinions. Regardless of which side has called the toxicologist to court, the toxicologist should testify with scientific objectivity. Bias toward his or her client and prejudgments should be avoided. An expert witness is called to provide informed assistance to the jury. The jury, not the expert witness, determines the guilt or innocence of the defendant.

After direct testimony, the opposing attorney questions the expert. During this cross-examination, the witness is challenged as to his or her findings and/or opinions. The toxicologist will be asked to defend his or her analytic methods, results, and opinions. The opposing attorney may imply that the expert's testimony is biased because of financial compensation, association with an agency involved in the litigation, or personal feelings regarding the case. The best way to prepare for such challenges before testimony is to anticipate the questions the opposing attorney may ask.

After cross-examination, the attorney who called the witness may ask additional questions to clarify any issues raised during cross-examination. This allows the expert to explain apparent discrepancies in his or her testimony raised by the opposing attorney. Often an expert witness is asked to answer a special type of question, the "hypothetical question." A hypothetical question contains only facts that have been presented in evidence. The expert is then asked for his or her conclusion or opinion based solely on this hypothetical situation. This type of question serves as a means by which appropriate facts leading to the expert's opinion are identified. Often these questions are extremely long and convoluted. The witness should be sure he or she understands all the facts and implications in the question. Like all questions, this type should be answered as objectively as possible.

ANALYTIC ROLE IN CLINICAL TOXICOLOGY

Analytic toxicology in a clinical setting plays a role very similar to its role in forensic toxicology. As an aid in the diagnosis and treatment of toxic incidents as well as in monitoring the effectiveness of treatment regimens, it is useful to clearly identify the nature of the toxic exposure and measure the amount of the toxic substance that has been absorbed. Frequently, this information, together with the clinical state of the patient, permits a clinician to relate the signs and symptoms observed to the anticipated effects of the toxic agent. This may permit a clinical judgment as to whether the treatment must be vigorous and aggressive or whether simple observation and symptomatic treatment of the patient are sufficient.

A cardinal rule in the treatment of poisoning cases is to remove any unabsorbed material, limit the absorption of additional poison, and hasten its elimination. The clinical toxicology laboratory serves an additional purpose in this phase of the treatment by monitoring the amount of the toxic agent remaining in circulation or measuring what is excreted. In addition, the laboratory can provide the data needed to permit estimations of the total dosage or the effectiveness of treatment by changes in known pharmacokinetic parameters of the drug or agent ingested.

While the instrumentation and the methodology used in a clinical toxicology laboratory are similar to those utilized by a forensic toxicologist, a major difference between these two applications is responsiveness. In emergency toxicology testing, results must be communicated to the clinician within hours for the results to be meaningful for therapy. A forensic toxicologist may carefully choose the best method for a particular test and conduct replicate procedures to assure maximum accuracy. A clinical laboratory cannot afford this luxury and frequently sacrifices accuracy for a rapid turnaround time. Additionally, because it is impossible to predict when toxicologic emergencies will occur, a clinical laboratory must provide rapid testing 24 h a day every day of the year. The most commonly encountered intoxicants in emergency toxicology testing and the rapid methodologies to detect their presence in serum and/or urine specimens are presented in Table 31-5.

Table 31-5 Most Commonly Encountered Drugs and Methods for Analysis in Emergency Toxicology

Primary examples of the usefulness of emergency toxicology testing are the rapid quantitative determination of acetaminophen, salicylate, alcohols, and glycol serum concentrations in instances of suspected overdose. Acetaminophen serum values related to the time after ingestion (Chap. 32) not only indicate an overdose, but provide a prognosis for possible delayed hepatotoxicity and the need to continue administration of *n*-acetylcystine antidote. In addition, continuous monitoring of serum values permits an accurate pharmacokinetic calculation of the ingested dose (Melethil et al., 1981). Similarly, salicylate serum values related to the time after ingestion may indicate an overdose, providing a prognosis for possible delayed severe metabolic acidosis and the need for life saving dialysis treatment. Continuous monitoring of serum salicylate values permits an accurate assessment of the efficacy of dialysis.

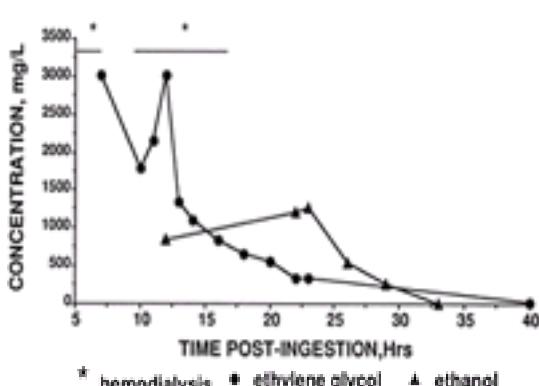
Ethanol is the most common agent encountered in emergency toxicology. While few fatal intoxications occur with ethanol, serum values are important in the assessment of behavioral and neurologic function, particularly in trauma cases where the patient is unable to communicate and surgery with the administration of anesthetic or analgesic agents is indicated. Intoxications from accidental or deliberate ingestion of other alcohols or glycols—such as methanol from windshield deicer or paint thinner, isopropanol from rubbing alcohol, and ethylene glycol from antifreeze—are often encountered in emergency departments. Following ingestion of methanol or ethylene glycol, patients often present with similar neurologic symptoms and severe metabolic acidosis due to the formation of toxic aldehyde and acid metabolites. A rapid quantitative serum determination for these intoxicants will indicate the severity of intoxication and the possible need for dialysis therapy. Alcohol infusion, in order to saturate the enzyme alcohol dehydrogenase, blocks the conversion of methanol and ethylene glycol to their toxic metabolites. Continuous monitoring of serum values not only permits an assessment of the clearance of the intoxicant by dialysis but also assures a proper infusion rate of alcohol for effective antidotal concentrations (Fig. 31-8). To provide effective service to the emergency department, laboratories should have available chromatographic methods for the rapid separation and detection of alcohols and glycols (Edinboro et al., 1993).


Figure 31-8. Serum ethylene glycol and ethanol concentrations monitored during dialysis and ethanol infusion therapy. (Data from the Toxicology Laboratory, Medical College of Virginia Hospital, Richmond, VA.)

The utilization of the analytic capabilities of a clinical toxicology laboratory has increased enormously in recent years. Typically, the laboratory performs not only testing not only for the emergency department but also for a wide variety of other medical departments, as drugs and toxic agents may be a consideration in diagnosis. Urine is analyzed from substance abuse treatment facilities to monitor the administration of methadone or other therapeutic agents and/or to assure that patients do not continue to abuse drugs. Similarly, psychiatrists, neurologists, and physicians treating patients for chronic pain need to know whether patients are self-administering drugs before such patients undergo psychiatric or neurologic examinations. Analysis for drugs of abuse in meconium and urine obtained from neonates is used to corroborate the diagnosis of withdrawal symptoms in newborns and document fetal exposure to controlled substances. Toxic metal determinations, such as blood lead concentration, are often performed to assess possible toxic metal exposure or severity of toxicity (Chap. 23). Analysis of heavy metals in 24-h urine specimens is often used to rule out toxic metal exposure as a cause of symmetrical peripheral neuropathy prior to the diagnosis of neurologic disorders such as Guillian-Barré syndrome. The clinical toxicology laboratory may often perform unique diagnostic tests that require sophisticated analytic capabilities such as GC/MS and HPLC analysis for organic acids and amino acids to detect inborn errors of metabolism in infants and children. Methods for the analysis of abnormal organic acids will also detect acidic drugs and other intoxicants such as salicylates, ethylene glycol, gamma-hydroxybutyric acid, and valproic acid. Another such diagnostic test requiring sensitive chromatography is the timed metabolism of lidocaine to its monoethylglycinexylidide (MEGX) metabolite (O'Neal and Poklis, 1996). The rate of this conversion is a sensitive indicator of hepatic dysfunction and is often used to assess hepatic viability in donor livers prior to transplantation. MEGX formation may also be useful in monitoring the severity of the histologic condition of patients with chronic hepatitis and cirrhosis (Shiffman et al., 1994).

ANALYTIC ROLE IN THERAPEUTIC MONITORING

Historically, the administration of drugs for long-term therapy was based largely on experience. A dosage amount was selected and administered at appropriate intervals based on what the clinician had learned was generally tolerated by most patients. If the drug seemed ineffective, the dose was increased; if toxicity developed, the dose was decreased or the frequency of dosing was altered. At times, a different dosage form might be substituted. Establishing an effective dosage regimen was particularly difficult in children and the elderly.

The factors responsible for individual variability in responses to drug therapy include the rate and extent of drug absorption, distribution and binding in body tissues and fluids, rate of metabolism and excretion, pathologic conditions, and interaction with other drugs (Blaschke et al., 1985). Monitoring of the plas-ma or serum concentration at regular intervals will detect deviations from the average serum concentration, which, in turn, may suggest that one or more of these variables need to be identified and corrected.

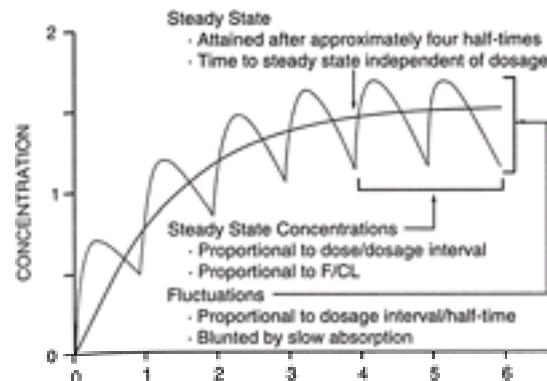
In a given patient, when the various factors are assumed to be constant, the administration of the same dose of a drug at regular intervals eventually produces a steady-state condition (Fig. 31-9) (Moyer et al., 1986). Monitoring of steady-state drug concentrations assures that an effective concentration is present. For drugs that have a defined correlation between serum values and undesired toxic effects, the lowest serum value immediately prior to dosing (trough) and the highest expected serum concentration (peak) are monitored to assure efficacy and minimize toxicity. Appropriate situations for therapeutic drug monitoring are presented in Table 31-6.


Figure 31-9. Fundamental pharmacokinetic relationships for the repeated administration of drugs.

The blue line is the pattern of drug accumulation during the repeated administration of a drug at intervals equal to its elimination half-time, when drug absorption is ten times as rapid as elimination. As the relative rate of absorption increases, the concentration maxima approach 2 and minima approach 1 during steady-state. The black line depicts the pattern during administration of equivalent dosage by continuous intravenous infusion. Curves are based upon the one-compartment model. Average concentration (Css) when steady state is attained during intermittent drug administration is Css = F × dose/Cl × T, where F = fractional bioavailability of the dose and T = dosage interval (time). By substitution of infusion rate for F × dose/T, the formula is equivalent to Eq. (1) and provides the concentration maintained at steady state during continuous intravenous infusion. [From Hardman JG, Limbird LE, Molinoff PB, et al (eds): *Goodman & Gilman's The Pharmacological Basis of Therapeutics,* 9th ed. New York: McGraw-Hill, 1995, p 23.]

Table 31-6 Appropriate Use of Therapeutic Drug Monitoring

Because the drug being administered is known, qualitative characterization of the analyte generally is not required. Quantitative accuracy is required, however. Frequently, the methodology applied is important, particularly in regard to its selectivity. For example, methods that measure the parent drug and its metabolites are not ideal unless the individual analytes can be quantified separately. Depending on the drug, metabolites may or may not be active to a different degree than the parent drug. The cardiac antiarrythmic drug procainamide is acetylated during metabolism to form *N*-acetylprocainamide (NAPA). This metabolite has antiarrythmic activity of almost equal potency to that of the parent drug, procainamide. There is bimodal genetic variation in the activity of the *N*-acetyltransferase for procainamide, so that, in "fast acetylators," the concentration of NAPA in the serum may exceed that of the parent drug. For optimal patient management, information should be available about the concentrations of both procainamide and NAPA in serum (Bigger and Hoffman, 1985).

Since absolute characterization of the analyte is not necessary for many drugs, immunoassay procedures are commonly used. This is particularly true of drugs with extremely low serum concentrations, such as cardiac glycosides, and drugs that are difficult to extract because of a high degree of polarity, such as the aminoglycoside antibiotics. In these cases, serum can be conveniently assayed directly by using commercially available kits for immunoassays.

The chromatographic methods in which an appropriate internal standard is added are favored when more than one analyte is to be measured or if metabolites with structures similar to those of the parent drugs must be distinguished. Since the nature of drugs is varied, many different analytic techniques may be applied, including atomic absorption spectrophotometry for measuring lithium used to treat manic disorders. Virtually all the tools of the analyst may be used for specific applications of analytic toxicology. Drugs that are commonly monitored during therapy, their usual effective therapeutic serum concentrations, "panic values," and typical analytic methodologies applied to serum measurements are presented in Table 31-7. The term *panic value* denotes a serum drug concentration associated with the development of potentially serious toxicity. In clinical laboratories, the "panic value" alerts the toxicologist that the treating physician must be *immediately* contacted and notified of the test result.

Table 31-7 Drugs Commonly Indicated for Therapeutic Monitoring

ANALYTIC ROLE IN BIOLOGICAL MONITORING

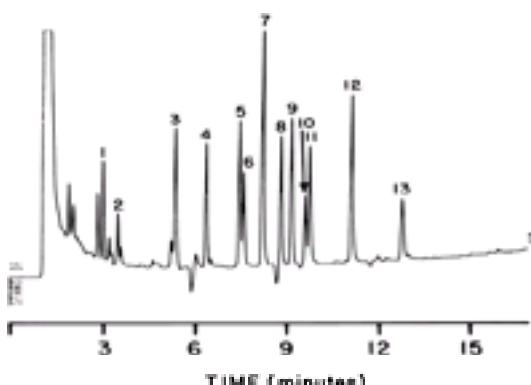
In the workplace, good industrial hygiene practices require monitoring of the environment to which workers are exposed in order to identify potentially harmful amounts of hazardous chemicals. Despite these precautions, it has become apparent that monitoring a worker directly can be a better indicator of exposure because it can show what has actually been absorbed. This is biological monitoring, and it can take a variety of forms. Often environmental exposures are to a mixture of compounds and/or to compounds that are converted to physiologically important metabolites. Thus, analytic methods must be capable of separating a family of chemical agents and their major metabolites (Fig. 31-10). Additionally, methods must be sufficiently specific and sensitive to measure minute concentrations of the compounds in complex biological matrices.


Figure 31-10. Capillary gas chromatographic separation of chlorinated hydrocarbon pesticides added to human serum at concentrations ranging from 1 to 4 ng/mL.

Peak number 1, a-lindane; 2, c-lindane; 3, heptachlor; 4, internal standard; 5, heptachlor epoxide; 6, oxychlordane; 7, c-chlordane; 8, a-chlordane; 9, *trans*-nonachlor; 10, dieldrin; 11, p,p9-DDE; 12, p,p-DDD; 13, p,p9-DDT. (Separation based on the method of Saady JJ, Poklis A: Determination of chlorinated hydrocarbon pesticides by solid phase extraction and capillary GC with electron capture detection. *J Anal Toxicol* 14:301–304, 1990.)

An example of biological monitoring is presented in Table 31-8, which shows data relating to benzene exposure of chemists engaged in pesticide residue analysis in a state regulatory laboratory. Air-monitoring devices in this laboratory indicated that the ambient benzene concentration never exceeded the time-weighted average (TWA) of 32 mg/m^3 (10 ppm). Monitoring of the breathing zones at different locations around the laboratory where benzene was in use showed other concentrations of this material. When expired air was monitored, one worker showed a significantly greater amount of benzene exposure than did others. Upon questioning, she recalled spilling some of the solvent on a laboratory bench, in the process saturating a portion of her laboratory coat. Presumably, her exposure by inhalation and skin absorption was considerably greater than was indicated by the air monitor.

SOURCE	BREATH BENZENE, ppm	AIR BENZENE, ppm

Fume hood breathing zone	—	51.2

Table 31-8 Benzene Exposure of Chemists Performing Pesticide Residue Analysis

In addition to the measurement of the chemical or its metabolites in the body fluids, hair, or breath of the worker, other, more indirect methods may be employed. Substances that interact with macromolecules may form adducts that persist for long periods. These adducts can be sampled periodically and potentially can serve as a means of integrating exposure to certain substances over long periods. For example, adducts of ethylene oxide with DNA or hemoglobin have been studied in workers. This technique may also be applicable in other situations that are not necessarily related to occupational hazards. Acetaldehyde, a metabolite of ethanol, forms adducts with hemoglobin. This marker may be of use in forensic cases (Stockham and Blanke, 1988).

Another approach that is useful in biological monitoring is to measure changes of normal metabolites induced by xenobiotics. The profile of glucuronic acid metabolites excreted in urine can be altered after exposure to substances that induce monooxygen-ase activity. Although monitoring the alteration of the urinary excretion of these metabolites may not indicate exposure to specific substances, this technique can be used in a generic fashion to flag a potentially harmful exposure to a hepatotoxic agent (Saady and Blanke, 1990). The early recognition of a toxicologic problem may permit the protection of a worker before irreversible effects occur.

SUMMARY

The analytic techniques initiated by forensic toxicologists have continued to expand in complexity and improve in reliability. Many new analytic tools have been applied to toxicologic problems in almost all areas of the field, and the technology continues to open new areas of research. Forensic toxicologists continue to be concerned about conducting unequivocal identification of toxic substances in such a manner that the results can withstand a legal challenge. The problems of substance abuse, designer drugs, increased potency of therapeutic agents, and widespread concern about pollution and the safety and health of workers present challenges to the analyst's skills. As these challenges are met, analytic toxicologists continue to play a significant role in the expansion of the discipline of toxicology.

CHAPTER 32

CLINICAL TOXICOLOGY

Louis R. Cantilena, Jr.

HISTORY OF CLINICAL TOXICOLOGY

Historical Aspects of the Treatment of Poisoning

The history of poisons and poisoners dates back to ancient times. Homer's *Odyssey* and shastras from approximately 600 B.C. contain references to antidotes. The first documented use of a specific antidote may be found in the *Odyssey*, where it is suggested to Ulysses that he take moli to protect himself from poisoning. Moli may actually be *Galanthus nivalis*, a plant-derived cholinesterase inhibitor that might counteract the effects of the anticholinergic plant *Datura stramonium* (Plaitakis and Duvoisin, 1983).

Galen (A.D. 129 to 200) wrote three books called *De Antidotis I, De Antidotis II,* and *De Theriaca ad Pisonem,* which described the development of a universal antidote known as a alexipharmic or theriac by King Mithridates VI of Pontus, who lived from 132 to 63 B.C. (Wax, 1998). The antidote reportedly contained 36 or more ingredients and was ingested every day, conferring protection against a broad spectrum of poisons such as venomous stings and bites from vipers, spiders, and scorpions (Jarcho, 1972).

The refinement of theriac (antidote) formulations is documented for centuries. Andromachus (first century of the Christian era) was physician to Nero and improved the theriac of Mithridates by modifying the formula to include up to 73 ingredients (Wax, 1998). The use of these ancient antidotes included treatment of acute poisoning and prophylactic treatment to make one "poisonproof." This theriac, with subsequent modifications, remained in use for nearly 2000 years. In 1745, William Heberden wrote *Antitheriaka: An Essay on Mithridatium and Theriaca,* in which he questioned the effectiveness of these products (Jarcho, 1972). However, their use and availability continued until the early twentieth century.

One of the earliest writings on the prevention of the gastrointestinal absorption of poisons was by Nicander (Major, 1934). In this ancient writing, the induction of emesis by ingestion of an emetic agent or mechanical stimulation of the hypopharynx was described as a method to prevent poison absorption. The use of ipecacuanha for induction of emesis was not introduced until the 1600s, when it was recommended by William Piso (Reid, 1970).

The use of charcoal, now a mainstay in the treatment of many human poisonings, can be dated to early Greek and Roman civilization, when wood charcoal was used for the treatment of maladies such as anthrax and epilepsy (Cooney, 1995). The antidotal properties of charcoal were demonstrated in the 1800s by the French, with dramatic demonstrations of a reduction in lethality when charcoal was ingested with potentially lethal doses of arsenic trioxide by Bertrand and strychnine by Touery (Holt and Holz, 1963). One of the earliest reported human studies examining the efficacy of charcoal in poisoning was done in 1948 by the American physician Rand (Holt and Holz, 1963). The use of superheated steam to treat the charcoal so as to enhance its adsorptive capacity was reported by Ostrejko, a Russian scientist, in 1900 (Greensher et al., 1987). By the 1960s, the use of activated charcoal was routinely recommended for the treatment of patients poisoned with substances thought to be adsorbed to charcoal.

Introduction of the Poison Control Center

The evolution in the field of clinical toxicology paralleled the evolution of the poison control centers. In the 1940s, several European communities developed hospital-based treatment facilities for poisoning (Manoguerra and Temple, 1984). A study by the American Academy of Pediatrics completed in 1952 reported that more than half of childhood accidents involved unintentional poisoning in the United States. Possibly in response to this study, Dr. Edward Press started the first poison control center in the United States in Chicago. These centers became valuable resources for providing information about product ingredients and recommendations for treatment of poisoned patients. Poison control centers proliferated over the next two decades. It was estimated that over 650 centers were in operation by 1978. Through regionalization, consolidation, and certification, the number of poison control centers have significantly decreased to less than a hundred since that time.

Staffing of a poison control center usually consists of a medical director (medical toxicologist), administrator or managing director, specialists in poison information, and educators for poison prevention programs. The medical toxicologist, managing director, and specialists in poison information are health care professionals who are credentialed by their respective boards. The American Board of Medical Subspecialties offers a subspecialty certificate to physicians who successfully complete the certifying examination. The American Board of Applied Toxicology (ABAT) offers a certification examination for nonphysicians, and the American Association of Poison Control Centers (AAPCC) provides a certification of the specialists in poison information, who are usually nurses or pharmacists. The managing director is usually either the same person as the medical director or a nonphysician certified by the ABAT.

The public health services provided by poison control centers have been well documented. These services include direct information to patients with recommendations for needed treatment, critical diagnostic and treatment information for health care professionals, education for health care personnel, and poison prevention activities through public education. An example of the cost benefit of poison information centers comes from a 1-year forced closure of the Louisiana State Poison Center. When there was no poison center to call, the community was left with the alternative but a visit to an emergency department (ED) or doctor's office for information on exposures and their possible treatment. It was estimated that the increased costs to the state for emergency medical services was $1.4 million for that year (King, 1991).

CLINICAL STRATEGY FOR TREATMENT OF THE POISONED PATIENT

The initial phases of treatment of the poisoned patient usually occur in the setting of a hospital ED, but initial treatment in other, less ideal settings such as the battlefield, workplace, home. or street setting can be required as well. Most clinical toxicologists agree that a methodically executed, stepwise approach to the treatment of the poisoned patient is required for optimal care (Goldfrank, 1998, Ellenhorn, 1997). This section refers primarily to the treatment of poisoned patients in the ED setting. There, the following general steps represent important components of the initial clinical encounter with a poisoned patient:

1. Stabilization of the patient
2. Clinical evaluation (history, physical, laboratory, radiology)
3. Prevention of further toxin absorption
4. Enhancement of toxin elimination
5. Administration of antidote
6. Supportive care and clinical follow-up

Clinical Stabilization

The first priority in the treatment of the poisoned patient is stabilization. Assessment of the vital signs and the effectiveness of respiration and circulation are the initial concerns. There is a wide range of severity of the clinical toxicity demonstrated by patients poisoned with even lethal doses of toxins early in the course of the poisoning. Some agents, such as a benzodiazepine, can cause pronounced clinical effects, such as sedation, early, but can have a comparatively mild clinical course, while other toxins, such as camphor, show little clinical effect initially but can produce a fatal outcome. Some toxins or drugs can cause seizures early in the course of presentation. Control of toxin-induced seizures can be an important component of the initial stabilization of the poisoned patient. The degree of clinical stabilization required for a poisoned patient therefore is highly variable. The steps and clinical procedures incorporated to stabilize a critically ill poisoned patient are numerous and include assessment—and, if appropriate, support—of ventilation, circulation, and oxygenation. A detailed description of the various clinical methods available to treat abnormalities in these parameters is beyond the scope of this chapter. The reader is referred to textbooks of emergency medicine for further information of this subject. Once the poisoned patient is clinically stabilized, the remaining assessment and treatment steps can proceed.

Clinical History in the Poisoned Patient

The primary goal of taking a medical history in poisoned patients is to determine, if possible, the substance ingested or the substance to which the patient has been exposed as well as extent and time of exposure. Unfortunately, in contrast to most specialties of medicine, the clinical history available during the initial clinical encounter in the treatment of poisoned patients is occasionally unreliable or unobtainable. In the case of intentional self-poisoning, patients may not provide any history or may give incorrect information so as to increase the possibility that they will successfully bring harm to themselves. For these reasons, ancillary sources for the clinical history are often enlisted to determine what substances the patient has been exposed to. Information sources commonly employed in this setting include family members, emergency medical technicians who were at the scene, a pharmacist who can sometimes provide a listing of prescriptions recently filled, or an employer who can disclose what chemicals are available in the work environment.

In estimating the level of exposure to the poison, one should generally maximize one's estimate of the possible dose received. That is, one should assume that the entire prescription bottle contents were ingested, that the entire bottle of liquid was consumed, or that the highest possible concentration of airborne contaminant was present in the case of a patient poisoned by inhalation. Maximizing the potential dose or exposure level reduces the probability of encountering an unexpected clinical outcome in a poisoned patient.

With an estimate of dose, the toxicologist can refer to various information sources to determine what the range of expected clinical effects might be from the exposure. The estimation of expected toxicity greatly assists with the triage of poisoned patients. Poison information specialists working in poison information centers routinely give telephone recommendations regarding the level of medical care required for a given ingestion based on the expected clinical effects from the reported ingestion. The vast majority of in-the-home accidental pediatric exposures are treated with observation or intervention with induction of emesis. In the hospital setting, ED staff use the estimation of expected clinical effects to effectively triage the poisoned patient. For example, a 3-year-old patient who accidentally ingested 25 children's chewable multivitamins without iron would be triaged to a noncritical-care area of the ED, whereas a 42-year-old patient who ingested a hundred 50-mg amitriptyline tablets in an apparent suicide attempt would be triaged to a section of the ED providing intensive care.

Estimating the timing of the exposure to the poison is frequently the most difficult aspect of the clinical history in the setting of treatment of the poisoned patient. Often the toxicologist must turn detective to determine the most likely window of time during which the exposure occurred. For example, if a pediatric patient was being watched by the baby-sitter at all times except for a 20-min period preceding the onset of symptoms and the discovery of an open prescription bottle for a benzodiazepine, one would estimate that the ingestion occurred in that 20-min window. Other situations require estimation of a far broader window for exposure. A person found with a suicide note could have taken the contents of the empty prescription bottle (or anything else available) at any time from when he or she was last seen by someone to a short time before being discovered.

Taking an accurate history in the poisoned patient can be very difficult in some cases. Despite diligent efforts, using both direct and external sources for the medical history information, the clinical toxicologist is sometimes left without a clear indication of the exposure history. In this setting, the treatment proceeds empirically as an "unknown ingestion" poisoning. This type of treatment is discussed further on in this chapter.

Physical Examination One of the most important aspects of the initial clinical encounter in the treatment of the poisoned patient is the physical examination. A thorough examination is required to assess the patient's condition, categorize the patient's mental status, and, if altered, determine possible additional causes such as trauma or central nervous system infection. Because gastric decontamination requires close attention to the patient's ability to protect his or her airway (see below), checking the gag reflex during the physical examination and periodically during the initial treatment phases is important. Whenever possible, the clinical toxicologist categorizes the patient's physical examination parameters into broad classes referred to as *toxic syndromes;* these have also been called *toxidromes* (Mofenson and Greensher, 1970). A toxidrome comprises a constellation of clinical signs and symptoms that, taken together, are likely associated with exposure from certain classes of toxicologic agents. The most important of these are the narcotic, cholinergic, sympathomimetic, and anticholinergic syndromes. Table 32-1 lists the clinical features of the major toxic syndromes.

	Blood Pressure	Pulse	Temperature	Pupil	Lung	Abdomen	Neurologic
Sympathomimetic	Increased	Increased	Slightly increased	Mydriasis	NC	NC	Hyperalert, increased reflexes
Anticholinergic	Slightly increased or NC	Increased	Increased	Mydriasis	NC	Decreased bowel sounds	Altered mental status
Cholinergic	Slightly decreased or NC	Decreased	NC	Miosis	Increased bronchial sounds	Increased bowel sounds	Altered mental status
Opioid	Decreased	Decreased	Decreased	Miosis	NC or rales (late)	Decreased bowel sounds	Decreased level of consciousness

Table 32-1 Clinical Features of Toxic Syndromes

In some cases, the agent responsible for the poisoning is not known during the critically important phase of initial treatment. Categorization of the patient's presentation into toxic syndromes allows for the initiation of rationale treatment based on the most likely category of toxin responsible. For example, if a patient presents in a coma, with miosis (pinpoint pupils), hypotension, bradycardia, a markedly reduced respiratory rate, and slight hypothermia with an otherwise nonlocalizing neurologic examination, this patient's clinical presentation could be characterized as consistent with the narcotic toxic syndrome. The presence of needle tracks on the skin would support this categorization. The treatment would then be directed at support of respiration and pharmacologic reversal with a mu-receptor opioid antagonist such as naloxone.

Laboratory Evaluation A common misconception concerning the early clinical care of the poisoned patient is that a definitive diagnosis of the specific agent or poison responsible for the patient's clinical presentation is frequently made by the clinical laboratory during the initial evaluation. Unfortunately, the repertoire of specific assays for toxins available in clinical laboratories on a rapid-turnaround basis (e.g., within 1 h) is very limited. Table 32-2 lists drugs, special laboratory tests, or other chemical substances that are typically available for immediate (stat) measurement in a hospital facility of the medical center type. As one can see, the number of agents for which detection, qualitative or quantitative, is possible in the rapid-turnaround clinical setting is extremely limited compared with the number of possible agents that can poison patients. This further emphasizes the importance of recognizing clinical syndromes for poisoning and for the clinical toxicologist to be able to initiate general treatment and supportive care for the patient with poisoning from an unknown substance.

Acetaminophen	Methemoglobin
Acetone	Osmolality
Carbamazepine	Phenobarbital
Carboxyhemoglobin	Phenytoin
Digoxin	Procainamide/NAPA
Ethanol	Quinidine
Ethyl alcohol	Salicylates
Gentamicin	Theophylline
Iron	Tobramycin
Lithium	Valproic acid

Table 32-2 Toxins and Special Laboratory Tests Commonly Measured in a Hospital Setting on a Stat Basis

For the relatively few substances that can be measured on a rapid-turnaround basis in an ED setting, the quantitative measurement can often provide both prognostic and therapeutic guidance. In some cases, measurement of an indicator of the biological effect of a poison provides sufficient information to guide the patient's definitive treatment. Measurement of methemoglobin concentration in a patient poisoned by one of many agents that can cause this chemical transformation of the hemoglobin molecule is sufficient to initiate treatment for methemoglobinemia without identification of the specific toxin that caused the condition. Similarly, most hospital laboratories can measure carboxyhemoglobin concentrations rapidly, which permits treatment of carbon monoxide poisoning based on the laboratory test measuring a surrogate marker for carbon monoxide exposure.

For some commonly ingested drugs, a nomogram has been established to predict the severity of the poisoning; this is important in some cases to guide therapeutic intervention based on the measured plasma concentration of the drug and the time elapsed from the exposure. Proper use of such nomograms is necessary for the clinical management of poisoning cases.

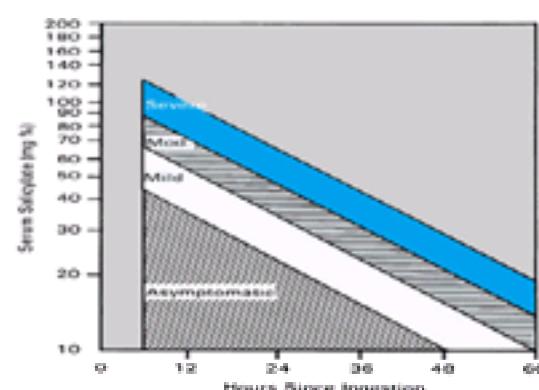
The clinical usefulness of a drug plasma concentration measured by the clinical laboratory was suggested for salicylates approximately 40 years ago. In 1960, Done published a nomogram to predict the clinical outcome from poisoning with salicylates (Done, 1960). The Done nomogram (Fig. 32-1) is still in use today as an aid to interpreting a given salicylate level as long as certain criteria are fulfilled. To use the Done nomogram properly, the blood sample from which the salicylate concentration was measured must be drawn at least 6 h after ingestion. In addition, the nomogram should be applied only to cases with a single, acute ingestion of salicylate. The Done nomogram is not useful in cases of subacute or chronic salicylate intoxication.


Figure 32-1. Done nomogram for salicylate poisoning. (From Done, 1960, with permission. Copyright American Academy of Pediatrics, 1960.)

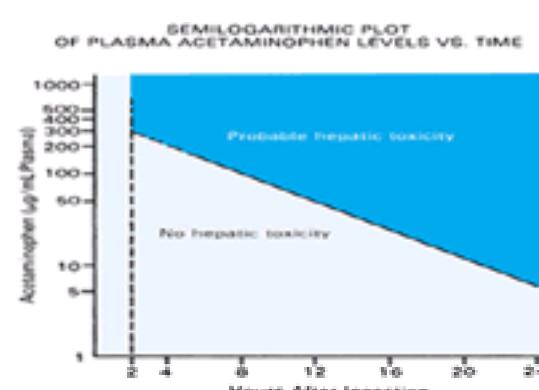
In 1975, Rumack and Mathew published the nomogram for acetaminophen poisoning shown in Fig. 32-2. It predicts clinical outcome and is also valuable to guide the clinician in deciding whether or not to administer *N*-acetyl cysteine (NAC), an antidote for significant acetaminophen ingestion. Laboratory evaluation of a patient potentially poisoned with acetaminophen is crucial to assess what hepatic injury may have already occurred and to determine plasma concentrations of acetaminophen. Accurate estimation of acetaminophen in the plasma should be done on samples drawn 4 h after ingestion, when or past the time that peak plasma levels can be expected. Once an accurate plasma concentration of acetaminophen has been obtained and the time of ingestion determined, it should be plotted on the Rumack-Matthew nomogram (Fig. 32-2) to determine whether NAC therapy is indicated. This nomogram is based on a series of patients with and without hepatotoxicity and their corresponding acetaminophen plasma concentrations at presentation.


Figure 32-2. Rumack-Mathew nomogram for acetaminophen poisoning. (From Rumack and Mathew, 1975, with permission. Copyright American Academy of Pediatrics, 1975.)

In the appropriate patient, the decision to treat is based on the plasma concentration of parent acetaminophen plotted on the nomogram. Treatment should be instituted in any patient with an acetaminophen plasma concentration in the "potentially toxic" range. It should be noted, however, that proper use of this nomogram is required: namely, that certain conditions should be met to apply the nomogram to a specific clinical case. The nomogram was validated for a single acetaminophen ingestion; the time of ingestion is critically important to establish the *x*-axis coordinate for the data point and the plasma concentration should have been obtained at least 4 h after ingestion to assure that the peak plasma concentration of parent acetaminophen has occurred.

Similar though perhaps less well established predictive relationships of drug plasma concentration and clinical outcome and/or suggested concentrations that require therapeutic interventions are available for several other agents including lithium, digoxin, iron, phenobarbital, and theophylline. Some authors have identified "action levels" or toxic threshold values for the measured plasma concentrations of various drugs or chemicals (Goldfrank, 1998). Generally, these values represent mean concentrations of the respective substance that have been retrospectively shown to produce a significant harmful effect. The pharmaco- (or toxico-) dynamic variability for a given toxin or for a combination of toxins is significant, however. For example, a patient with a "normal" or "nontoxic" digoxin level may display significant toxic effects; conversely, a patient with an elevated or "toxic" plasma concentration of digoxin may not show any sign of harmful effects. The clinical toxicologist must critically evaluate the laboratory data and treat the patient and not just the laboratory value.

Because of the limited clinical availability of "diagnostic" laboratory tests for poisons, toxicologists utilize specific, routinely obtained clinical laboratory data to

determine what poisons may have been ingested. There are two laboratory values—the anion gap and the osmol gap—that are routinely obtained in the acute clinical setting and can be helpful to the toxicologist in evaluating certain poisoned patients. An abnormal anion or osmol gap suggests a differential diagnosis for significant exposure. Both calculations are used as diagnostic tools when the clinical history suggests poisoning and the patient's condition is consistent with exposure to agents known to cause elevations of these parameters (i.e., metabolic acidosis, altered mental status, etc.).

The anion gap is calculated as the difference between the serum Na ion concentration and the sum of the serum Cl and HCO_3 ion concentrations.

$$\text{Anion gap} = [\text{Na meq/L} - (\text{Cl meq/L} + HCO_3 \text{ meq/L})]$$

A normal anion gap is <12. When there is laboratory evidence of metabolic acidosis, the finding of an elevated anion gap would suggest systemic toxicity from a relatively limited number of agents. Table 32-3 lists the agents that include metabolic acidosis with an elevated anion gap as part of the clinical presentation seen when patients have been poisoned by these agents.

A	Alcohol (ethanol ketoacidosis)
T	Toluene
M	Methanol
U	Uremia
D	Diabetic ketoacidosis
P	Paraldehyde
I	Iron, isoniazid
L	Lactic acid
E	Ethylene glycol
S	Salicylate

Table 32-3 Differential Diagnosis of Metabolic Acidosis with Elevated Anion Gap: "AT MUD PILES"

The second calculated parameter from clinical chemistry values is the osmol gap. The osmol gap is calculated as the numerical difference between the measured serum osmolality and the serum osmolarity calculated from the clinical chemistry measurements of the serum sodium ion, glucose, and blood urea nitrogen (BUN) concentrations (Smithline and Gardner, 1976).

$$\text{Osmol gap} = \text{measured serum osmolality (mOsm)} - \text{calculated serum osmolarity}$$
$$\text{where calculated serum osmolarity} = 2 \times \text{Na meq/L} + \text{Glucose mg/dL} /18 + \text{BUN mg/dL} /2.8$$

The normal osmol gap is <10 mOsm. Note that the serum osmolality must be measured by freezing-point depression and not boiling-point elevation, as the latter method can fail to detect the osmolality contribution of volatile, low-molecular-weight substances due to vaporization of the substance during measurement.

An elevated osmol gap in the setting of a poisoned patient suggests the presence of an osmotically active substance in the plasma that is not accounted for by the Na, glucose, or BUN concentrations. Table 32-4 lists several substances that, when ingested, can be associated with an elevated osmole gap in humans.

Ethanol
Ethylene glycol
Isopropanol
Methanol

Table 32-4 Differential Diagnosis of Elevated Osmol Gap

While calculation of both the anion gap and the osmol gap can provide very useful information from readily available clinical chemistry measurements, these determinations must sometimes be interpreted cautiously in certain clinical settings. For example, even though a patient may have ingested a large, significantly toxic amount of methanol, if measured late in the clinical course of the exposure, the osmol gap may not be significantly elevated, as most of the osmotically active methanol has left the plasma and has been biotransformed or cleared but is still producing serious clinical effects.

Radiographic Examination The use of clinical radiographs to visualize drug overdose or poison ingestions is relatively limited. This is due primarily to the lack of radiopacity of many oral forms of medication. Early radiographic surveys of the radiopacity of oral medications revealed that the vast majority of commercially available tablets and capsules surveyed were essentially undetectable by radiograph (Handy, 1971; O'Brien et al., 1986). These and other studies have shown that relatively few formulations of drugs are radiopaque and would therefore not be likely to be detectable by plain x-ray of the abdomen. Generally, plain radiographs can detect a significant amount of ingested oral medication containing ferrous or potassium salts. However, a study of the in vitro and in vivo visualization of chewable oral formulations of iron supplements showed that once the chewable iron was ingested, it was no longer detectable by plain abdominal radiograph (Everson et al., 1989). In addition, certain formulations that have an enteric coating or certain types of sustained release products are radiopaque as well (Savitt et al., 1987; Nelson et al., 1993).

The most useful radiographs ordered in a case of overdose or poisoning include the chest and abdominal radiographs and the computed tomography (CT) study of the head. The abdominal radiograph has been used to detect recent lead paint ingestion due to pica in children for many years. Although the presence of radiographic evidence of lead-based paint chips probably underrepresented the proportion of children with moderate to severe lead poisoning in one study, an abdominal radiograph showing pica was associated with significantly elevated blood lead concentrations (McElvaine et al., 1992). Another situation in which an abdominal radiograph may be helpful is in the setting of a halogenated hydrocarbon such as carbon tetrachloride or chloroform. If a sufficient amount of either liquid is ingested, it is likely that, on the abdominal film, these organic solvents will be visualized as a radiopaque liquid in the gut lumen (Dally et al., 1987). Finally, abdominal plain radiographs have been helpful in the setting where foreign bodies are detected in the gastrointestinal tract. An example of this is in the situation where an international traveler coming to the United States becomes acutely ill with signs of severe sympathomimetic excess and numerous foreign bodies are visualized throughout the gastrointestinal tract. This patient would probably be a "body packer," or one who smuggles illegal substances by swallowing latex or plastic storage vesicles filled with cocaine or some other substance (Beerman et al., 1986; McCarron et al., 1983; Sporer et al., 1997). Occasionally these storage devices rupture and the drug is released into the gastrointestinal tract, with serious and sometimes fatal results. Aside from these relatively uncommon situations, the overall clinical utility for detection and diagnosis of poisons by radiography is limited.

In contrast to the clinical utility of plain radiography to identify a specific poison or diagnose poisoning, plain radiography and other types of diagnostic imaging in clinical toxicology can be extremely valuable for the diagnosis of toxin-induced pathology and to aid the clinical toxicologist in the ongoing treatment and patient management phases of the drug overdose. Detection of drug-induced noncardiac pulmonary edema is associated with serious intoxication with salicylates and opioid agonists (Stern et al., 1968; Heffner, et al., 1990). Plain chest radiography can detect this abnormality, which would likely correlate with the findings observed during

physical examination of the lungs. This radiographic finding would increase the severity classification of the poisoning and potentially alter the planned therapeutic strategy for the patient.

Another example of the use of radiologic imaging in clinical toxicology is with CT of the brain. Significant exposure to carbon monoxide (CO) has been associated with CT lesions of the brain consisting of low-density areas in the cerebral white matter and in the basal ganglia, especially the globus pallidus. Although not clinically employed for diagnostic purposes in the acute phases of a CO poisoning, these CT findings of the brain have been useful for estimating the clinical prognosis of a patient who survives the initial phase of such poisoning (Miura et al., 1985; Jones et al., 1994).

The initial clinical evaluation is a critically important phase of the therapeutic process to treat poisoned individuals. The physical, laboratory, and radiologic examination all contribute to the initial diagnostic steps for poison treatment. The physical and laboratory examinations are generally more important from a diagnostic standpoint, while the radiologic examination tends to be more useful for the detection and management of toxin-induced pathology.

Prevention of Further Poison Absorption During the early phases of poison treatment or intervention for a toxic exposure via the oral or the topical route, a significant opportunity exists to prevent further absorption of the poison by minimizing the total amount that reaches the systemic circulation. For toxins presented by the inhalation route, the main intervention to prevent further absorption is removal of the patient from the environment where the toxin is found and providing adequate ventilation and oxygenation for the patient. For topical exposures, clothing containing the toxin must be removed and properly disposed of in airtight wrappings or containers making sure the rescuers and health care providers are adequately protected from secondary exposure. Most topical exposures require gentle washing of the skin with water and mild soap, taking care not to cause cutaneous abrasions of the skin that may enhance dermal absorption.

The optimal time to intervene in order to prevent continued absorption of an oral poison is as soon as possible after the ingestion. The three primary methods currently available for this purpose are: induction of emesis with syrup of ipecac, gastric lavage, and oral administration of activated charcoal. Historically, induction of emesis with a variety of agents was the sole modality employed to treat poisoning by seeking to reduce the gastrointestinal absorption of poisons. "Tartar emetic" was an antimony salt used for induction of emesis and other medicinal purposes. Other emetic agents used later on included mustard mixed in water, concentrated solutions of copper and zinc salts, and various botanical substances. In hospitals, apomorphine injection was given even into the 1980s to cause emesis in patients with a history of potentially toxic ingestion.

Currently syrup of ipecac is the only agent used for induction of emesis in the treatment of a potentially toxic ingestion. Home use of syrup of ipecac upon advice of a poison information center remains the most widely used poison treatment intervention today. Syrup of ipecac has been available in the United States since the early 1960s. Typically, 15 to 20 mL of syrup of ipecac is given orally with water, and vomiting (usually more than a single episode) can be expected within the ensuing 30 min. Controlled studies have demonstrated significant variability in the amount of drug or test markers removed by administration of syrup of ipecac. In addition, a shorter time interval between ingestion and syrup of ipecac administration is more efficacious for gastric emptying (Neuvonen et al., 1983). The accepted contraindications for use of syrup of ipecac are (1) in children less than 6 months of age; (2) in the ingestion of a caustic agent (acid or alkali); (3) in a patient with a depressed level of consciousness or gag reflex or when the toxin ingested is expected to cause either condition within a short period of time; or (4) when there is a significant risk of aspiration of gastric contents, as for ingestion of a liquid hydrocarbon with low viscosity or low surface tension.

The use of gastric lavage—the technique of placing an orogastric tube into the stomach and aspirating fluid, then cyclically instilling fluid and aspirating until the effluent is clear—has diminished significantly in recent years. The reasons for the decline in use of this technique include a growing appreciation of the risk of aspiration during the lavage procedure and growing evidence that the effectiveness of gastric lavage may be more limited than originally thought. Careful attention to the patient's gag reflex prior to initiation of this procedure is important. If the patient does not exhibit a gag reflex, endotracheal intubations must be performed to adequately protect the airway and prevent aspiration. Most clinical toxicologists would agree that the current role of gastric lavage, if there is a role at all, would be in the initial treatment of the overdose patient who had a recent (within 1 h) oral ingestion. It is essential that the orogastric tube be of sufficient size (40 to 44 Fr for an adult) to be useful. Even with a large-bore orogastric tube, some tablets or capsules may not be able to pass through the tube. In the pediatric patient, there are practical limitations to the use of large-bore tubes. In this case, orogastric lavage may be useful only to attempt removal of liquid toxins or possibly dissolved tablets or capsules. Due to recent questioning of the effectiveness of the technique and the availability of data showing that other modalities for prevention of further toxin absorption (e.g., oral activated charcoal) are possibly as or more effective, the use of gastric lavage is decreasing.

As described earlier, the medicinal use of charcoal dates back more than 150 years. The first reported medicinal use of oral charcoal to adsorb an ingested toxin is credited to the American physician Hort, who, in 1834, used large amounts of powdered charcoal to successfully treat a patient poisoned with a chloride salt of mercury. A dramatic demonstration of the adsorptive effect of oral charcoal was that by Tourey, a French pharmacist who reportedly mixed a lethal dose of strychnine with charcoal and consumed the combination before his colleagues at the French Academy in 1930 (Andersen, 1946). Early in vitro investigations of the adsorptive properties of activated charcoal demonstrated the effect of charcoal on various chemical substances in aqueous solutions (Andersen, 1946), the effect of pH on charcoal adsorption properties (Andersen, 1947), and the effect of activated charcoal on the adsorption of strychnine from gastric contents (Andersen, 1948).

During the last 20 to 30 years there has been growing use of oral charcoal as a therapeutic intervention for oral poisoning. For many years, orally administered activated charcoal has been routinely incorporated into the initial treatment of a patient poisoned by the oral route. The term *activated* refers to the substantially increased adsorptive capacity that results from the processing of charcoal obtained from the burning of carbonaceous substances such as wood pulp, sugars, organic material, and industrial wastes. The processing—which involves extensive treatment with steam, carbon dioxide, oxygen, zinc chloride, sulfuric acid, or phosphoric acid at temperatures of 500 to 900° F—"activates" the residue, leading to a significant increase in surface area through the creation of small pores in the material. Many organic molecules are significantly bound to activated charcoal. Generally, low-molecular-weight, polar compounds such as ethanol tend to be less well bound. Substances such as lithium, iron, and certain inorganic salts are not appreciably bound to activated charcoal. In acute oral overdose, activated charcoal is typically administered at a dosage of 1.0 to 2.0 g/kg. When the patient is unable to drink the charcoal slurry safely, it is placed into the stomach via orogastric or nasogastric tube.

Some controversy exists regarding which modality or method of gastric decontamination to employ to prevent further absorption of oral poison. In fact, the data in the majority of published prospective clinical trials show that activated charcoal alone or activated charcoal preceded by gastric lavage is superior to ipecac. By contrast, some studies show that induced emesis results in a greater risk of adverse effects, primarily aspiration pneumonitis resulting from aspiration of gastric contents into the trachea and lung. No published studies show that induced emesis results in fewer adverse effects compared with oral activated charcoal (Kulig et al., 1985; Albertson et al., 1989; Merigian et al., 1990; Rumack, 1985; Vale et al., 1986; Rodgers et al., 1986; Kornberg et al., 1991; Underhill et al., 1990; Saetta et al., 1991; Saetta and Quinton, 1991). Controlled human trials with orally administered radiotracer in capsules have shown that ipecac-induced emesis resulted in removal of more tracer than did gastric lavage (Young et al., 1993). Many treatment centers are beginning to favor use of activated charcoal without gastric decontamination (lavage or ipecac) for treatment of oral poisoning and drug overdose. The use of ipecac syrup is now typically limited to individual patients in whom it is likely to make a difference in outcome, in whom it appears to be the most effective method available in that particular set of circumstances, or in whom it is the only method available to achieve the goal of gastric emptying. Typically, ipecac use is confined to the home at the direction of a poison information center or health care personnel.

Enhancement of Poison Elimination There are several methods available to enhance the elimination of specific poisons or drugs once they have been absorbed into the systemic circulation. The primary methods employed for this use today include alkalinization of the urine, hemodialysis, hemoperfusion, hemofiltration, plasma exchange or exchange transfusion, and serial oral activated charcoal.

The use of urinary alkalinization results in enhancement of the renal clearance of weak acids. The basic principle is to increase the pH of urinary filtrate to a level sufficient to ionize the weak acid and prevent reabsorption of the molecule by the renal tubules. This is also referred to as *ion trapping*. The ion-trapping phenomenon occurs when the pK_a of the agent is such that, after glomerular filtration in the renal tubules, alteration of the pH of the urinary filtrate can ionize and "trap" the agent in the filtrate. Once the toxin is ionized, reabsorption from the renal tubules is impaired; as a result, more of the drug is excreted in the urine.

Clinical use of this alkalinization procedure requires adequate urine flow and close clinical monitoring, including that of the pH of the urine. The procedure is accomplished by adding sterile sodium bicarbonate to sterile water with 5% dextrose for intravenous infusion and titrating the urine pH to 7.5 to 8.5. The drugs for which this procedure has been shown efficacious for are salicylate compounds and phenobarbital, which have p K_as of 3.2 and 7.4, respectively. For example, the increase in total body clearance of salicylate by increasing urinary pH from 5.0 to 8.0 can be substantial.

Although there are potentially similar advantages to be gained from acidification of the urine in order to enhance the clearance of drugs such as amphetamine and phencyclidine (pK_as 9.8 and 8.5, respectively), significant adverse effects are associated with acidification, such as acute renal failure and acid-base and electrolyte

disturbances. For this reason, acidification of the urine is no longer recommended as a therapeutic intervention in the treatment of poisoning.

The dialysis technique, either peritoneal dialysis or hemodialysis, relies on passage of the toxic agent through a semipermeable dialysis membrane so that it can equilibrate with the dialysate and subsequently be removed. Hemodialysis incorporates a blood pump to pass blood next to a dialysis membrane, which allows agents permeable to the membrane to pass through and reach equilibrium. In order for this method to be clinically beneficial, the toxin must have a relatively low volume of distribution, low protein binding, a relatively high degree of water solubility as well as a low molecular weight. Treatment with hemodialysis of a toxin with the latter three characteristics but with a relatively high volume of distribution, such as digoxin, would not be clinically beneficial because the vast majority of the drug is not in the physiologic compartment (blood) accessible to the dialysis membrane. Therefore, despite the fact that hemodialysis is able to effectively clear the digoxin in plasma during the dialysis run, most of the body burden of digoxin is located outside the blood compartment and is not appreciably affected by the procedure. Similarly, if a drug is highly protein-bound, only a small percentage (the free fraction) would be available to pass through the dialysis membrane and be cleared from the body. Some drugs, such as phenobarbital, can readily cross these dialysis membranes and go from a high concentration in plasma to a lower concentration in the dialysate. Phenobarbital has a relatively low volume of distribution (0.5 to 0.7 L/kg) and protein binding (30 to 50 percent), so there is a reasonable opportunity for enough drug to be removed from the total body burden to make the technique valuable in serious cases of overdose (Brown et al., 1985; Cutler et al., 1987). Drugs and toxins for which hemodialysis has been shown to be clinically effective in the treatment of poisoning by these agents is shown in Table 32-5.

Amphetamines	Isoniazid
Antibiotics	Meprobamate
Boric acid	Paraldehyde
Bromide	Phenobarbital
Calcium	Potassium
Chloral hydrate	Salicylates
Fluorides	Strychnine
Iodides	Thiocyanates

Table 32-5 Agents for which Hemodialysis Has Been Shown Effective as a Treatment Modality for Poisoning

The technique of hemoperfusion is similar to hemodialysis except there is no dialysis membrane or dialysate involved in the procedure. The patient's blood is pumped through a perfusion cartridge, where it is in direct contact with adsorptive material (usually activated charcoal or Amberlite resin) that has a coating of material such as cellulose or a heparin-containing gel to prevent the adsorptive material from being carried back to the patient's circulation. The principal characteristics for a drug or toxin to be successfully removed by this technique are low volume of distribution and adsorption by activated charcoal. This method can be used successfully with lipid-soluble compounds and with higher-molecular- weight compounds than for hemodialysis. Protein binding does not significantly interfere with removal by hemoperfusion. Because of the more direct contact of the patient's blood with the adsorptive material, the medical risks of this procedure include thrombocytopenia, hypocalcemia, and leukopenia. This technique is primarily used for the treatment of serious theophylline overdose and possibly exposure to Amanita as well as paraquat and meprobamate poisoning.

The technique of hemofiltration is relatively new in clinical toxicology applications, and there is much less experience with its use for enhancement of toxin elimination. As in the case of hemodialysis, the patient's blood is delivered through hollow fiber tubes and an ultrafiltrate of plasma is removed by hydrostatic pressure from the blood side of the membrane. Different membrane pore sizes are available, so the size of the filtered molecules can be controlled during the procedure. The perfusion pressure for the technique is generated either by the patient's blood pressure (for arteriovenous hemofiltration) or by a blood pump (for venovenous hemofiltration). Needed fluid and electrolytes removed in the ultrafiltrate are replaced intravenously with sterile solutions. The procedure has the advantage of continuous use compared to the 4- to 6-h limitation for a hemodialysis run. Further studies with this technique for poison treatment are under way. Currently, the most common use of the technique is to aid in the removal of substances such as aminoglycoside antibiotics in the setting of significant renal insufficiency.

The use of either plasma exchange or exchange transfusions has been relatively limited in the field of clinical toxicology. While the techniques afford the potential advantage of being able to remove high-molecular-weight and/or plasma protein–bound toxins, their clinical utility in poison treatment has been limited. Plasma exchange, or pheresis, involves removal of plasma and replacement with frozen donor plasma, albumin, or both with intravenous fluid. The risks and complications of this technique include allergic-type reactions, infectious complications, and hypotension (Mokrzycki et al., 1994). Exchange transfusion involves replacement of a patient's blood volume with donor blood. The use of this technique in poison treatment is relatively uncommon and mostly confined to inadvertent drug overdose in a neonate or premature infant in the setting of a neonatal intensive care unit.

Serial oral administration of activated charcoal, also referred to as multiple-dose activated charcoal (MDAC), has been shown to increase the systemic clearance of various drug substances. The mechanism for the observed augmentation of nonrenal clearance caused by repeated doses of oral charcoal is thought to be transluminal efflux of drug from blood to the charcoal passing through the gastrointestinal tract (Berg et al., 1982). In addition, MDAC is thought to produce its beneficial effect by interrupting the enteroenteric-enterohepatic circulation of drugs. After absorption, a drug may reenter the gut lumen by passive diffusion if the intraluminal drug concentration is lower than the concentration in blood. The rate of this passive diffusion depends on the concentration gradient and the intestinal surface area, permeability, and blood flow. The activated charcoal in the gut lumen serves as a "sink" for toxin. A concentration gradient is maintained and the toxin passes continuously into the gut lumen, where it is adsorbed to charcoal. The characteristics of toxins that favor enhanced elimination by MDAC include (1) significant enteroenteric-enterohepatic circulation, including the formation of active recirculating metabolites; (2) prolonged plasma half-life after an overdose; (3) small (<1.0 L/kg) volume of distribution; (4) limited (<60 percent) plasma protein binding; (5) a pK_a that maximizes transport of drug across cell membranes; (6) sustained-release/resin-form tablets and/or capsules; and (7) onset of organ failure (e.g., kidney) that results in reduced capacity of the major route of elimination of the toxin so that MDAC may make a considerable contribution to total body clearance.

The technique involves continuing oral administration of activated charcoal beyond the initial dosage (described above) every 2 to 4 h with approximately one-half the initial dose, or 0.5 g/kg. The charcoal is generally mixed as an aqueous slurry and a cathartic substance is not incorporated due to the potential for electrolyte abnormalities with repeated administration of cathartic agents. An alternative technique for MDAC is to give the activated charcoal via an orogastric tube or nasogastric tube a loading dose of 1.0 g/kg of an aqueous slurry of activated charcoal (not the combination product that contains the cathartic sorbitol), followed by a continuous infusion intragastrically of ³12.5 g/h has been recommended for adults. The duration of gastric infusion depends on the clinical status of the patient and repeated monitoring of plasma drug levels where indicated (AACT, EAPCC, 1999; Ilkhanipour et al., 1992; Ohning et al., 1986; Chyka et al., 1993; Goulbourne et al., 1994; Mofenson et al., 1985; Park et al., 1983, 1986; Pollack et al., 1981; Van de Graaff et al., 1982).

Studies in animals and human volunteers have shown that MDAC increases drug elimination significantly, but no prospective randomized, controlled clinical studies in poisoned patients have been published showing a reduction in patient morbidity or mortality when MDAC is employed. The early use of MDAC is an attractive alternative to more complex methods of enhancing toxin elimination, such as hemodialysis and hemoperfusion, although in only a relatively small subset of patients. Generally, patients with certain life-threatening intoxications may benefit the most from MDAC. The decision to use MDAC depends on the clinical situation, including the specific toxin involved, the presence of contraindications (e.g., intestinal obstruction) to the use of MDAC, and the likely effectiveness of alternative methods of therapy. A list of agents for which MDAC has been shown to be an effective means of enhanced body clearance is given in Table 32-6.

| Dapsone |
| Phenobarbital |
| Quinine |
| Theophylline |

Table 32-6 Agents for which Multiple-Dose Activated Charcoal has been Shown Effective as a Treatment Modality for Poisoning

Use of Antidotes in Poisoning A relatively small number of specific antidotes are available for clinical use in the treatment of poisoning. This is partially due to a paucity of effort in drug development for antidotes as drugs. There are likely many reasons for this, but they include a small projected market for antidotes and the practical difficulties in performing clinical trials in overdose patients—an important component of an application for drug approval. The U.S. Food and Drug Administration (FDA) has placed incentives for sponsors to develop drugs for rare diseases or conditions through the Orphan Drug Act. Recently, an antidote for a fairly common poisoning was approved using the orphan drug pathway. In December 1997, fomepazole (4-methylpyrazole), a chemical inhibitor of alcohol dehydrogenase, was approved as an antidote for ethylene glycol poisoning. It remains to be seen whether further antidote research and development is stimulated by this regulatory incentive.

The mechanism of action of various antidotes is quite different. For example, a chelating agent or Fab fragments specific to digoxin will work by physically binding the toxin, preventing the toxin from exerting a deleterious effect in vivo, and, in some cases, facilitating body clearance of the toxin. Other antidotes pharmacologically antagonize the effects of the toxin. Atropine, an antimuscarinic, anticholinergic agent is used to pharmacologically antagonize at the receptor level; the effects of organophosphate insecticides which produce cholinergic, muscarinic effects, which if sufficient, can be lethal. Certain agents exert their antidote effects by chemically reacting with biological systems to increase detoxifying capacity for the toxin. For example, sodium nitrite is given to patients poisoned with cyanide to cause formation of methemoglobin, which serves as an alternative binding site for the cyanide ion thereby making it less toxic to the body.

The time course for the onset of action of currently available antidotes is highly variable. Intravenous naloxone can have a dramatic effect on the level of consciousness of an opiate-poisoned patient within minutes. Chelating agents such as desferoxamine may require multiple dosages over many days before a clinically detectable effect is seen.

Skillful therapeutic use of antidotes is essential to optimize the treatment of the poisoned patient. Many antidotes have a relatively narrow safety margin or low therapeutic index. Excessive dosing with an antidote can in some instances be more harmful than the expected effects of the toxin itself. Some antidotes require an adjustment of their dosage based on a measured blood concentration of the toxin (for example, digoxin Fab fragments) or based on the clinical assessment of the patient, as with sodium bicarbonate usage in a tricyclic antidepressant overdose. A significant part of the clinical training in the field of medical toxicology is devoted to learning the appropriate use of antidotes.

An important area of research in clinical toxicology has been in the study of prognostic indicators of poisoning severity and predictors for the level of treatment required. For practical reasons, much of this work has been retrospective in nature, but it has resulted in significant aids to guide the treatment rendered by clinical toxicologists. Several authors have proposed "action levels" marking the threshold for a certain level of clinical intervention based upon a measured plasma concentration of the toxin or a clinical manifestation of the poisoning. For example, a patient with a measured plasma theophylline concentration of 90 mg/L after a single oral exposure would be expected to exhibit significant toxicity. If the patient's clinical condition correlated with the measured laboratory plasma concentration (i.e., laboratory error was unlikely), the patient would likely require aggressive treatment measures. Similarly, a worker exposed to significant amounts of topical methanol and who demonstrated a metabolic acidosis with an elevated anion gap, an osmol gap, and visual symptoms would likely undergo hemodialysis even in the absence of a confirmatory measurement of the methanol concentration in serum. These relationships, the correlation of serious clinical effects with a theophylline level above 90 mg/L (Weisman, 1998), or visual symptoms in a methanol-poisoned patient (Ellenhorn, 1997) have come from years of observational study by investigators in the field of medical toxicology. Early on, the majority of publications were of the case report type, making it difficult to determine the relative effectiveness of various treatments that were being tried in different parts of the world. The case series or metanalysis type of scientific analysis was an important step to advance the study of clinical outcomes and assess the quality of treatment provided to poisoned patients. An example of the case series study includes the publication that described the relationship of the QRS interval on the patient's 12-lead ECG to the severity of poisoning by tricyclic antidepressant agents (Boehnert et al., 1985). This important observational study helped to stratify patients poisoned with an overdose of first-generation tricyclic antidepressants into risk categories for the development of seizures or cardiac arrhythmias. Later on, the field began to utilize prospective, controlled clinical trials, which have enabled clinicians to validate (or dismiss) new therapeutic modalities and treatment strategies.

Supportive Care of the Poisoned Patient Once the initial treatment phase in the clinical management of the poisoned patient has been completed, those patients who require admission are generally shifted to an inpatient hospital setting. This supportive care phase of poison treatment is very important. Poisoned patients who are unstable or at risk for significant clinical instability are generally admitted to a medical intensive care unit (ICU) for close monitoring. In addition, patients who are excessively sedated from their poisoning or who require mechanical ventilation or invasive hemodynamic monitoring are usually candidates for an ICU stay. Not only are there certain poisonings that have delayed toxicity such as acetaminophen, paraquat, and diphenoxylate, but there are also toxins that exhibit multiple phases of toxicity, including delayed effects (i.e., ethylene glycol, salicylate).

Like other ill, hospitalized patients, those admitted for continued treatment of poisoning are at risk for nosocomial infections, iatrogenic fluid and electrolyte disturbances, and potential harmful effects from the initial therapies they received for treatment of their poisoning. For example, gastric lavage or orogastric infusion of activated charcoal can cause aspiration and lead to pneumonitis. Any drug that severely alters a patient's mental status, causing obtundation, can allow aspiration of gastric contents associated with a loss of the gag reflex. Close clinical monitoring can detect these later-phase poisoning complications and allow for prompt medical intervention to minimize morbidity and mortality. These are but a few of the reasons that close vigilance is a very important component of the support phase of poison treatment.

Another important component of the supportive care phase of poison treatment is the psychiatric assessment. For intentional self-poisonings, a formal psychiatric evaluation of the patient should be performed prior to discharge. In many cases, it is not possible to perform a psychiatric interview of the patient during the early phases of treatment and evaluation. Once the patient has been stabilized and is able to communicate, a psychiatric evaluation should be obtained. Generally a patient who has attempted suicide should be constantly monitored until he or she has been evaluated by the psychiatric consultant and judged to be "safe" (i.e., acceptable risk) to remove from constant surveillance.

Case Examples of Specific Poisonings

Acetaminophen A 36-year-old male patient came to the ED and reported taking "a lot" of acetaminophen approximately 6 h earlier in an attempt to commit suicide. Apparently he was discharged from his job earlier that day and could not face disappointing his family. He now regretted taking the acetaminophen and admitted to taking an entire bottle (500 mg capsules). He reported having some abdominal pain approximately 1 h after the ingestion and vomiting twice approximately 3 to 4 h prior to arrival in the ED. He denied taking any other medications or substances with the acetaminophen. He denied regular or recent use of prescription or over-the-counter medications or dietary supplements as well as regular consumption of alcoholic beverages. The estimate of the maximum amount of acetaminophen consumed was 25 g, well above what is considered a highly toxic dosage.

On physical examination, the vital signs were as follows: blood pressure, 138/88; pulse, 92/min and regular; respiratory rate, 20/min; and temperature 37.2° C. He was awake, alert, and oriented and responded to questions appropriately. The remainder of the physical examination was significant for normal bowel sounds and mild epigastric tenderness without guarding or rebound; the rectal examination was normal and the stool was without detectable occult blood. The neurologic examination

was within normal limits.

Routine clinical laboratory studies were ordered stat (electrolytes, creatinine, blood urea nitrogen, glucose, complete blood count with differential, coagulation studies, urine analysis, and urine toxicology screen) and a plasma acetaminophen level. Chest and abdominal radiography were normal.

The patient was given 1.5 g/kg of oral activated charcoal prepackaged with sorbitol cathartic. The patient was closely monitored in the ED while the laboratory tests were being performed. Within 1 h, the laboratory results returned, significant for an acetaminophen concentration of 290 µg/mL. Based on the Rumack-Mathew nomogram (Fig. 32-2), a plasma acetaminophen concentration of 290 µg/kg at approximately 6 h after ingestion is well within the "probable hepatic toxicity" range; therefore treatment with *N*-acetylcysteine (NAC) was required. The patient received his first dosage of oral NAC in the ED and was admitted to the medical ward to complete the treatment course of NAC. Only mild (below four times the upper limit of normal) elevation of hepatic transaminases was measured on follow-up assessments. The patient was seen by the psychiatry consultation service and judged not to be actively suicidal. He was discharged from the hospital 4 days after admission with scheduled psychiatric and medical follow-up appointments.

Acetaminophen has been used as an analgesic and antipyretic since the mid-1950s and has become more prominently recognized as a potential hepatotoxin in the overdose situation since the original British reports in the late 1960s (Proudfoot and Wright, 1970). Work on the mechanisms of the liver toxicity of this drug has provided a theoretical basis for therapy (Mitchell et al., 1973).

The clinical presentation of patients poisoned with acetaminophen is sufficiently confusing, and in some cases it is difficult to estimate the time of ingestion. Due to the paucity of clinical symptoms with acute overdose, waiting for the appearance of symptoms is an inadequate strategy for the clinical decision-making process regarding institution of treatment.

Acetaminophen in normal individuals is inactivated by sulfation (approximately 52 percent) and glucuronide conjugation (42 percent). About 2 percent of the drug is excreted unchanged. The remaining 4 percent is biotransformed by the cytochrome P450 mixed-function oxidase system. The P450 isozyme responsible for acetaminophen biotransformation is CYP2E1. Metabolism by CYP2E1 results in a potentially toxic metabolite that is normally detoxified by conjugation with glutathione and excreted as the mercapture. Evidence extrapolated from animals estimates that when 70 percent of endogenous hepatic glutathione is consumed, the toxic metabolite becomes available for covalent binding to hepatic cellular components. However, patients who are concurrently using agents that induce CYP2E1, as in the case of chronic ethanol exposure or phenobarbital use, may produce more than 4 percent of the toxic metabolite. In estimating the risk of hepatic necrosis in any given individual, it is therefore important to determine, whenever possible, whether the patient's CYP2E1 system may be induced. When there is evidence (medical history) of concurrent agents that induce CYP2E1, the treatment nomogram for acetaminophen should be modified to a lower threshold for treatment with NAC (Rumack et al., 1981).

Follow-up liver biopsy studies of patients 3 months to a year after their recovery from hepatotoxicity have demonstrated no long-term sequelae or chronic toxicity (Clark et al., 1973). A very small percentage (0.25 percent) of patients in the national multiclinic study conducted in Denver may progress to hepatic encephalopathy with subsequent death. The clinical nature of the overdose is one of a sharp peak of serum glutamic oxaloacetic transaminase (SGOT) by day 3, with recovery to less than 100 IU/L by day 7 or 8. Patients with SGOT levels as high as 20,000 IU/L have shown complete recovery and no sequelae 1 week after ingestion (Arena et al., 1978).

Laboratory evaluation of a potentially poisoned patient is crucial in terms of both hepatic measures of toxicity and plasma levels of acetaminophen. Accurate estimation of acetaminophen in the plasma should be done on samples drawn 4 h after ingestion, when peak plasma levels can be expected.

Once an accurate plasma level has been obtained, it should be plotted on the Rumack-Matthew nomogram to determine whether NAC therapy is indicated (Fig.32-2). This nomogram is based on a series of patients with and without hepatotoxicity and their corresponding blood levels.

Treatment should be instituted in any patient with a plasma level in the potentially toxic range. Standard support with administration of activated charcoal or gastric lavage (for very recent acetaminophen ingestions) should be followed by oral administration of *N*-acetylcysteine (Mucomyst, NAC). The protective effect of NAC in acetaminophen poisoning was demonstrated when NAC-treated patients were contrasted with controls who had not received antidotal therapy (Rumack et al., 1981; Smilkstein et al., 1988). Because NAC is most effective if it is given within 24 h of acetaminophen ingestion, patients in whom blood levels cannot initially be obtained should have NAC treatment instituted and therapy terminated only if their initial blood level is determined to be in the "nontoxic" range. The dosing regimen for NAC is a loading dose of 140 mg/kg orally, followed by 70 mg/kg orally for 17 additional doses (Peterson and Rumack, 1977). An intravenous form of NAC is available in some European countries and under an Investigational New Drug Application (IND) in the United States. Children less than 9 to 12 years of age have a lower incidence of hepatotoxicity after an overdose than do adults (Rumack, 1984) but at present are still treated with NAC according to the same nomogram. Patients with trivial or "nontoxic" acetaminophen ingestions should not be given NAC therapy because the antidote can produce clinical significant adverse events.

Methanol A 27-year-old male was brought to the ED after an apparent suicide attempt. The patient was obtunded but responsive to pain and without obvious signs of trauma. At the scene, emergency medical personnel found no pill containers or chemicals. A suicide note was found but contained no information regarding what might have been taken or used to attempt suicide. No further history was available. Physical exam was significant for a blood pressure of 105/56; pulse, 74/min; respiratory rate, 28/min; and body temperature, 37.0°C. The pupils measured 3 mm and were slowly reactive to light. The lung and heart examinations were normal. Abdominal examination revealed diminished but present bowel sounds, no tenderness, and no organomegaly or masses. The rectal examination was normal and the stool contained no detectable occult blood. The neurologic exam was without focal motor abnormalities with a diminished gag reflex.

The patient was placed on a cardiac monitor, an intravenous line was started, and clinical laboratory specimens were obtained; he was placed on oxygen and given naloxone, thiamine, and dextrose (50%), intravenously. Chest and abdominal radiography was without abnormality. A 12-lead ECG was also normal. Because of the diminished gag reflex, he was endotracheally intubated to protect his airway before an orogastric tube was placed. Activated charcoal (2.0 g/kg) was placed into the stomach along with a cathartic.

Clinical laboratory results returned showing the following:

Serum chemistries: Na, 140 meq/L; K, 3.0 meq/L; Cl, 94 meq/L; HCO_3, 8 meq/L; BUN, 12 mg/dL; glucose, 100 mg/dL
Arterial blood gases (ABG): pH, 7.20; P_{CO_2} 20 mmHg; P_{O_2} 98 mmHg

The complete blood count was normal, the urinalysis was normal, measured serum osmolarity was 330 mOsm/kg, acetaminophen and salicylate levels were below the limits of detection, and the urine toxicology screen was negative.

The laboratory results were interpreted as follows: a metabolic acidosis with elevated anion gap (AG, 38) and an elevated osmole gap (40 mOsm). The primary agents being considered as likely responsible for the poisoning were methanol or ethylene glycol (note cross-referencing Table 32-3 and Table 32-4). A blood sample for measurement of methanol and ethylene glycol was sent for analysis. The patient was treated with sodium bicarbonate intravenously and sent for hemodialysis. After 4 h of hemodialysis, his acid-base and electrolyte abnormalities corrected. Approximately 9 h after the blood specimen was sent, the laboratory reported a "toxic" serum methanol concentration of 67 mg/dL. The patient underwent a second 4 h course of hemodialysis 8 h later, when the metabolic acidosis recurred. He regained normal consciousness within 12 h and recovered completely. Subsequently the patient admitted to consuming a methanol-containing gasoline additive to attempt suicide. Psychiatric consultation recommended inpatient psychiatric hospitalization once he was medically stabilized.

This case demonstrates the importance of utilizing the anion and osmole gap calculations in overdose patients. Although not considered diagnostic (Walker et al., 1986), the presence of both a metabolic acidosis with an anion gap and an osmole gap is highly suggestive of either methanol or ethylene glycol, given the patient's presentation and despite a scant history. It is quite possible that if the clinicians had not instituted therapy until the confirmatory laboratory test (i.e., the methanol level) had returned, the patient may have had a fatal or significantly morbid outcome. It is quite common for hospital clinical laboratories to have to "send out" blood specimens for ethylene glycol and methanol analysis, since these are not routinely performed onsite. A turnaround time of 6 to 12 h for this test result to be available is not uncommon.

Methanol exerts is primary toxicity after undergoing biotransformation by alcohol dehydrogenase to formaldehyde and then to formic acid by the action of aldehyde dehydrogenase. The formic acid is thought to be responsible for both the ocular (blindness) and the acid-base toxicity of methanol (Swartz et al., 1981). If untreated or treated too late, methanol poisoning can result in fatal cerebral edema with seizures as a preterminal event. Hemodialysis can remove the unmetabolized methanol,

eliminating the substrate for production of the toxic metabolite. If hemodialysis is unavailable, an inhibitor or competing substrate for alcohol dehydrogenase can be administered while the patient is being transported to a health care facility where hemodialysis is available. Ethanol (sterile, for intravenous administration) can be given to effectively inhibit the metabolism of methanol and prevent the potentially devastating effects of the poisoning.

Tricyclic Antidepressants An 18-year-old college freshman came to the ED and told the desk nurse that he had just taken an overdose of a tricyclic antidepressant. The patient was driven to the hospital by friends but walked into the ED. He was immediately taken to the acute or intensive care section of the ED. His friends reported that he took his entire prescription of amitriptyline approximately 90 min prior to arrival at the ED in an apparent suicide attempt. He denied any other ingestion, which was confirmed by his friends. The patient's initial vital signs were blood pressure, 125/70; pulse, 94/min; respiratory rate, 20/min; and temperature, 37.2°C. The unit clerk called his pharmacy to confirm a recent prescription of thirty 50-mg tablets of imipramine. Within 15 min, the patient became unresponsive. His vital signs at that time were blood pressure, 80/55; pulse, 135/min; respiratory rate, 8/min; and temperature, unchanged. Intravenous lines were started, and intravenous fluids were administered as rapidly as possible. The cardiac monitor revealed sinus tachycardia.

The remainder of the physical examination showed the patient to be well dressed without obvious signs of trauma; his skin is warm and dry, without track marks. The pupils measured 7 mm and were poorly reactive to light. Other significant findings included the examination of the abdomen, which showed markedly diminished bowel sounds. The rectal examination was negative for occult blood. The neurologic examination revealed coma without focal motor abnormalities and an absent gag reflex.

Initial laboratory tests showed no significant acid-base disturbance, no elevated anion or osmole gap, and normal glucose, liver function, and renal function tests. The chest and abdominal radiographs were normal. The 12-lead ECG revealed sinus tachycardia, a right-axis deviation, first-degree heart block, and a prolonged QRS interval of 120 ms.

A Foley catheter was inserted and 600 mL of urine obtained. The patient had a generalized seizure lasting approximately 20 s. Endotracheal intubation was performed, followed by gastric lavage; only a few pill fragments were seen in the lavage fluid. Activated charcoal (2.0 g/kg) was administered via the orogastric tube immediately following the lavage procedure. The blood pressure continued to remain low despite intravenous fluid administration. The patient developed intermittent (nonsustained) ventricular tachycardia. Sodium bicarbonate was administered intravenously and an arterial monitor instituted to closely track the arterial pH. The patient then became clinically stabilized, with return of normal blood pressure and cardiac rhythm. He was transferred to the medical ICU and closely monitored. Alkaline intravenous fluid was continued for 8 h to maintain the arterial pH at 7.50. MDAC was employed for approximately 12 h. The patient regained consciousness and was evaluated by the psychiatry service, which recommended close outpatient follow-up after discharge from the hospital.

Tricyclic antidepressants (TCAs) can be very deadly in overdose situations. During the 1980s the TCAs were consistently ranked very high on the list of drugs most frequently involved in cases of fatal drug overdose reported to the AAPCC. No diagnostic laboratory tests are available to acutely aid the clinician treating a patient poisoned with a TCA. Clinically, anticholinergic effects appear early. The TCAs are the most deadly cause of the anticholinergic toxic syndrome. The clinical presentation of the TCA overdose is complex, with central nervous system (CNS), cardiovascular, and respiratory components most prominent. Usually, serious toxicity from TCAs appears within 2 to 3 h of ingestion. The prognostic value of the QRS interval from the 12-lead ECG was discussed above (Boehnert et al., 1985). In this case, the prolonged QRS interval would have predicted the observed systemic toxicity of the reported overdose and specifically an increased likelihood of seizures.

The TCAs are available in a wide variety of brands, including amitriptyline, doxepin, and imipramine, and also in combination with phenothiazine drugs. TCAs have three primary pharmacologic actions: anticholinergic effects, reuptake blockade of catecholamines at the adrenergic neuronal site, and quinidine-like (fast sodium channel) effects on cardiac tissue. The newer TCAs, such as amoxapine, are associated with a significantly higher incidence of seizures and a lower incidence of cardiac arrhythmias than the older TCAs. TCA overdose represents a life-threatening episode (Crome, 1986; Frommer et al., 1987). The initial symptoms seen are CNS depression with manifestations of lethargy, disorientation, ataxia, respiratory depression, hypothermia, and agitation. Severe toxicity may be associated with hallucinations, loss of deep tendon reflexes, muscle twitching, coma, and convulsions. The anticholinergic or atropinic effects of these drugs include dry mouth, hyperpyrexia, dilated pupils, urinary retention, tachycardia, and reduced GI motility, which may result in marked delay of the onset of symptoms. The life-threatening sequelae of the TCAs are the cardiovascular effects, resulting in cardiac arrhythmias such as supraventricular tachycardia, premature ventricular contractions, ventricular tachycardia, ventricular flutter, and ventricular fibrillation frequently associated with hypotension and shock. The ECG characteristically demonstrates a prolonged PR interval, widening of the QRS complex, QT prolongation, T-wave flattening or inversion, ST segment depression, and varying degrees of heart block progressing to asystole. Widening of the QRS complex has been reported to correlate well with the severity of the toxicity after acute overdose ingestions (Bigger, 1977b). Widening of the QRS complex past 100 ms or greater within the first 24 h is an indication of severe toxicity (Boehnert and Lovejoy, 1985).

Lavage as appropriate may be indicated, followed by the administration of activated charcoal. Patients admitted with TCA overdose but without symptoms should be monitored for a minimum of 6 h to detect any possible delayed onset of symptoms. Vital signs and the ECG should be monitored in symptomatic patients, as fatal cardiac arrhythmias have occurred late in the course. Hypotension should be treated with fluids and may respond to sodium bicarbonate as well as vasopressors such as dopamine or norepinephrine. Adjustment of blood pH with bicarbonate to pH greater than 7.45, coupled with appropriate antiarrhythmic drugs (i.e., lidocaine or bretylium), is the primary approach to therapy for cardiac arrhythmias. Seizures may also be responsive to diazepam, phenytoin, or barbiturates.

SUMMARY

Clinical toxicology encompasses the expertise in the specialties of medical toxicology, applied toxicology, and clinical poison information. The clinical science has significantly evolved to the present state of the discipline over the past 50 years or more. The evolution of the poison control center or poison information center has paralleled that of the discipline. The incorporation of evidence-based, outcome-driven practice recommendations has significantly improved the critical evaluation of treatment modalities and methods for poison treatment. Application of a stepwise approach to the poisoned patient as described above is a useful method for the evaluation and treatment of poisoning. A careful diagnostic approach to a poisoned patient is essential, as the important medical history is often absent or unreliable. Skillful use of antidotes is an important component of the practice of medical toxicology. Continued research will increase the repertoire of effective treatments for poisoning and ultimately improve clinical practice.

CHAPTER 33

OCCUPATIONAL TOXICOLOGY

Peter S. Thorne

INTRODUCTION

For centuries the work environment has contributed significant risk of adverse health effects due to chemical and biological hazards. Early writings by Agricola (1494–1555) and Paracelsus (1492–1541) revealed the toxic nature of exposures in mining, smelting, and metallurgy. A systematic treatise by Ramazzini (1633–1714) described the hazards to miners, chemists, metal workers, tanners, pharmacists, grain sifters, stonecutters, sewage workers, and even corpse bearers. Today we continue to be concerned with occupational health and safety in these and other work environments. Although occupational settings are safer now than in the past, the levels of risk deemed acceptable have decreased and the recognition of the causal link of exposures to chronic diseases or diseases with long latencies has improved.

Occupational toxicology is the application of the principles and methodology of toxicology toward chemical and biological hazards encountered at work. The objective of the occupational toxicologist is to prevent adverse health effects in workers arising from their work environment. Since nonoccupational exposures can act as confounders or can increase the susceptibility of individual workers, occupational toxicologists must evaluate the spectrum of exposures of the work force under their consideration. Occupational toxicology is a discipline that draws on occupational hygiene, epidemiology, occupational medicine, and regulatory toxicology. The occupational toxicologist must have an intimate knowledge of the work environment and be able to recognize and prioritize exposure hazards. Since the work environment often presents exposures to complex mixtures, the occupational toxicologist must also recognize exposure combinations that are particularly hazardous.

It is often difficult to establish a causal link between a worker's illness and job. First, the clinical expressions of occupationally induced diseases are often indistinguishable from those arising from nonoccupational causes. Second, there may be a protracted but biologically predictable latent interval between exposure and the expression of disease. Third, diseases of occupational origin may be multifactorial with personal or other environmental factors contributing to the disease process. Nevertheless, it has been shown repeatedly that the dose of toxicant is a strong predictor of the likelihood, severity, and type of effect.

WORKPLACES, EXPOSURES, AND STANDARDS

The Nature of the Work Force

The demographics and distribution of the work force in industrialized nations has undergone a progressive shift over the past three decades away from jobs in heavy industry and toward jobs in the service sector and high-technology industries. There are currently 134.5 million people in the United States in the civilian, paid work force (seasonally adjusted data). This represents 67.5 percent of all citizens 16 years of age or older and is the highest proportion in history (USDL, 2000b). The 15 countries of the European Union have an estimated 155 million workers (European Union, 1998), and Japan has about 65 million. Table 33-1 shows the breakdown of employment in the United States. This illustrates that there are about 25.4 million workers (18.9 percent) engaged in manufacturing, construction, and agriculture, occupations that have the potential for significant exposure to chemical and biological agents. Furthermore, there are occupations in the service sector, such as automobile repair and employment in botanical gardens, that can also include exposures to hazardous chemicals. Service-producing occupations account for the majority (78.6 percent) of U.S. jobs. On average, weekly hours worked in service-sector jobs are less than in the goods-producing sector. Farm work employs an estimated 3.4 million workers 16 years of age and older and the U.S. Bureau of Labor Statistics has documented an average of 42.2 h worked per week. Work in agriculture is markedly different from most other occupations in four fundamental ways. First, 52 percent of those employed in agriculture are self-employed. Second, the overwhelming majority of farm establishments (91.4 percent) have fewer than 10 employees and these work sites represent 46 percent of the agricultural work force (USDL, 2000a). Third, although the annual average hours worked per week is slightly over 42, many farmers, ranchers, and farm workers have periods when they work as many as 20 h per day, 7 days per week. Fourth, according to the U.S. Bureau of the Census there are in excess of 290,000 children who identify agricultural work as their major employment (GAO/HEHS, 1998). Department of Labor data indicate that, on average, 128,500 hired farm workers between the ages of 14 and 17 were working annually in crop production (GAO/HEHS, 1998). Thus, children make up 7 percent of all hired farm workers working on crops. The presence of children in the work force has important ramifications for body burdens, disease latency, toxicokinetics, and biotransformation of toxicants.

Table 33-1 The U.S. Seasonally Adjusted Civilian Labor Market

Determinants of Dose

Dose is defined as the amount of toxicant that reaches the target tissue over a defined time span. In occupational environments, exposure is often used as a

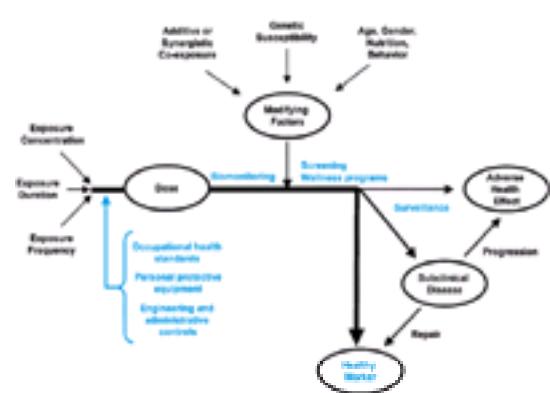
surrogate for dose. The response to a toxic agent is dependent upon both host factors and dose. Figure 33-1 illustrates the pathway from exposure to subclinical disease or to adverse health effect and suggests that there are important modifying factors: contemporaneous exposures, genetic susceptibility, age, gender, nutritional status, and behavioral factors. These modifying factors can influence whether a worker remains healthy, develops subclinical disease that is repaired, or progresses to illness. Workplace health protection and surveillance programs (shown in blue) can reduce exposures, disrupt the exposure-dose pathway or identify internalized dose and early effects before irreparable disease develops. These programs help to ensure a safe workplace and a healthy workforce.


Figure 33-1. Pathway from exposure to disease, showing modifying factors and opportunities for intervention.

As illustrated in Fig. 33-1, dose is a function of exposure concentration, exposure duration, and exposure frequency. Individual and environmental characteristics also can affect dose. Table 33-2 indicates determinants of dose for exposure via the inhalation and dermal routes. For inhalation exposure, environmental conditions such as concentration, particle size distribution, and properties of the agent are important. However, respiratory rate and breathing volume as well as other host factors contribute. Protection afforded by personal protective equipment (especially respirators) will reduce but not eliminate exposure. The degree of reduction of exposure for a particular respirator (the workplace protection factor) varies with respirator design, fit, maintenance, and environmental conditions.

Table 33-2 Determinants of Toxicant Dose

Dermal exposures depend upon toxicant concentration; work conditions, including the degree and duration of wetness; and the ambient conditions at the work site (Table 33-2). Some determinants of dermal dosing relate to the physicochemical properties of the chemical as they affect the percutaneous absorption rate. These include solubility, temperature, pH, molecular size, and chemical characteristics of the vehicle. Host factors also influence dermal absorption and distribution. Important factors include the surface area of the skin that is exposed, the integrity of the skin, blood flow, and biotransformation. Since the stratum corneum, the outer layer of the epidermis, is the principal barrier to dermal uptake, the thickness of this layer in the exposed area has great significance. As an example, the absorption of hydrocortisone through the plantar foot arch is 25-fold lower than through the back and 300-fold lower than through scrotal skin (Bason et al., 1991). The use of protective gloves and clothing or aprons and the application of barrier creams can greatly reduce exposure. For maximal protection, it is important that the material of construction of the glove be tailored to the toxicant(s) of concern.

Occupational Exposure Limits

One of the roles of the occupational toxicologist is to contribute data to the process of establishing standards or determining the appropriateness of those standards. Workplace exposure limits exist for chemical, biological, and physical agents and are recommended as guidelines or promulgated as standards in order to promote worker health and safety. For chemical and biological agents, exposure limits are expressed as acceptable ambient concentration levels (occupational exposure limits) or as concentrations of a toxicant, its metabolites, or a specific marker of its effects (biological exposure indices).

Occupational exposure limits (OELs) are established as standards by regulatory agencies or as guidelines by research groups or trade organizations. In the United States, the Occupational Safety and Health Administration (OSHA) under the Department of Labor promulgates legally enforceable standards known as permissible exposure limits (PELs). These are designed to apply the best scientific evidence to assure "to the extent feasible . . . that no employee will suffer material impairment of health or functional capacity" with regular exposure "for the period of his working life." However, there are relatively few PELs compared to the number of compounds to which workers are exposed and some of the existing PELs do not reflect current knowledge. The National Institute for Occupational Safety and Health (NIOSH), under the Centers for Disease Control and Prevention, publishes recommended exposure limits (RELs) that are more frequently updated and are generally more stringent than PELs. NIOSH also performs research and disseminates information on workplace hazards and their prevention. Most developed countries have governmental inspectorate agencies analogous to OSHA that are responsible for establishing and enforcing OELs. In some countries the insurance system also plays a significant role.

The American Conference of Governmental Industrial Hygienists (ACGIH) is a trade organization that annually publishes occupational exposure limits for chemicals and for physical agents. These take the form of threshold limit values (TLVs) and biological exposure indices (BEIs). They are frequently revisited and generally reflect current knowledge in occupational toxicology and industrial hygiene. They are developed as guidelines and are not enforceable standards; however, many industries adopt TLVs and BEIs as internal occupational exposure limits. As stated by the ACGIH, TLVs "refer to airborne concentrations of substances and represent conditions under which it is believed that nearly all workers may be repeatedly exposed day after day without adverse health effects" (ACGIH, 2000).

Three types of TLVs are suggested, depending on the time scale of adverse effects inducible by the toxicants. The time-weighted average TLV (TLV-TWA) is an occupational exposure limit for exposures averaged over an 8-h day, 5-day week work regimen. These are generally applied to toxicants that exert their effects over long periods. The short-term exposure limit (TLV-STEL) is an occupational exposure limit for a 15-min measurement period. The TLV-STEL should not be exceeded in any 15-min sampling window and there should be 60 min or more between exposures in this range. The ceiling limit (TLV-C) represents a concentration that should never be exceeded. These usually are applied to toxicants that cause acute effects (such as potent sensory irritation) and for which real-time monitoring devices are available. Biological exposure indices are guidelines for biological monitoring and represent levels "most likely to be observed in specimens collected from healthy workers who have been exposed to chemicals to the same extent as workers with inhalation exposure at the Threshold Limit Value" (ACGIH, 2000). BEIs are recommended for analysis of urine, blood, and exhaled air. While hair and fingernails are used in forensic toxicology, there are no BEIs for these specimens. The appendix lists ACGIH TLVs and OSHA PELs for over 800 toxicants.

It is important to recognize that occupational exposure limits do not correspond to exposure conditions devoid of health risk. The concept of acceptable exposure level must be understood as the level of exposure below which the probability of impairing the health of the exposed workers is acceptable. The process of deciding what is an acceptable risk to occupational or environmental hazards blends the scientific disciplines of exposure assessment and toxicology with often vexing policy issues.

Historically, acceptable risk in a society is related to the general health of the population and to a host of factors that influence how risks are perceived. To determine that the risks from an occupational hazard are acceptable, it is necessary to characterize the hazard, identify the potential diseases or adverse outcomes, and establish the relationship between exposure intensity or dose and the adverse health effects. If biological markers of exposure or early reversible effects are identified, this can aid in the risk-assessment process.

OCCUPATIONAL DISEASES

Routes of Exposure

Diseases arising in occupational environments involve exposure primarily through inhalation, ingestion, or dermal absorption. In the vast majority of work environments, inhalation of toxicants is a primary concern, with dermal exposure also of importance. Inhalation exposures can occur with gases, vapors, liquid aerosols, particulate aerosols, fumes and mixtures of these. Dermal exposures can arise from airborne materials as well as liquids splashed onto the skin, immersion exposures, or from material handling.

Additional exposure hazards exist for infectious agents. Exposures leading to occupational infections may arise through inhalation or ingestion of microorganisms but can also arise from needlesticks in health care workers or through insect bites among farmers, natural resource workers, and others who work outdoors. Additionally, poisonings from toxic plants or venomous animals can occur through skin inoculation (e.g. zookeepers, horticulturists, or commercial skin divers).

Occupational Respiratory Diseases

Because of the importance of the inhalation route of exposure, many of the major occupational diseases affect the lung and airways. Table 33-3 presents a list of the major occupational diseases and examples of agents that cause them. This is not intended to be all-inclusive. Rather it is meant to highlight what are historically the most important occupational diseases plus those that continue to be prevalent in the workplace. The toxicants listed are those for which there is a strong association with the disease or the most conclusive data to support causality. Examples are shown for cancer and for diseases of the lung and airways, heart, liver, kidney, skin, nervous system, immune system, and reproductive system. Several examples of occupational infectious diseases are also listed to highlight the fact that, in many work settings, infectious agents may constitute the major hazard and may coexist with chemical hazards. Most of the occupational diseases listed in Table 33-3 are associated with industrial chemicals. These are discussed in other chapters throughout this book. Presented below is the prevalence of some very important occupational lung diseases and a discussion of several common diseases in occupational toxicology that are not described elsewhere.

Table 33-3 Examples of Occupational Diseases and the Toxicants That Cause Them

Occupational lung diseases have been studied extensively and are largely responsible for the creation of the occupational regulatory framework. Deaths due to occupational lung diseases such as coal workers' pneumoconiosis, silicosis, asbestosis, byssinosis, and occupational asthma led to important legislation such as the U.S. Occupational Safety and Health Act (1970). These occupational lung diseases continue to have significant morbidity associated with them. Table 33-4 lists the crude U.S. death rate and annual deaths and illustrates that while the death rates are fairly low, there are still about 3600 deaths per year attributable to asbestos, silica, coal dust, and other pneumoconiotic dusts and 343 from hypersensitivity pneumonitis. However, fatalities are just the tip of the iceberg. Hypersensitivity pneumonitis is rarely fatal but is often debilitating. Moreover, there are 11,000 yearly hospital discharges related to cases of asbestosis and 13,500 for coal workers' pneumoconiosis. OSHA has compiled data on inspector-collected samples in a variety of work environments and 3.9 to 24.9 percent of these exceed the PEL for asbestos, coal dust, silica, or cotton dust (Table 33-4).

Table 33-4 Crude U.S. Death Rates (1987–1996) and Deaths in 1996 Attributed to Selected Occupational Lung Diseases

Many of the diseases listed in Table 33-3 are known by other names that refer to a particular occupation or agent. One example is hypersensitivity pneumonitis, an allergic lung disease marked by interstitial lymphocytic pneumonitis and granulomatous lesions. Hypersensitivity pneumonitis is also known as extrinsic allergic alveolitis, farmer's lung disease, bagassosis (sugar cane), humidifier fever, Japanese summer house fever, pigeon breeder's lung, and maple bark stripper's lung, depending upon the occupational setting in which it arises. Although we often think of these as the same disease, it is important to recognize that the exposures and physiologic responses they induce are complex and may differ in the manifestation of the disease.

The U.S. Bureau of Labor Statistics tracks data for respiratory conditions arising from exposure to toxic agents. These conditions include pneumonitis, pharyngitis, rhinitis, and acute lung congestion. Table 33-5 shows data for rates and cases for 1995 by industry division. These data are representative of values over the 1990s and indicate 24,000 cases per year of respiratory conditions attributed to toxic agents. The manufacturing and services industries contributed 72 percent of these cases. Eight specific industries that consistently have case rates exceeding 4.5 per 10,000 workers are listed in the footnote to Table 33-5.

INDUSTRY DIVISION†	RATE PER 10,000	CASES
Manufacturing	5.1	9,400
Services	3.4	7,900
Transportation and public utilities	3.2	1,800
Finance	2.3	1,400
Construction	1.7	800
Mining	1.5	100
Agriculture	1.4	200
Wholesale and retail sales	1.3	2,000
Total	3.0	24,000

Table 33-5 Reported Respiratory Conditions* in Private Industry due to Toxic Agents, 1995 Data

Toxic gas injuries are often characterized by leakage of both fluid and osmotically active proteins from the vascular tissue into the interstitium and airways. Important determinants of the severity and location of injury are the concentration and water solubility of the toxic gas or vapor. Anhydrous ammonia, with its extremely high solubility, primarily damages the eyes, sinuses, and upper airways. The vapors combine with water in the tissue and form ammonium hydroxide, quickly producing liquefaction necrosis. Chemicals with lower solubility, such as nitrogen dioxide, act more on the distal airways and alveoli and take longer to induce tissue damage.

Occupational asthma may be defined as a "disease characterized by a variable air flow limitation and/or airway hyper-responsiveness due to causes and conditions attributable to a particular occupational environment and not to stimuli encountered outside the workplace" (Bernstein et al., 1999). The Third National Health and Nutrition Examination Survey (NHANES III) has provided data on the prevalence of asthma based upon usual industry and smoking status (Table 33-6). These data indicate that asthma prevalence is highest in health services, hospitals, and agriculture and lowest in mining. Interestingly, in some industries current smokers demonstrate the highest prevalence (e.g., rubber, plastics, and leather products), while in other industries the highest prevalence is seen among former smokers (e.g., textile mill products, health services).

Table 33-6 U.S. Asthma Prevalence by Usual Industry and Smoking Status for Selected Industry Codes

There are a variety of industries in which there is increased risk of developing work-related asthma. In chemical-based industries, plastic and rubber polymer precursors, diisocyanates, reactive dyes, and acid anhydrides are recognized low-molecular-weight sensitizing compounds. Biocides and fungicides used in metal fabrication and machining, custodial services, lawn and turf growing, and agriculture are also chemicals associated with occupational asthma. A number of metals can induce sensitization and asthma, including chromium, cobalt, nickel, platinum, and zinc. Many enzymes can pose significant risks for occupational asthma. Examples include a-amylase among bakery workers (Houba et al., 1996) and subtilisin, a protease used in laundry detergents (Flindt, 1969; Sarlo et al., 2000; Thorne et al., 1986). The enzyme production industry has had to adopt strict environmental and process controls to reduce the risk of occupational asthma in their production facilities.

Those working with animals or animal products are at increased risk of developing occupational asthma. Animal handlers, processors, and laboratory technicians who work with animals can become immunologically sensitized to urine or salivary proteins in many vertebrates; proteins in bat guano and bird droppings; animal dander; serum proteins in blood products; dust from horns, antlers, and tusks; or shells of crustaceans. Very high rates of sensitization can occur in shellfish processors (Glass et al., 1998). Arthropods such as insect larvae, cockroaches, mites, or weevils are recognized inducers of work-related asthma. Plants and plant products (e.g., soy flour, spices, and coffee beans) can also cause asthma among workers. In a variety of occupations, exposure to fungi—especially of the genera *Aspergillus, Penicillium, Rhizopus, Mucor,* and *Paecilomyces* are associated with allergic rhinitis and asthma. These are especially important in sawmills, wood-chip handling, and composting facilities (Duchaine et al., 2000; Eduard et al., 1992; Halpin et al., 1994). Apart from the contaminating microorganisms, certain woods themselves produce chemical sensitizing agents. Examples include western red cedar, redwood, and some tropical hardwoods. Asthma has emerged as a major occupational health concern among health care workers. In order to reduce the risk of hepatitis B and other infectious diseases, health care workers have increasingly adopted the use of natural rubber latex gloves for barrier protection. Proteins from the latex of the rubber tree, *Hevea braziliensis,* are the sensitizing agents. Seven of these high-molecular-weight proteins have now been characterized as allergens. Many other plants of less commercial value produce a similar milky fluid when cut and have similar sensitizing properties.

Studies of asthma prevalence in occupational settings with exposure to low-molecular-weight agents have suggested prevalence rates of 8.3 to 11.0 percent for toluene diisocyanate (Becklake et al., 1999; Pepys et al., 1972a; Weill et al., 1975), 3.2 to 18 percent for anhydrides (Venables et al., 1985; Wernfors et al., 1986), 4 percent for plicatic acid from western red cedar (Chan-Yeung et al., 1984), and 54 percent in a platinum refinery (Pepys et al., 1972b; Venables et al., 1989). For high-molecular-weight allergens, prevalence among shellfish processors was estimated at 21 to 26 percent (Cartier et al., 1984; Desjardin et al., 1995; Glass et al., 1998), 11 to 44 percent among lab animal workers (Cullinan et al., 1994; Fuortes et al., 1996, 1997; Hollander et al., 1997), and 26 percent among bakers exposed to wheat and alpha-amylase (Houba et al., 1996). Surveillance through the NIOSH SENSOR program in California, Massachusetts, Michigan, and New Jersey indicates that of 1100 cases reported in 1993–1995, 19 percent were for work-aggravated asthma and 81 percent for new-onset asthma (NIOSH, 2000).

Agricultural workers exposed to grain dust, cotton dust, or atmospheres in swine or poultry confinement barns are at risk for the development of an asthma-like syndrome. This syndrome is an acute nonallergic airway response characterized by self-limited inflammation with neutrophilic infiltrates and increased proinflammatory cytokines (TNF-a, IL-6, and IL-8), but it does not include persistent airway hyperreactivity, as in occupational asthma (Schenker et al., 1998). Asthma-like syndrome includes cough, mild dyspnea, fever, malaise, and cross-shift declines in lung function. Endotoxin in combination with other inflammatory bioaerosols are the likely etiologic agents (Douwes et al., 2001; Schwartz et al., 1994; Schwartz et al., 1995).

Other Occupational Diseases

Occupational toxicants may induce diseases in a variety of sites distant from the lung or skin. These include tumors arising in the liver, bladder, gastrointestinal tract, or hematopoietic system attributable to a variety of chemical classes. For further discussion of other occupational diseases and the toxicants listed in Table 33-3, the reader is referred to the relevant chapters in Units 4 and 5 of this text.

Nervous system damage can be central, peripheral, or both. It may be acute, as with some organophosphate exposures, or chronic, as with organomercury poisoning or acrylamide-induced neuropathy. Injury affecting the immune system may arise from the immunosuppressive effects of chemicals such as dioxins or toxic metals. Many occupational diseases of the immune system occur due to hypersensitivity leading to respiratory or dermal allergy or systemic hypersensitivity reactions. Autoimmune syndromes have been associated with occupational exposures to crystalline silica and vinyl chloride.

Occupational diseases of the cardiovascular system include atherosclerosis, a variety of arrhythmias, problems with coronary blood supply, systemic hypotension, and cor pulmonale (right ventricular hypertrophy usually due to pulmonary hypertension as with chronic obstructive pulmonary disease). Liver diseases such as carbon tetrachloride–induced fatty liver and hepatocellular death due to toxic concentrations of acetaminophen have classically been used to illustrate chemical mechanisms of cellular injury leading to organ failure. These are thoroughly discussed in Chap. 13. Occupational diseases of the reproductive system can be gender- and organ-specific; but several toxicants—including carbon disulfide, lead, and vinyl chloride—may affect both sexes.

Exposures to infectious agents are a part of a variety of occupations. Veterinarians, health care workers, and biomedical researchers studying infectious agents have exposures that are largely known, and infection control strategies can limit their risks. For others, such as farmers and foresters, specific risks may be less obvious. Zoonotic diseases such as Q-fever, rabies, leptospirosis, and brucellosis may affect abattoir workers, zookeepers, animal handlers, and veterinarians. Foresters, field biologists, and natural resource workers who spend time in wooded areas experience tick- and mosquito-borne illnesses with increased frequency over the general population. These illnesses include the arboviral encephalitides, Rocky Mountain spotted fever, Lyme disease, and ehrlichiosis. Occupational infections may arise as a result of work settings bringing people into close proximity with other people or animals, thus facilitating the transmission of microorganisms. Occupational infectious diseases attributable to the clustering of people affect workers in day care centers, schools, health care settings, correctional facilities, dormitories, military barracks, shelters for the homeless, and so on. Industrial settings can place large numbers of workers in a shared space, leading to increased transmission of diseases. This is especially true for diseases with annual outbreaks, such as influenza and Norwalk-like viruses. Exposures to chemicals may increase the susceptibility of workers to infection through irritation of mucosa or the pulmonary epithelium or through immunosuppression leading to impaired host defense.

Both industrial and nonindustrial indoor environments may pose occupational hazards due to the presence of chemical or biological agents. With ineffective ventilation or decreased ventilation rates and increased utilization of synthetic building materials, there has been a rise in complaints associated with occupancy in buildings. In some cases, workers in a problem building develop specific clinical conditions with recognized etiology. This is defined as building-related illness. In other cases, symptoms are nonspecific and disappear when the worker leaves the problem building. When this occurs with sufficient prevalence, it is termed *sick building syndrome*. Volatile and semivolatile chemicals are released from manufacturing process materials, building materials, floor coverings, furniture, cleaning products, biocides, and microorganisms. Office buildings and residences develop a complex ecology consisting of people, molds, mites, volatile organic compounds of microbial and nonmicrobial origin, and sometimes plants, pets, and vermin (Thorne and Heederik, 1999b). An important example of this relationship involves skin cells, fungi, and house dust mites. People slough as much as 1 g of skin cells per person daily. Fungi colonize these skin cells in carpets, bedding, and upholstery, where they then serve as a food source for mites. The mites produce gastric enzymes to aid in the digestion of the fungi and skin cells, and these enzymes are potent human allergens. Excrement from the mites contains these allergenic molecules, which, when inhaled, complete the exposure pathway that can lead to allergy and asthma. Exposure to chemicals and biomolecules such as endotoxin may enhance this process (Michel et al., 1996). In some cases the occupied space of a building may be clean and dry, but local amplification sites for molds may develop. These may arise in ventilation systems, utility closets, subfloors or basements that serve as return air plenums, or in local sites of water damage. Such sites can become sources of microorganisms and aeroallergens of sufficient volume to generate significant bioaerosol exposures throughout the environment. Airborne viruses, bacteria, and fungi are responsible for a variety of building-related illnesses arising from organisms that are pathogenic to humans. Nonpathogenic microorganisms may induce symptoms or diseases through inflammatory processes, by stimulating the immune response, or by releasing noxious odors, allergenic compounds, or bioactive macromolecules. These may combine with industrial chemicals released into the air to create complex exposure environments. There are many challenges to assessing exposures to microorganisms and chemicals in these environments (Thorne and Heederik, 1999a).

TOXICOLOGIC EVALUATION OF OCCUPATIONAL AGENTS

Evaluation of Occupational Risks

In most instances of prolonged exposure to chemicals, there is a continuum between being healthy and being ill. The exposures may impart biochemical or functional changes that are without signs or symptoms, subclinical changes, or more significant toxicity manifest as clinical disease. The health significance of the identified changes resulting from exposure to a particular agent must be assessed in order to determine which are adverse. Following this assessment, one must consider the interindividual variability or susceptibility factors that influence the risks. There is no one single dose-effect relationship but a distribution of responses. Therefore, to recommend an acceptable exposure level to an industrial chemical, one must attempt to define the risk associated with adverse effects in the most sensitive populations exposed. It then remains to decide what proportion of exposed subjects may still develop an adverse effect at the proposed acceptable exposure level. This acceptable risk level will vary according to a value judgment of the severity, permanence, and equality of the potential adverse effects and the characteristics of the most susceptible population. Clearly, inhibition of an enzyme without functional consequences will be viewed as more acceptable than a more serious toxic effect, such as teratogenicity leading to a congenital malformation.

Establishing Causality In complex occupational environments it may be difficult to establish a causal relationship between a toxic substance and a disease. For this reason a number of systematic approaches have been devised to help define causation. In 1890 Robert Koch proposed postulates for "proving" that a specific organism caused a specific disease. T. M. Rivers extended this approach to viruses in 1937. Sir Austin Bradford Hill suggested epidemiologic criteria for assessing causality in 1965. These schema and modern weight-of-evidence determination criteria were later combined to suggest a set of postulates for the evaluation of evidence for disease agents in organic dust (Donham and Thorne, 1994). A matrix was developed and is extended here to evaluate the weight of evidence for a causal association between a toxicant and an occupational disease (Fig. 33-2). Evidence from well-conducted in vitro studies, animal studies, and human challenge studies, case reports, and epidemiologic investigations are evaluated with regard to data quality and clarity of evidence in support of the establishment of causality. This evaluation is guided by seven criteria (shown in blue). If a chemical were thoroughly studied in animals, humans, and in vitro studies and produced clear and convincing evidence of an exposure-response relationship in controlled studies that used appropriate models and relevant endpoints, that would constitute compelling evidence of a causal relationship between that chemical and that disease. Figure 33-2 reminds us that a consortium of study types contributes data used for the evaluation of occupational hazards. These are discussed below.

Figure 33-2. Matrix for assessing the strength of an association between a toxicant and an occupational disease.

To evaluate with some degree of confidence the level of exposure at which the risk of health impairment is acceptable, a body of toxicologic information is required. Five sources of data may be available to inform the occupational risk-assessment process.

- In vitro assays
- Animal toxicology studies
- Human challenge studies
- Case reports
- Epidemiology studies

In Vitro Assays A number of useful in vitro assays have been developed over the past several decades in order to provide screening data and, in some cases, mechanistic insight without the need or expense of exposing animal or human subjects. While at this time there are few validated methods to determine complex

toxicologic responses such as immune hypersensitivity or peripheral neuropathy, there are validated and very useful screening assays. Notable examples are the *Salmonella typhimurium* reverse mutation assay, or Ames test, and the Corrositex assay for dermal corrosivity potential of chemicals (NIH-99-4495, 1999). In addition, quantitative structure-activity relationships can help suggest potential toxicologic effects for an unstudied compound if structurally similar compounds have been evaluated.

Animal Toxicology Studies Animal toxicology studies serve an important function in terms of identifying adverse effects, providing mechanistic data, establishing dose-response relationships, and aiding the process of establishing standards. Since animal studies can be conducted before there is any human exposure, these studies play an important role in hazard identification and prevention of human disease. There are numerous animal models for occupational injury and illness; these are described throughout this textbook in the context of the affected organ system and the classes of toxicants. Generation of animal toxicology data to predict health effects in workers is a central function of experimental toxicologists. Toxicologic investigations using animals often serve to establish a tentative acceptable exposure level. Other important information that may also be derived from these investigations concerns the relationships between the metabolic handling of the chemical and its interactions with target molecules (mechanism of action), identification of methods for biological monitoring of exposure and early health effects, and of preexisting pathologic states that may increase susceptibility to the chemical. However, animal testing can provide only an estimate of the toxicity of a chemical for humans. Animals do not always respond to chemical exposure the same way humans do. For instance, there are very significant species and strain differences in responsiveness to aryl hydrocarbon receptor agonists such as polychlorinated dibenzo- *p*-dioxins (Abnet et al., 1999 ; Whitlock et al., 1996 ; Wilson and Safe, 1998). In some instances, interspecies differences in metabolism or mechanism of action cause certain chemicals to induce cancer in rodents but not in humans. One such example is kidney cancer, attributable to the accumulation of a rat-specific protein (a $_{2u}$-globulin) in proximal tubular cells, produced in male rats chronically exposed to unleaded gasoline (Hard et al., 1993). There are a few compounds for which animal models have not been found. As discussed further on, skin and internal cancers caused in humans by excessive oral exposure to inorganic arsenic have not been reproduced during classic carcinogenicity studies in animals (ATSDR, 1993).

Human Challenge Studies Human challenge studies, or clinical exposure studies, are a useful approach for verifying findings from animal toxicology studies in humans and for establishing whether biotransformation pathways in the animal models represent those in exposed humans. Human challenge studies help to establish biomarkers of exposure. For reversible conditions, they can be useful for testing therapeutic options. Extreme caution must be exercised to ensure the safety of subjects. Idiosyncratic responses can cause a subject to be exceptionally sensitive. For inhalation studies, equipment malfunction can result in overexposure. In the past 20 years, there have been several serious injuries and fatalities associated with human challenge studies. These have been attributed to hypersensitivity reactions and generally used mock workplace simulations without rigorous control and monitoring of exposures, as is the current standard of practice.

Case Reports When new toxicants or new combinations of toxicants enter the workplace, a case or outbreak of cases can occur. These may be identified through workplace surveillance systems or through workers associating their disease with workplace exposures. These may end up being reported as case reports or case series. NIOSH has a Health Hazard Evaluation (HHE) program in place in which employees or their authorized representatives or employers at a job site can request an investigation to evaluate a potentially hazardous situation. This program issues HHE Reports to disseminate information regarding the hazard. NIOSH also publishes NIOSH Alerts, Criteria Documents, Special Occupational Hazard Reviews, Occupational Hazard Assessments, and Current Intelligence Bulletins. While useful for hazard identification, case reports and HHE Reports do not establish incidence or prevalence of diseases associated with an occupational hazard.

Epidemiology Studies Epidemiology studies help to unravel the associations between occupational diseases, exposures, and personal risk factors. Several types of epidemiologic studies are used to gather data on the association of workplace exposures with human disease. Cross-sectional studies compare disease prevalence or health status between groups of workers classified according to job title, work site, or exposure status. Cohort studies compare exposed workers versus unexposed workers either prospectively or retrospectively in order to associate the occurrence of disease with exposure. Since many occupational diseases have a long induction period or occur only rarely, prospective cohort studies may require a long time and need a large number of subjects to establish significant findings. Retrospective cohort studies can resolve the latency problem but require that relevant exposure data have been collected over time. Exposure misclassification is frequently a problem in retrospective studies. Case-control studies are useful for investigating rare diseases or diseases with long induction periods. As the name suggests, case-control studies compare workers with disease to workers without disease with regard to their exposure intensity, frequency, and duration, plus other postulated risk factors. In some instances where the exposure-disease relationship is not understood, it may be difficult to identify an appropriate control group

Animal Toxicology Testing for Establishing Acceptable Levels of Exposure

It is evident that certainty as to the complete safety of a chemical can never be obtained whatever the extent of toxicologic investigations performed on animals. Nevertheless, animal studies provide valuable data from which to estimate the level of exposure at which the risk of health impairment is acceptable. Guidelines and protocols for assessing experimentally the toxicologic hazards of chemicals have been formulated by various national and international agencies. These tests include local and systemic acute toxicity tests, tests of toxicity following repeated exposure, investigations of metabolism and mechanism of action, short-term tests for detecting potential mutagens and carcinogens, studies of effect on reproduction and of teratogenic activity, chronic studies to detect carcinogenesis and other long-term effects, interaction studies, tests for immunosuppression, and dermal and pulmonary hypersensitivity tests. The need for performing these testing protocols should be carefully evaluated for any occupational toxicant to which workers will be exposed. In selecting the studies most appropriate for safety evaluation the toxicologist should be guided by an understanding of the following:

- Physicochemical properties of the chemical
- Potential for the generation of toxic derivatives when the chemical is submitted to heat, pH changes, and UV light
- Conditions of use
- Type of exposure (continuous, intermittent, or incidental)
- Degree of exposure

Toxicologic information already available on other chemicals with similar chemical structure and reactive chemical groups can suggest potential hazards and reactivity.

Conclusions drawn from any toxicologic investigation are useful only if the composition and physical state of the tested preparation is known. This would include the nature and concentration of impurities or degradation products, speciation of inorganic compounds, characterization of physical properties for inhaled materials, and characterization of the vehicle (if any). Sensitive and specific methods of analysis of the chemical in solution, air, and biological material also should be available. The assessment of the toxicity of malathion in the 1970s illustrates this point. Malathion is an organophosphate insecticide normally with relatively low human toxicity. This pesticide was responsible for a 1976 episode of mass poisoning among malaria workers in Pakistan because the specific product contained impurities (mainly isomalathion) capable of inhibiting tissue and plasma carboxyesterases (Baker et al., 1978 ; Aldridge et al., 1979). The toxicity evaluation for malathion had not anticipated isomalathion coexposure.

The duration of tests necessary to establish an acceptable level for occupational exposure is primarily a function of the type of toxic action suspected. It is generally recognized that for systemically acting chemicals, subacute and short-term toxicity studies are usually insufficient for proposing OELs. Subacute and short-term toxicity tests are usually performed to find out whether the compound exhibits immunotoxic properties and cumulative characteristics. They also aid in selection of the doses for long-term-exposure studies and the kind of tests that may be most informative when applied during long-term exposures. A number of studies have drawn attention to the fact that the reproductive system may also be the target organ of industrial chemicals (e.g., glycol ethers, styrene, lead, dibromochloropropane). Thus, studies designed to evaluate reproductive effects and teratogenicity should also be considered during routine toxicologic testing of occupational toxicants.

Information derived from exposure routes similar to those sustained by workers is clearly most relevant. For airborne pollutants, inhalation exposure studies provide the basic data on which provisional OELs are based. Experimental methodology is certainly much more complicated for inhalation studies than for oral administration experiments and requires more specialized equipment and expertise (Thorne, 2000). For example, in the case of exposure to an aerosol, particle size distribution must be evaluated and the degree of retention in the respiratory tract of the animal species under study should be established. Ideally, particle size should be selected according to the deposition pattern of dry or liquid aerosols in the particular animal species used in order to represent human lung deposition with occupational exposures. Particle deposition and retention curves have been published for human, monkey, dog, guinea pig, rat, and mouse (Hsieh et al., 1999 ; Schlesinger, 1985). It also should be kept in mind that the concentration of the material in the air and the duration of exposure do not give a direct estimate of the dose, since retained dose is also dependent on the minute volume and the proportion of inhaled particles retained. Measurement of pulmonary dust retention following exposure to a radiolabeled or fluorescently tagged test aerosol should be performed prior to conducting acute, subchronic, or chronic studies. This allows one to assess deposition and determine whether the selected levels of exposure may overwhelm pulmonary clearance mechanisms (Lewis et al., 1989 ; Morrow, 1992).

The choice of what studies to perform using which routes of administration must be evaluated scientifically for each toxicant. Important considerations include its

target sites and mechanism of action, metabolism, the nature of its adverse effects, and how workers are exposed to the toxicant. The morphologic, physiologic, and biological parameters that are usually evaluated, either at regular intervals in the course of the exposure period or at its termination, are described in Units 4 and 5 of this text. Knowledge of the absorption, distribution, biotransformation, and excretion of the chemical and its mechanism of action are of major interest. Investigations that can make use of specific physiologic or biochemical tests, based on knowledge of the principal target organ or function, produce highly valuable information and increase confidence in the OEL derived from them.

Worker Health Surveillance

The primary objective of occupational toxicology is to prevent the development of occupational diseases. The monitoring of exposures to toxicants in the workplace may play an important role in detecting excessive exposures before the occurrence of significant biological disturbances and health impairment. A scheme for biological monitoring of exposure and of early biological effects is possible only when sufficient toxicologic information has been gathered from animal studies on the mechanism of action and the metabolism of xenobiotics to which workers are exposed. When a new chemical is being used on a large scale, the careful clinical surveillance of workers and monitoring of workplaces should be instituted in order to address three aims: (1) to identify overexposure or adverse effects on the health of the workers and quickly intervene, (2) to evaluate the validity of a proposed occupational exposure limit derived from animal experiments, and (3) to test the validity of a proposed method for a biological monitoring.

Evaluation of the validity of the proposed OEL derived from animal experiments through workplace surveillance is the major aim, since "studies and observations on [humans] will always be the final basis for deciding whether [an OEL] set originally on the basis of tests on animals is, in fact, truly acceptable as one that will not produce any signs of intoxication" (Barnes, 1963). This means that sensitive clinical, biochemical, physio-logic, or behavioral tests for detecting an adverse effect of a toxicant should ideally be performed on the workers concurrent with exposure assessment. It is helpful if human challenge studies or studies on workers can include the same biomarkers as used in prior animal studies. The occupational toxicologist cannot rely solely on the diagnostic tools used in clinical medicine, as they were established primarily to reveal advanced pathologic states and not to detect early adverse effects at a stage when they are still reversible. For example, the measurement of serum creatinine is still a widely used clinical test for assessing renal integrity; yet it is known that the glomerular filtration rate of the kidney must be reduced by more than 50 percent before serum creatinine rises significantly.

The main limitation of current OELs or BEIs is that some are based on limited experimental data or clinical studies in which only late effects have been investigated and correlated with past exposure. Furthermore, several BEIs are derived from the study of external-internal exposure relationships and not from relationships between internal dose and early adverse effects. The validity of an OEL is much stronger if it is based on the study of dose-response relationships in which the dose is expressed in terms of the cumulative target dose and the monitored effect reflects a critical biological event. However, it should be noted that for some chemicals and some adverse effects (e.g., induction of hypersensitivity and possibly genotoxic effects), the frequency of peak exposure may be more important for health risk assessment than the integrated dose. For example, long-term low-level exposures to commercial enzymes rarely induce sensitization. However, a single exposure to a high concentration can produce hypersensitivity and occupational asthma.

Epidemiologic studies designed to assess exposure-response relationships can be carried out by using a variety of variables for assessing the exposure and health changes. Exposure may be characterized using a surrogate measure such as job classification, seniority, or via questionnaire or more directly through ambient or personal exposure monitoring or measurement of the internalized dose. Adverse effects may be expressed in terms of mortality, incidence or prevalence of clinical disease, irreversible or reversible functional changes, or critical biological changes. It is evident that the assessment of the health risk resulting from exposure will have more validity if it results from exposure-response studies in which both the target dose and the critical biological changes are monitored. Of course, the use of such parameters requires knowledge of the fate of the chemical in the organism and its mechanism of action. However, this approach is more expensive than simpler epidemiologic study designs and may result in a trade-off between sophistication and study sample size.

Because early biomarkers of effect are subtle and individual variations exist in the response to a chemical insult, results generally require a statistical comparison between a group of exposed workers and a similar group of workers without the exposure of interest. The group of unexposed workers should be matched on variables such as age, race, gender, socioeconomic status, and smoking habits. The importance of selecting a control group that is well matched with the exposed group and that undergoes the same standardized clinical, biological, or physiologic evaluation at the same time as the exposed group must be emphasized. Comparison with the general population is not valid because an employed population is a highly selected group and may have a higher degree of physical fitness. Since occupational epidemiologic studies often last for several years, all methods of investigation—such as questionnaires, instrumentation, and analytic techniques—must be validated and standardized before the start of the study. The number of subjects under study should be chosen based on a sample size calculation to be able to detect a difference between exposed and unexposed subjects (should there be a difference) and should take into account labor turnover and those declining participation in any aspects of the study. If exposures are high enough to induce an adverse effect, it is expected that these studies may permit establishment of the relationship between integrated exposure (intensity × time) and frequency of abnormal results and, consequently, a redefinition of the OEL.

In cases where a surveillance program was not instituted before the introduction of a new chemical, it is more difficult to establish the efficacy of the OEL. In this situation, evaluation depends on retrospective cohort studies or case-control studies or on cross-sectional studies on workers who have already sustained exposure. Evaluation of a "no observed adverse effect level" (NOAEL) is difficult because information on past exposures is often incomplete and frank effects are generally the focus of retrospective or case-control studies. Provided that a satisfactory assessment of past exposure is possible, cross-sectional studies that rely on preclinical signs of toxicity may, to a certain extent, overcome these difficulties. Whether or not clinical investigations are planned from the introduction of a new chemical or process, it is essential to keep standardized records of occupational histories and exposure. The need may arise for mortality or case history studies in order to answer an urgent question on a suspected risk.

Case reports of isolated overexposures resulting from specific incidents such as containment breaches, chemical spills, vessel or pipe ruptures can provide useful information. Although such observations are usually not helpful for determining the NOAEL in humans, they may indicate whether human symptomatology is similar to that found in animals and may suggest functional or biological tests that might prove useful for routine monitoring of exposed workers.

Human challenge studies with occupational toxicants are usually designed to answer very specific questions regarding rates of uptake, biotransformation pathways, the time course of metabolite excretion during and after exposure, evaluation of the threshold concentration for sensory responses (odor, irritation of the nasal mucosa, etc.), and acute effects of toxicant exposure on perception, vigilance, and function. For ethical reasons, such studies can be undertaken only when the same results cannot be obtained through other means and under circumstances in which the risk for volunteers can reasonably be estimated as negligible.

In most cases, studies on human subjects encompass the collection of samples from the subjects or data obtained through interaction with the subjects. Since this often includes identifiable private information, subjects are rightfully concerned about issues of confidentiality. The guiding principle is that the value of the study does not outweigh the rights of the subjects. U.S. and international law requires that subjects must always have the right to refuse participation and investigators must have written consent from a duly informed volunteer obtained without coercion.

Linkage of Animal Studies and Epidemiologic Studies

In the field of occupational toxicology, perhaps more than in other areas of toxicology, close cooperation between those conducting animal studies and studies of workers is essential for examining risks associated with overexposure to chemicals and other toxicants. A few examples will serve to illustrate the complementarity of these disciplines.

Several occupational carcinogens have been identified clearly through combined epidemiologic and experimental approaches (IARC, 1987). For example, the carcinogenicity of vinyl chloride was first demonstrated in rats (Viola et al., 1971), and a few years later, epidemiologic studies confirmed the same carcinogenic risk for humans (Creech and Johnson, 1974; Monson et al., 1974). This observation stimulated several investigations on the metabolism of vinyl chloride in animals and on its mutagenic activity in in vitro systems. Identification of vinyl chloride metabolites led to the conclusion that there is microsomal oxidation leading to the formation of an epoxide derivative, which acts as a proximate carcinogen (ATSDR, 1997). This finding triggered further studies on the biotransformation of structurally related halogenated ethylenes, such as vinyl bromide, vinylidene chloride, 1,2-dichloroethene, tri-chloroethylene, perchloroethylene (Bonse et al., 1975; Uehleke et al., 1977; Dekant et al., 1987). Comparison of their oncogenic activity in relation to their metabolism suggested that an interplay between the stability and reactivity in reaching the DNA target and reacting with it after being formed would determine their genotoxic risk (Bolt, 1984). It is now recognized that vinyl chloride produces DNA adducts by inducing the formation of an additional ring in adenine and cytosine on DNA molecules (Birner et al., 1993; NTP, 2000).

1,3-Butadiene is a known human carcinogen that is used in the manufacture of synthetic rubber products. Experimental studies in rats and mice demonstrated

carcinogenicity, with mice being particularly sensitive (NTP, 2000). Subsequent to these findings 1,3-butadiene was shown to follow the same metabolic pathway in humans as in rats and mice forming mutagenic and carcinogenic epoxides. That led to cohort and case-control studies establishing 1,3-butadiene as a human carcinogen (NTP, 2000). Recent studies have considered the relative importance of the metabolic pathway leading to formation of the reactive metabolite 1,2-epoxy-3-butene, which reacts with hemoglobin to form 1- and 2-hydroxy-3-butenyl valine adducts (MHBVal) and with DNA to form guanine adducts. Under the assumption of a genotoxic mechanism and cross-species comparisons of hemoglobin and DNA binding, these data facilitate a more informed cancer risk assessment. This analysis suggests that for exposures to 1,3-butadiene, the cancer risk is lower for humans than rats or mice on an equivalent dose basis (Van Sittert et al., 2000). Furthermore, this work illustrates that the measurement of the MHBVal adducts is a sensitive method for monitoring 1,3-butadiene metabolism via the epoxide-forming pathway in workers.

In 1973, an outbreak of peripheral neuropathy occurred in workers exposed to the solvent methyl butyl ketone (MBK) (McDonough, 1974; Allen et al., 1975). The same lesion was reproduced in animals (Mendell et al., 1974; Spencer et al., 1975). Biotransformation studies were then undertaken in rats and guinea pigs, and some MBK metabolites (2,5-hexanedione, 5-hydroxy-2-hexanone) were also found to possess neurotoxic activity (Spencer and Schaumburg, 1975; DiVincenzo et al., 1976; DiVincenzo et al., 1977). Similar oxidation products are formed from *n*-hexane, the neurotoxicity of which is probably due to the same active metabolite as that produced from MBK. Since methyl isobutyl ketone and methyl ethyl ketone cannot give rise to 2,5-hexanedione, they were suggested as replacement solvents.

These examples demonstrate that studies of the metabolic handling of occupational toxicants in animals are instrumental in the characterization of reactive intermediates and may suggest unsuspected risks or indicate new methods of biological monitoring. Conversely, clinical observations on workers may stimulate studies of the metabolism or the mechanism of toxicity of a toxicant in animals, thereby revealing the health significance of a biological disturbance.

Arsenic is one of the very few compounds for which there are limited data of predictive value from animal studies to human health effects. Arsenic has been used as a medicine since the time of Hippocrates. Initially used to treat ulcers, arsenicals achieved notoriety as medicinals for a wide variety of ailments, and then, in the first half of the twentieth century, for the treatment of syphilis and parasites. Many foods and beverages contaminated with arsenic have been associated with accidental and intentional poisonings. Inorganic pentavalent arsenic (arsenate) is readily absorbed across tissues and converted to the trivalent form (arsenite). This is then methylated to form monomethylarsenic acid and dimethylarsenic acid (NRC, 1999). These are primarily transported in the blood bound to sulfhydryl groups in proteins. The half-life in humans for arsenic compounds is 2 to 4 days and the major excretion is via the urine (Nriagu, 1994). These organic arsenicals have lower toxicity than the inorganic arsenic compounds.

Inorganic arsenic was first noted as a human carcinogen by Hutchinson in 1887 (Hutchinson, 1887). Epidemiologic studies led to classification of arsenic by the International Agency for Research on Cancer (IARC) as a skin and lung carcinogen in 1980 (IARC, 1980). Since then studies among occupationally exposed pop-ulations and populations with high arsenic in their drinking water have shown conclusively that arsenic causes human cancers of the skin, lung, bladder, kidney, liver, nasal tissue, and prostate. There is also evidence for arsenic-associated cutaneous effects, cardiovascular and cerebrovascular disease, diabetes mellitus, and adverse reproductive outcomes (EPA, 2000).

A large number of carefully executed cancer bioassays in mice, rats, beagles, and monkeys have been performed using sodium arsenate, sodium arsenite, lead arsenite, arsenic trioxide, and dimethylarsinic acid. These studies have been uniformly negative. A number of subsequent studies that tested for tumor-promotion activity following dosing with recognized tumor initiators also yielded negative results. Negative results in animal studies in the face of unquestionable oncogenic activity in humans suggest that inorganic arsenic may follow a nongenotoxic mode of action (NRC, 1999).

The examples above demonstrate that the occupational toxicologist cannot rely solely on animal or epidemiologic studies. A combined approach is necessary in order to identify, elucidate, and prioritize risks and to develop interventions and techniques for worker health surveillance.

EXPOSURE MONITORING

Two important applications of occupational toxicologic investigations are compared below: environmental monitoring and biological monitoring. As described above under "Occupational Health Standards," both are important in worker health surveillance and are essential elements of toxicology studies with dosing via the inhalation or dermal routes.

Environmental Monitoring for Exposure Assessment

An important objective of experimental and clinical investigations in occupational toxicology is the proposal of safe levels of exposure. It is evident that with the accumulation of new information on the toxicity of industrial chemicals, OELs must be reevaluated at regular intervals. It should also be made clear that these levels may not protect everyone and should not supplant close medical surveillance of workers. Various private and official institutions regularly review the toxicologic information on chemicals in order to propose or update permissible levels of exposure. These include governmental organizations worldwide and trade organizations such as the ACGIH and the European Centre for Ecotoxicity and Toxicology of Chemicals (ECETOC). A critical element of establishing OELs is the accurate and uniform assessment of exposure. Methodology for exposure assessment must be specifically tailored to the agent under study and the environment in which it appears. To assess airborne exposures for compliance purposes, personal samples taken in the breathing zone are generally used. In a few specific environments, area samples form the basis of an exposure standard (e.g. the standard for exposure to raw cotton dust specifies use of the vertical elutriator or an equivalent method). Occupational environmental surveys may use area sampling to determine areas with higher or lower toxicant concentrations. However, concentrations determined from personal samples typically exceed area concentrations, depending on the work practices and environmental controls. For example, geometric mean concentrations of inhalable dust assessed from 159 personal samples in dairy barns were 1.78 mg/m^3, compared with 0.74 mg/m^3 for 252 area samples collected simultaneously in two locations in the same barns (Kullman et al., 1998). Thus, in this environment, area sampling alone would underestimate personal exposures by a factor of 2.4.

Repeated random sampling is theoretically the best approach to developing unbiased measures of exposure. However, this is rarely the approach that is taken. Variability in exposure, especially variability over time, is usually large; therefore a considerable number of repeated measurements are needed to obtain an accurate proxy of the true exposure. When the number of repeats is insufficient, the slope of the exposure-response relationship will be biased, usually leading to considerable underestimation of the relationship (Heederik and Attfield, 2000). Recent studies have demonstrated that group-based approaches are more efficient in terms of measurement effort to obtain a desired level of accuracy. In a group-based approach, workers are grouped by job title or task performed and the group mean is used as the average exposure for each worker (Kromhout et al., 1996). Further statistical modeling of the exposure data can reduce problems of bias and large temporal and spatial variability (Preller et al., 1995; Tielemans et al., 1998). While this approach is gaining acceptance among occupational epidemiologists for evaluating exposure-response data and assessing risks, it is not generally used for compliance monitoring.

Although one cannot assess dose directly through exposure monitoring, it has distinct advantages over biomonitoring. Exposure monitoring allows one to quantify exposure by route through selective air monitoring in the breathing zone of the worker and dermal dosimetry using absorptive material affixed to the workers' skin or clothing. Biomonitoring cannot provide route-specific exposure data. Environmental monitoring techniques are generally less expensive and less invasive than techniques involving the collection and analysis of biological samples such as blood or urine. Thus, a larger population of workers can be studied for the same amount of money. Workers are accustomed to wearing personal samplers for exposure assessment and generally quite willing to do so. However, they are often unwilling to give a blood or urine sample, fearing that the sample will be surreptitiously used for drug testing, DNA testing, or experimentation. Some express fear that they will contract a serious infectious disease during the process of giving a blood sample. Another benefit of air sampling in the workplace is that spatial, temporal, and work practice associations can be established and can suggest better interventions and engineering controls. Finally, analytic interferences and variabilities are generally lower with environmental samples than with biological samples.

A fully validated sampling and analysis method requires specification of the sampling methods, sample duration, sample handling, and storage procedures; the analytic method and measurement technique; the range, precision, accuracy, bias, and limits of detection; quality assurance issues; and known interferences. It is also important to document intralaboratory and interlaboratory variability. Once a standard method is established, it must be followed in every detail in order to assure consistency of results.

The development of accurate and precise analytic methods for environmental assessment is an ongoing effort. NIOSH publishes the extensive *NIOSH Manual of Analytical Methods* (Casinelli and O'Connor, 1994), and these are widely used. The American Society for Testing Materials (ASTM) has also established a rigorous system for the establishment of methods. It generally requires 5 or more years to establish a new ASTM method for exposure assessment. The International Organization for Standardization (ISO) is a global federation of national standards bodies with over 125 member countries. The subcommittee on workplace

atmospheres is administered by the American National Standards Institute (ANSI). ISO has completed harmonization on a number of air sampling methods—for example, the determination of the number concentration of airborne inorganic fibers by phase contrast optical microscopy. The American Industrial Hygiene Association (AIHA) and the ACGIH publish compilations with descriptions of analytic devices and methodology (Cohen and Hering, 1995; DiNardi, 1997). Methods have also been developed for bioaerosol exposure assessment, and these have been recently reviewed (Eduard and Heederik, 1998; Heederik et al., 2001; Thorne and Heederik, 1999a; Willeke and Macher, 1999).

Biological Monitoring for Exposure Assessment

Biological monitoring of exposure assesses health risk through the evaluation of the internal dose. Depending on the chemical and the analyzed biological parameter, the term *internal dose* may have different meanings. A biological parameter may reflect the amount of chemical absorbed shortly before sampling, as with the concentration of a solvent in the alveolar air or in the blood during the workshift. It may reflect exposure during the preceding day, as with the measurement of a metabolite in blood or urine collected 16 h after the end of exposure. For toxicants with a long biological half-life, the measured parameter may reflect exposure accumulated over a period of weeks. *Internal dose* may refer to the amount of chemical stored in one or in several body compartments or in the whole body (*the body burden*).

When biological measurements are available to assess the internal dose, the approach offers important advantages over monitoring the air of the workplace. Its greatest advantage is that the biological parameter of exposure is more directly related to the adverse health effects than environmental measurements. Therefore, it may offer a better estimate of the risk than can be determined from ambient monitoring. Biological monitoring accounts for uptake by all exposure routes. Many industrial chemicals can enter the organism by absorption through the skin or the gastrointestinal tract as well as the lung. For example, some solvents (e.g., dimethylformamide) and many pesticide formulations exhibit substantial exposure via the dermal route. In these situations, exposures determined through monitoring airborne concentrations underestimate true exposure.

Several factors can influence uptake. Personal hygiene habits vary from one person to another, and there is some degree of individual variation in the absorption rate of a chemical through the lungs, skin, or gastrointestinal tract. Use of size-selective air sampling to determine the inhalable or respirable fraction can strengthen the exposure estimate. However, biological factors such as ventilatory parameters can affect the strength of such a correlation. For example, increased workload can markedly increase the respiratory uptake of an airborne toxicant. Because of its ability to encompass and evaluate the overall exposure (whatever the route of entry), biological monitoring also can be used to test the overall efficacy of personal protective equipment such as respirators, gloves, or barrier creams. Another consideration with biological monitoring is the fact that the nonoccupational exposures (hobbies, residential exposures, dietary habits, smoking, second jobs) also may be expressed in the biological level. The organism integrates the total external (environmental and occupational) exposure into one internal load. While this is beneficial for worker health and safety, it may be confounding in epidemiologic studies or compliance monitoring.

The value of biological monitoring is heightened when the relationships between external exposure, internal dose, and adverse effects are established. Normally, biological monitoring of exposure cannot be used for assessing exposure to substances that exhibit their toxic effects at the sites of first contact and are poorly absorbed. Examples include dermally corrosive compounds and primary lung irritants. In this situation, the only useful relationship is that between external exposure and the intensity of the local effects.

Relationships between air monitoring and biological monitoring may be modified by factors that influence the fate of an occupational toxicant in vivo. Metabolic interactions can occur when workers are exposed simultaneously to chemicals that are biotransformed through identical pathways. Exposure to chemicals that modify the activity of the biotransformation enzymes (e.g., microsomal enzyme inducers or inhibitors) may also influence the fate of another compound. Furthermore, metabolic interferences may occur between occupational toxicants and alcohol, tobacco, food additives, prescription drugs, natural product remedies, or recreational drugs. Changes in any of several biological variables (weight, body mass, pregnancy, diseases, immune status, etc.) also may modify the metabolism of an occupational chemical. These factors have to be taken into consideration when the results of biological exposure tests are interpreted. Whatever the parameter measured, whether it is the substance itself, its metabolite, or an early biomarker of effect, the test must be sufficiently sensitive and specific to be of practical value.

Some chemicals have a long biological half-life in various body compartments (e.g., blood or urine), and the time of sampling may not be critical. For other chemicals, the time of sampling is critical because, following exposure, the compounds or their metabolites may be rapidly eliminated from the organism. In these cases, the biological sample is usually collected during exposure, at the end of the exposure period, or sometimes just before the next work shift. When biological monitoring consists of the sampling and analysis of urine, it is usually performed in "spot" specimens, because routine collection of 24-h samples from workers is impractical. It is standard practice to correct the results for the dilution of the urine by expressing the results per gram of creatinine. Analyses performed on very dilute urine samples are not reliable. The World Health Organization has specified acceptable limits for urine specimens of between 0.3 and 3.0 g/L creatinine (or 1.010 to 1.030 specific gravity) (ACGIH, 2000). When the large interindividual variability or high "background" level of the biological parameter selected makes the interpretation of a single measurement difficult, it is sometimes useful to analyze biological material collected before and after the exposure period. The change in the biological parameter specifically due to exposure can sometimes be better assessed by this method.

Environmental monitoring plays an important role for evaluating and preventing excessive exposure to toxicants in the workplace. However, the prevention of acute toxic effects on the respiratory tract, skin, or eye mucosa can only be achieved by keeping the concentration of the irritant substance below a certain level or eliminating exposure. Local acute effects of chemicals do not lend themselves to a biological surveillance program. Likewise, biological monitoring is usually not indicated for detecting peak exposure to dangerous chemicals such as arsine (AsH_3), carbon monoxide, or prussic acid (HCN). Furthermore, identification of emission sources and the evaluation of the efficiency of engineering control measures are usually best performed by ambient air analysis. Table 33-7 lists the approaches most useful for controlling inhalation exposures in the workplace. It should be emphasized that process changes and application of engineering controls are preferable to reliance on personal protective equipment.

Change the process to use or produce less hazardous compounds.

Automate and enclose the process to isolate the compounds.

Incorporate administrative and work practice controls to reduce duration or intensity of exposure.

Install or upgrade local exhaust systems and dilution exhaust.

Institute a comprehensive program for personal protective equipment use where necessary.

Table 33-7 Control Approaches for Occupational Inhalation Hazards

In summary, environmental and biological monitoring should not be regarded as opposites but as complementary elements an occupational health and safety program. They should be integrated as much as possible to ensure low levels of contaminants and optimal health for workers.

CONCLUSION

The working environment will always present the risk of overexposure of workers to various toxicants. Recognition of these risks should not wait until epidemiologic studies have defined hazardous levels. A combined experimental, clinical, and epidemiologic approach is the most effective for evaluating the potential risks. One can then promulgate scientifically based occupational health standards, apply effective workplace controls to ensure adherence to those standards, and institute worker health surveillance programs to identify unexpected effects in susceptible individuals.

CHAPTER 34

REGULATORY TOXICOLOGY

Richard A. Merrill

THE ROLES OF SCIENCE AND REGULATION

This chapter deals with the use of the results of toxicologic studies by governmental regulatory agencies and with the requirements these agencies impose for the conduct of such studies. It does not attempt to justify government agencies' handling of toxicology-related issues but rather seeks to explore the interaction of scientific and regulatory institutions in this field.

This explanation begins by recognizing a central difference between the goals of science and those of government: Science investigates and attempts to explain natural phenomena; it is cautious, incremental, and truth-seeking. Government, in its capacity as regulator, seeks to affect human behavior and settle human disputes; it is episodic and peremptory and pursues resolution rather than truth. It often happens that a regulator cannot withhold a decision or reserve judgment on a problem even when the facts appear to call for a delay, for even a pause to delay out of respect for "getting all the information" has real-world consequences. Because the field of toxicology continuously generates information about the effects of chemicals (though it less often provides information about the magnitude of their effects or the frequency of exposure associated with these effects), regulators invariably are forced to intervene (i.e., to decide) before knowledge is complete.

Scientists are also often frustrated by another feature of American regulatory institutions. In the United States, government officials are accorded less discretion to make political or social judgments than in any other industrialized society. Government actions affecting private interests are constrained by the demand that they be authorized by the legislature and that they rest on a factual XXX predicate that the legislature has specified for such decisions. Furthermore, our legal system requires regulators to set forth the facts on which they rely, and we allow the opponents of regulatory measures numerous opportunities to contest them. Participants in the regulatory process start from the assumption that the available evidence can be construed in the light most favorable to their position. Regulators, for their part, often overstate the evidence for their decisions, just as those who challenge them do, with the result that both sides frequently appear to distort the facts.

THE RELATIONSHIP BETWEEN THE DISCIPLINE OF TOXICOLOGY AND REGULATORY INSTITUTIONS

The foregoing observations could apply to any scientific discipline whose investigations underpin governmental decision making. But over the past three decades regulation and toxicology have become intertwined in distinctive ways. The most obvious connection is that regulators whose job is to protect health rely heavily on toxicologic principles and experimental data for their evaluation of problems that present the need for a decision. Whether the decision is to assign priorities among a group of compounds or to approve a new substance or restrict the use of an old one, the findings of toxicologic investigations are likely to be influential, and often decisive.

Regulators are not merely consumers of experimental results but also shape toxicologic science in ways that may be unexpected. Regulatory demands have provided a major impetus for improvements in toxicologic methods, and they have stimulated a demand for major toxicologic studies. Some programs, such as the programs of the Food and Drug Administration (FDA) for licensing drugs and food additives and that of the Environmental Protection Agency (EPA) for registering pesticides, explicitly demand toxicologic studies of new, and in some cases marketed, compounds. Such studies constitute a major part of the discipline's research agenda. But even if no government agency were empowered to demand toxicologic studies, concern for public health would lead marketers of new products to turn to toxicology to evaluate their possible health hazards.

Regulatory agencies also have exercised important influence over the design and conduct of toxicologic studies. For example, the EPA is empowered by the Toxic Substances Control Act (TSCA) to promulgate standards for different types of toxicologic (and other scientific) investigations. Likewise, the FDA has long issued guidelines for laboratory studies submitted in support of food additives and drugs. Both agencies have adopted requirements governing laboratory operations and practice. Communication between government officials and laboratory scientists flows in both directions. Government testing standards are influenced strongly by the prevailing consensus among toxicologists, many of whom work in regulatory agencies. The procedures for adopting these standards always permit if not encourage the expression of privately held views by members of the discipline.

The balance of this chapter focuses on two of these prominent linkages between toxicology and regulation. The next section outlines the legal and administrative contexts in which regulators rely on toxicologic data in making critical decisions. In the final section, the focus is on government as a regulator of toxicology—as the source of guidance for and limitations on the design and conduct of laboratory experiments. This chapter does not, however, provide a comprehensive treatment of the legal and regulatory requirements that impinge on toxicology, nor does it discuss every program that relies on toxicologic data. It also omits such topics as the laws and regulations designed to protect laboratory personnel, legal restrictions on the handling of dangerous substances, and local requirements for the operation of laboratories.

REGULATORY PROGRAMS THAT RELY ON TOXICOLOGY

An Overview of Approaches to Toxic Chemical Regulation

This section surveys current federal programs for controlling human exposure to toxic chemicals. The discussion highlights the features of regulatory programs that influence both the quantity and the quality of data needed to support an agency's decisions. One such regulatory feature, sometimes overlooked by nonlawyers, is the law's allocation of the "burden of proof," which is the responsibility for demonstrating whether a substance is safe or hazardous. The range of possible approaches can be observed by comparing laws such as the Food Additives Amendment, which requires users of new substances to prove lack of hazard *before* humans may be exposed, with laws such as the Occupational Safety and Health Act (1970), which requires regulators to show that a substance *is* hazardous *before* exposures can be restricted. The approach chosen by Congress powerfully influences an agency's ability to require comprehensive toxicologic investigation of compounds and thus affects the quality of data on which decisions ultimately are based.

A parallel distinction, observable even in programs that mandate premarket testing of new products, is made between substances not yet on the market and those

previously approved on the basis of studies that inevitably appear inadequate as investigatory methods improve.

Typology of Regulatory Approaches

At least two issues must be resolved to justify government action to regulate human exposure to a substance. First, it must be determined that the substance is capable of harming persons who may be exposed. Second, it must be determined that humans are likely to be exposed to the substance in ways that could be harmful. In the absence of affirmative answers to both questions, government intervention to control exposure would be difficult to justify. A few statutes require only these two findings. Most laws under which chemicals are regulated, however, mandate or permit consideration of other criteria as well, such as the *magnitude* of the risk posed by a substance and the *consequences and costs* of regulating it.

Agencies Involved

At the federal level, four agencies are chiefly responsible for regulating human exposure to chemicals: the FDA, the EPA, the Occupational Safety and Health Administration (OSHA), and the Consumer Product Safety Commission (CPSC). Together they administer some two dozen statutes whose primary goal is the protection of health. The statutes administered by these four agencies convey different levels of concern about risks to human health and about the weight to be given economic costs (OTA, 1981). This diversity has several explanations. The statutes were enacted in different eras. They originated with different political constituencies and remain under their influence. Perhaps most significant, statutory standards often reflect differences in the technical capacity to control different types of exposures, and they embody different congressional judgments about the economic implications of limiting exposures.

Summary of Current Approaches

For at least two decades, federal regulatory agencies have distinguished between cancer and all other toxic effects. However, it is in their treatment of carcinogens that existing statutes appear to display the greatest diversity. For other (noncarcinogenic) chemicals, regulators have generally embraced a standard safety assessment formula, built around the concept of *acceptable daily intake* (ADI). (In recent years, the EPA has adopted the term *reference dose* in order to avoid any implication that any exposure to a toxic material is "acceptable.") The ADI for a chemical is derived by applying a safety factor—usually 100, but sometimes a larger number if the toxicologic data are sparse or occasionally a smaller number if the data are complete—to the human equivalent of the lowest "no observed effect level" (NOEL) revealed in animal experiments. When estimated human exposure to a chemical falls below the ADI, it—or the quantity of it that results in that exposure—is adjudged "safe." It is only when exposure is likely to exceed the ADI that the regulator must turn to any other considerations made relevant by the applicable statute.

However, this traditional approach to conventional toxicants has not been considered appropriate for carcinogens. Regulators in the United States and many of their counterparts in other countries have operated on the premise that carcinogens as a class cannot be assumed to have "safe" or threshold doses. Furthermore, they have assumed that any chemical shown convincingly in animal studies to cause cancer should be considered a potential human carcinogen. Accordingly, for this group of compounds, which has grown to exceed 500 as more chemicals have been subjected to long-term testing, U.S. regulators have generally assumed that no finite level of human exposure can be considered risk-free. As research has begun to illuminate the different mechanisms by which chemicals may cause cancer, however, regulatory agencies have cautiously accepted the possibility that "safe" thresholds may be established for particular carcinogens.

No Risk The traditional approach is epitomized, indeed codified, by the famous Delaney clause, enacted in 1958 as part of the Food Additives Amendment. The amendment itself requires that any food additive be found "safe" before the FDA may approve its use (FD&C Act, 1958). The Delaney proviso stipulates that this finding may not be made for a food additive that has been shown to induce cancer in humans or in experimental animals. The Delaney clause has been characterized as a categorical risk-benefit judgment by Congress that no food additive is likely to offer benefits sufficient to outweigh any risk of cancer (Turner, 1971).

Negligible Risk Because the risk posed even by a carcinogenic substance depends on the dose as well as its potency, it may be possible to reduce human exposure to such low levels that any associated risk is small enough to ignore without considering any other criteria. No current health statute explicitly prescribes such a "negligible risk" approach, but the FDA has adopted it administratively for some classes of environmental carcinogens. For example, under a 1962 amendment to the Delaney clause, the FDA may approve a carcinogenic drug for use in food-producing animals if no residue will be found in edible tissues of treated animals (FD&C Act, 1938). The FDA announced that it will calibrate its tests for residues so that they only register toxins with carcinogenic potency (FDA, 1985) and will approve a carcinogenic drug if the sponsor provides an analytic method capable of detecting residues in meat, milk, or eggs large enough to pose a lifetime dietary risk greater than 1 in 1 million, as determined by extrapolation from animal bioassays. In 1996, Congress amended the provisions of the Food, Drug, and Cosmetics (FD&C) Act applicable to pesticide residues on food, adopting a standard that, though not expressed in these words, is understood to permit a tolerance for a carcinogenic pesticide if the estimated cancer risk is extremely small, on the order of 1 in 1 million (Food Quality Protection Act, 1996).

Any "negligible" or "de minimis" risk approach requires data depicting carcinogenic potency. This is not a major problem when an agency can require a product's sponsor to conduct the necessary tests, but programs in which regulation responds to already extant exposures often lack such leverage. The approach also requires a method for quantifying the risk associated with low doses of a carcinogen. As a practical matter, a negligible risk approach will not suffice when exposures to toxic substances cannot be reduced to very low levels without sacrificing other values.

Trade-off Approaches These embrace a variety of verbal formulas that have one common feature: each requires the regulatory agency to weigh factors in addition to the health risks posed by substances targeted for regulation. One version is illustrated by the Occupational Safety and Health Act, which directs OSHA in setting workplace standards for toxic materials, to elect the standard "which most adequately assures, *to the extent feasible* . . . that no employee will suffer material impairment of health or functional capacity" (OSHA, 1970). OSHA has interpreted this language as requiring it to consider, in addition to the risk posed by a substance, the availability of technology for reducing exposure and the financial ability of the responsible industries to pay for the necessary controls. The agency need not, however, balance the health benefits of mandated exposure controls against the costs of achieving them (*American Textile Manufacturers Institute v. Donovan,* 1982).

A more expansive "trade-off" law is the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA), which requires the EPA to refuse or withdraw registration of a pesticide if its use is likely to result in "unreasonable adverse effects on health or the environment" (FIFRA, 1972). The EPA interprets this language as requiring that it weigh all the effects of a pesticide—its contribution to food production as well as its possible adverse effects on applicators, consumers, and the natural environment—in determining whether, or on what terms, to permit registration. The Toxic Substances Control Act (TSCA, 1976) uses more explicit language to mandate the balancing of risks and benefits. TSCA further dictates that, in seeking the right balance, the EPA must adopt the "least burdensome" controls on the use of or exposure to a chemical (*Corrosion Proof Fittings v. EPA,* 1991).

PROGRAMS FOR REGULATING CHEMICAL HAZARDS

Food and Drug Administration

The oldest of the major health regulation laws, the FD&C Act, was enacted in 1938 and covers food for humans and animals, human and veterinary drugs, medical devices, and cosmetics.

Food The original 1906 Food and Drug Act contained two prohibitions addressed to foods containing hazardous constituents; both remain part of the current law. The first forbids the marketing of any food containing "any *added* poisonous or deleterious *substance which may render it injurious* to health," a provision that the FDA has interpreted as barring foods presenting any significant risk. The second forbids the marketing of foods containing *nonadded* toxicants that make them "*ordinarily injurious* to health," a standard that accords a preferred status to traditional components of the American diet [FD&C Act § 402(a)]. Neither of these original provisions required premarket approval; the FDA had the burden of proving that a food was, in the legal vernacular, "adulterated."

Congress has since amended the act several times to improve the FDA's ability to ensure the safety of foods. Each time, it identified a class of additives for which it prescribed a form of premarket approval, thus giving the FDA the authority not only to evaluate a substance's safety before humans are exposed but also to specify the kinds of studies necessary to obtain approval (FDA, 1994).

The most important of these amendments was the 1958 Food Additives Amendment. For food additives, the law requires safety to be demonstrated prior to marketing. The critical standard for approval is that the substance is "reasonably certain to be safe"; no inquiry into the benefits of an additive is undertaken or authorized (Cooper, 1978). But the amendment does not apply to all food ingredients. Congress excluded substances that are "generally recognized as safe" (GRAS) by

qualified scientific experts. In effect, it instructed the FDA to pay less attention to ingredients that had been in use for many years without observable adverse effects. Congress also excepted ingredients sanctioned by either the FDA or the U.S. Department of Agriculture (USDA) prior to 1958. The practical significance of this exception is that a "prior-sanctioned" ingredient is not subject to the Delaney clause because it is not in the technical legal sense a food additive.

Three classes of indirect food constituents—pesticide residues, animal drug residues, and food-contact materials—are subject to distinct regulatory standards. Pesticide residues on raw agricultural commodities for years were regulated by the EPA under a 1954 amendment to the FD&C Act, which allowed residues if they meet a tolerance established by the agency (FD&C Act § 348). In setting tolerances, the EPA could consider both the potential adverse health effects of residues and the value of pesticide uses. If the concentration of a pesticide in a processed food exceeded the established tolerance, however, and the pesticide was a carcinogen, the Delaney clause prohibited its approval for that use (*Les v. Reilly,* 1992). This framework was revised by Congress in 1996 to exempt pesticide residues from the operation of the Delaney clause but also restrict sharply the circumstances in which food production "benefits" could be considered in setting tolerances. The amended law requires that any pesticide tolerance, whether on raw or processed food, whether for a carcinogen or a conventional toxicant, must be "safe," a standard defined as "reasonable assurance of no harm" (Food Quality Protection Act, 1996).

Any animal drug residue must be shown to be safe for humans under essentially the same standards that apply to food additives, with a notable exception. The FDA has interpreted the 1962 authorization for approval of carcinogenic compounds ("if . . . no residue of the additive will be found") as allowing residues that pose no more than a negligible risk.

A food-contact substance requires approval as a food additive if, when used as intended, it "may reasonably be expected to become a component of food." This vague language presents two issues. First, the Delaney clause appears to preclude approval if the material induces cancer, as some important food-packaging materials, such as acrylonitrile and polyvinyl chloride, clearly do. Second, the scientific principle of diffusion supports the argument that all food-contact substances are properly characterized as food additives. The FDA has attempted to cushion this potential collision between toxicologic findings and advances in analytic chemistry. It has declined to apply the Delaney clause to carcinogenic migrants whose extrapolated risk does not exceed 1 in 1 million, because these migrants present only a minimal risk (FDA, 1984). Before 1997, the law required affirmative FDA approval of all such "indirect food additives," burdening both the agency and producers of food-contact materials with a slow and expensive process for evaluating chemicals that could migrate into food, if at all, only at extremely low levels. In omnibus legislation that addressed most of FDA's regulatory programs, Congress substituted a premarket notification system for food-contact materials that permits the agency to delay introduction if it questions a material's safety but does not require affirmative agency approval (FDA Modernization Act, 1997).

Human Drugs Environmental contaminants constitute the final category of food constituents of concern to regulators. The FDA relies on a provision of the 1938 act authorizing the establishment of tolerances for "added poisonous or deleterious substances" that cannot be avoided through good manufacturing practice. In setting such tolerances, the FDA weighs three factors: (1) the health effects of the contaminant, usually estimated on the basis of animal data; (2) the ability to measure the contaminant; and (3) the effects of various tolerance levels on the price and availability of the food (Merrill and Schewel, 1980).

Preclinical studies in animals play an important role in the FDA's evaluation of human drugs. The current law requires premarket approval, for both safety and efficacy, of all "new" drugs, a category that embraces virtually all prescription drug ingredients introduced since 1938 (Hutt and Merrill, 1991). Investigation of therapeutic agents in humans has long been accepted, and the primary evidence of safety (as well as effectiveness) accordingly comes from clinical and not laboratory studies. However, animal studies are the sole source of information about a substance's biological effects before human trials are begun, and their results influence not only the decision whether to expose human subjects but also the design of clinical protocols (FDA, 1994).

Medical Devices In 1976, Congress overhauled the FD&C Act's requirements for medical devices, according the FDA major new authority to regulate their testing, marketing, and use. The elaborate new scheme contemplates three tiers of control, the most restrictive of which is premarket approval similar to that required for new drugs. To obtain FDA approval of a so-called class III device, the sponsor must demonstrate safety and efficacy. The bulk of the data supporting such applications will be derived from clinical studies but also will include toxicologic studies of any constituents likely to be absorbed by the patient.

Cosmetics The statutory provisions governing cosmetics do not require premarket approval of any ingredient or demand that manufacturers test their products for safety, though most manufacturers routinely do so. The basic safety standard for cosmetics is similar to that for food ingredients: no product may be marketed if it contains "a poisonous or deleterious substance which may render it injurious to health" [FD&C Act § 601(a)]. The case law establishes that this language, too, bars distribution of a product that poses any significant risk of more than transitory harm when used as intended, but it places on the FDA the burden of proving a violation (Hutt and Merrill, 1991). The FDA has brought few cases under this standard, in part because acute toxic reactions to cosmetics are readily detected and immediately result in abandonment of the offending ingredient.

While the law does not require premarket proof of safety for most cosmetic ingredients generally, it does mandate safety testing for color additives. The scheme enacted by Congress in 1960 (FD&C Act § 706) resembles that for food additives except that no colors are exempt; every color additive must be shown, with "reasonable certainty," to be safe. A separate version of the Delaney clause precludes approval of any carcinogenic color additive, no matter how small a risk it presents (*Public Citizen v. Young,* 1987).

Environmental Protection Agency

Created in 1970, the EPA became responsible for administering an expanding portfolio of laws protecting human health and the environment. A comprehensive review of the EPA's numerous programs is not possible here; the following summary focuses on those EPA activities in which toxicologic evidence plays a central role: pesticide regulation, regulation of industrial chemicals, regulation of drinking water supplies, hazardous waste control, and regulation of toxic pollutants of water and of air.

Pesticides Under the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA), no pesticide may be marketed unless it has been registered by the EPA. The law specifies that a pesticide shall be registered if it is effective, bears proper labeling, and "when properly used . . . will not generally cause unreasonable adverse effects on the environment" (FIFRA § 136b). Congress defined this last criterion as "any unreasonable risk to man or the environment, taking into account the economic, social and environmental costs and benefits of the use of any pesticide." Most of the data supporting a product's initial registration—mainly toxicologic studies—are provided by the sponsor.

In the early 1970s, the EPA engendered controversy by canceling registrations for a number of pesticides based primarily on studies suggesting that they were carcinogenic in animals. Criticism of its "hair-trigger" approach to regulation, coupled with court rulings that the agency was obligated to initiate the process of cancellation whenever a pesticide's safety came into question, led to important changes in the law. Congress added procedural safeguards for pesticide manufacturers and created a panel of outside scientists to review contemplated actions against pesticides (FIFRA, 1972). The EPA itself established a procedure, now named "special review," for public ventilation of disputes over the risks and benefits of pesticides before the formal cancellation process is undertaken (EPA, 1980). A pesticide will be subjected to close scrutiny if the EPA concludes that it induces cancer in experimental mammalian species or in humans. The agency published guidelines for assessing whether a pesticide or any other substance poses a cancer risk to humans (EPA, 1984), and a decade later issued a proposed revision of these guidelines which remains the subject of fierce debate as this volume goes to press (EPA, 1996). Even if a pesticide is convincingly shown to be a carcinogen, however, the law would allow it to be registered if the EPA concluded that its economic benefits outweighed the risk.

The EPA has for nearly two decades been engaged in a comprehensive review of previously registered pesticides and "reregistration" of those that meet contemporary standards for marketing. Under this program, many older pesticides have been subjected to comprehensive toxicologic testing, including carcinogenicity testing, for the first time, and the results have required modification of the terms of approved use and, in some instances, cancellation for several agents. In 1988, Congress amended the law to require the EPA to accelerate this reregistration effort (FIFRA Amendments, 1988). The agency was specifically requested to increase the stringency of its requirements for neurotoxic and behavioral testing to include tests "related to chronic exposure, prenatal, and neonatal effects." The EPA has since published additional testing data requirements for hundreds of active pesticide ingredients and has issued decisions on reregistration eligibility for over 70, but the project remains a work in progress.

Industrial Chemicals The Toxic Substances Control Act (TSCA, 1976) represents Congress's most ambitious effort to control the hazards of chemicals in commercial production. The TSCA covers all chemical substances manufactured or processed in or imported into the United States, except for substances already regulated under other laws. *A chemical substance* is defined broadly as "any organic or inorganic substance of a particular molecular identity."

The TSCA gives the EPA three main powers. The agency is empowered to restrict or even ban the manufacture, processing, distribution, use, or disposal of a

chemical substance when there is a reasonable basis to conclude any such activity poses an "unreasonable risk of injury to health or environment." In determining whether a chemical substance presents an unreasonable risk, the agency is instructed (TSCA § 6) to consider the effects of such substance or mixture on the health and the magnitude of the exposure of human beings to such substance or mixture; the effects of such substance or mixture on the environment and the magnitude of the exposure of the environment to such substance or mixture; the benefits of such substance for various uses and the availability of substitutes; and the reasonably ascertainable economic consequences of the rule, after consideration of the effect on the national economy, small business, technologic innovation, the environment and public health.

The EPA also must consider any rule's positive impact on the development and use of substitutes as well as its negative impact on manufacturers or processors of the chemical and weigh the economic savings to society resulting from reduction of the risk. The TSCA's trade-off approach to regulation has proved a major challenge to the EPA. The agency has not often used its authority often under TSCA § 6. In 1989, it issued a comprehensive rule prohibiting the future manufacture, importation, processing, and distribution of almost all products containing asbestos. Despite the documented hazards of asbestos, a court overturned the rule; the ban failed to satisfy the statutory requirement that the EPA promulgate the "least burdensome" regulation required to protect the environment (*Corrosion Proof Fittings v. Environmental Protection Agency*, 1991). The ban continues to govern products that were not in manufacture as of mid-1989, but even a decade later the EPA has not attempted to issue a new rule regulating existing asbestos-containing products, nor has it attempted to use what was once assumed to be its potent authority under Section 6 to regulate any other chemical substance.

If the EPA suspects that a chemical *may* pose an unreasonable risk but lacks sufficient data to take action, the TSCA empowers it to require testing to develop the necessary data. Similarly, it may order testing if the chemical will be produced in substantial quantities that may result in significant human exposure whose effects cannot be predicted on the basis of existing data. In either case, the EPA must consider the "relative costs of the various test protocols and methodologies" and the "reasonably foreseeable availability of the facilities and personnel" needed to perform the tests (TSCA § 4).

Finally, to enable the EPA to evaluate chemicals before humans are exposed, the TSCA requires the manufacturer of a new chemical substance to notify the agency 90 days prior to production or distribution [TSCA § 5(a)(1)]. The manufacturer's or distributor's notice must include any health effects data it possesses. However, the EPA is not empowered to require that manufacturers routinely conduct testing of all new chemicals to permit an evaluation of their risks; Congress declined to confer the kind of premarket approval authority that the FDA exercises for drugs and food additives and the EPA exercises for pesticides.

The system for regulating new and existing chemical substances in the European Union (E.U.) highlights both the advantages and disadvantages of the U.S. system under the TSCA. Since 1979, the E.U. has required manufacturers of new chemical substances to submit notification to a member state at least 45 days prior to *marketing* the substance. The notification for substances produced in excess of 1 ton per year must include a base set of data that assess acute and subacute toxicity, mutagenicity, and carcinogenic screening. Additional tests may be required if the production level exceeds specified volumes or if the base set of data suggests a possible hazard. In 1992, the E.U. expanded its regulatory scheme by imposing health effects testing requirements on chemicals produced in amounts of less than 1 ton per year and by lengthening the waiting period from 45 to 60 days. In addition, member states that receive notification are now obligated to conduct risk assessments on new substances in accordance with guidelines adopted by the E.U.

The E.U. and U.S. systems for regulating new chemicals thus differ significantly. The E.U. scheme requires manufacturers to generate and submit a base set of data concerning the health risks of most new chemicals; the EPA is authorized to order testing only in limited situations. The TSCA, however, permits regulatory intervention at a much earlier stage than the E.U. by requiring notification prior to manufacturing. Perhaps most importantly, the E.U. system addresses only notification, labeling, and packaging, while member states retain their independent authority over the control of new substances.

In 1993, the E.U. adopted a scheme for regulating approximately 100,000 existing chemicals listed on the European Inventory of Existing Chemical Substances (EINECS). The E.U. system for regulating existing chemicals closely resembles the TSCA approach. Manufacturers of existing chemicals must submit existing data on the chemicals. Based on these data, E.U. regulators select priority chemicals each year and assign the responsibility for assessing these chemicals to member states. Manufacturers of priority chemicals must submit data for the assessments and perform new studies if necessary.

Hazardous Wastes Several statutes administered by the EPA regulate land disposal of hazardous materials. The principal law is the Resource Conservation and Recovery Act (RCRA), enacted in 1976. The RCRA established a comprehensive federal scheme for regulating hazardous waste. Directed to promulgate criteria for identifying hazardous wastes, the EPA specified these as ignitability, corrosivity, reactivity, and toxicity. The agency has identified accepted protocols for determining these characteristics and established a list of substances whose presence will make waste hazardous.

The RCRA directs the EPA to regulate the activities of generators, transporters, and those who treat, store, or dispose of hazardous wastes. Standards applicable to generators, transporters, and handlers of hazardous wastes must "protect human health and the environment." The EPA's regulations applicable to generators and transporters establish a manifest system that is designed to create a paper trail for every shipment of waste, from generator to final destination, to ensure proper handling and accountability. The agency has the broadest authority over persons who own or operate hazardous waste treatment, storage, or disposal facilities. Pursuant to the RCRA, it has issued regulations prescribing methods for treating, storing, and disposing of wastes; governing the location, design, and construction of facilities; mandating contingency plans to minimize negative impacts from such facilities; setting qualifications for ownership, training, and financial responsibility; and requiring permits for all such facilities (EPA, 1993).

Toxic Water Pollutants The EPA has had responsibility for regulating toxic water pollutants since 1972. As originally enacted, Section 307 of the Federal Water Pollution Control Act required the EPA to publish within 90 days and periodically add to a list of toxic pollutants for which effluent standards (discharge limits) would then be established. Section 307(a)(4) of the act originally specified that, in establishing standards for any listed pollutant, the EPA was to provide an " *ample margin of safety* " —a difficult criterion to meet for most toxic pollutants and arguably impossible for any known to be carcinogenic. The law also mandated both a rapid timetable and a complex procedure for standard setting.

The EPA's disturbingly slow implementation of these instructions precipitated a series of lawsuits. The agency eventually reached a court-sanctioned settlement that fundamentally altered the federal approach toward toxic pollutants of the nation's waterways. The settlement allowed the EPA to act under other provisions of the act that focused on economic cost and technologic feasibility in setting limits and thus freed the agency from the rigid demands of Section 307. Congress incorporated the terms of this settlement in 1977 amendments to the statute.

In 1987, Congress again amended the Federal Water Pollution Control Act to toughen standards for toxic pollutants. Under the prior law, the EPA had developed health-based "water quality criteria" for 126 compounds it had identified as toxic. These criteria essentially described *desirable* maximum contamination levels which, because the EPA's discharge limits were technology-based, generally were substantially lower than the levels actually achieved. The 1987 amendments gave what had been advisory criteria real bite by requiring that states incorporate them in their own mandatory standards for water quality and impose additional effluent limits on operations discharging into below-standard waterways (Heineck, 1989).

Drinking Water The 1974 Safe Drinking Water Act (SDWA) was enacted to ensure that public water supply systems "meet minimum national standards for the protection of public health." Under the SDWA, the EPA is required to regulate any contaminants "which may have an adverse effect on human health." The means prescribed was the establishment of national primary drinking water regulations for public water systems. For each contaminant of concern, the agency was to prescribe a maximum contaminant level (MCL) or a treatment technique for its control. The original 1974 act prescribed a two-stage process. The EPA first was required to promulgate *interim* national primary drinking water regulations, uniform minimum standards at levels that would "protect health to the extent feasible . . . (taking costs into consideration)." These interim regulations were later supplanted by regulations formulated on the basis of a series of reports by the National Academy of Sciences (NAS). The charge to the NAS committee was to recommend the MCLs necessary to protect humans from any known or anticipated adverse health effects. In turn, the EPA was to specify enforceable limits as close as feasible to the levels recommended by the NAS. By 1986, the EPA had established MCLs for just 23 contaminants and treatment techniques for none.

In that year Congress amended the Safe Drinking Water Act to cover more contaminants, apply more pressure to states and localities to clean up their drinking water supplies, and strengthen the EPA's enforcement role. The EPA was required to adopt regulations for a total prescribed list of 83 contaminants within 3 years (including all but one of those originally regulated). The 1986 amendments sharpened the distinction between optimal drinking water conditions—renamed maximum contaminant level goals (or MCLGs)—and legally enforceable, technology- and cost-based contaminant levels or treatment requirements, which continued to bear the label "MCL."

Continuing criticism of the EPA SDWA effect through the following decade precipitated yet another legislative attempt at reform. In 1996, Congress once again

amended the act to encompass an expanded list of contaminants to be regulated and revise the schedule for standard setting. At the urging of industry, it also included a provision that specifically directs the EPA, in setting MCLGs and MCLs, to use the "best available science."

In March 2000, the latter change in the law led to one of the most significant judicial rulings in the environmental health field. The case was a challenge to the EPA's decision to retain a MCLG for chloroform of zero in the face of evidence, accepted by its own scientists, that the mechanism by which chloroform produces tumors in rodents is threshold-limited. The reviewing court held that given its acceptance of the evidence of a threshold, the EPA was required by the SDWA's "best available" evidence provision to base its decision on that evidence (*Chlorine Chemistry Council v. EPA,* 2000). This ruling marks the first time that a court has directed a federal regulatory agency to recognize a "safe" finite level of exposure for an animal carcinogen.

Toxic Air Pollutants Section 112 of the Clean Air Act (CAA) now provides a list of 189 hazardous air pollutants, which the EPA may modify by adding or deleting items. The EPA must establish national emissions standards for sources that emit any listed pollutant. The original 1970 version of Section 112 required the standards to provide "an ample margin of safety to protect the public health from such hazardous air pollutants." The implication of this language—that standards were to be set without regard to the costs of emissions control—generated intense debate from the beginning and contributed to the EPA's glacial pace of implementation. The EPA finally attempted to escape the strict language of Section 112 when it issued a standard for vinyl chloride in 1986. In this instance the agency claimed it could consider costs and declined to adopt a standard dictated solely by safety. A court ruled that the EPA had improperly considered costs, but it did make clear that in determining what emissions level was safe, even for a carcinogen, the EPA was not obligated to eliminate exposure. The court also said the EPA could consider costs in deciding what, if any, additional margin of protection to prescribe (*Natural Resources Defense Council, Inc., v. United States Environmental Protection Agency,* 1987).

Amendments to the CAA in 1990 responded to the difficulties presented by the strict approach of old Section 112. The amendments replace the health-based standard with a two-tiered system of regulation. The EPA must first issue standards that are technology-based, designed to require the "maximum degree of emission reduction achievable" (MACT) [CAA § 112(d)(2)]. If the MACT controls are insufficient to protect human health with an "ample margin of safety," the EPA must issue residual risk standards [CAA § 112(f)]. The 1990 Amendments essentially define "ample margin of safety" for carcinogens by requiring the EPA to establish added residual risk limits for any pollutant that poses a lifetime excess cancer risk of greater than 1 in 1 million.

Occupational Safety and Health Administration

The 1970 Occupational Safety and Health Act requires employers to provide employees with safe working conditions and empowers OSHA to prescribe mandatory occupational safety and health standards (OSHA, 1970). OSHA's most controversial actions involved its attempts to set exposure limits for toxic chemicals.

While manufacturers of food additives, drugs, and pesticides must demonstrate the safety of their products prior to marketing, no employer need obtain advance approval of processes or materials or conduct tests to ensure that its operations will not jeopardize worker health. OSHA must first discover that a material already in use threatens worker health before it may attempt to control exposure. Standards for toxic chemicals typically set maximum limits on employee exposure and prescribe changes in employer procedures or equipment to achieve this level.

The act specifies that in regulating toxic chemicals, OSHA shall adopt the standard "which most adequately assures, to the extent feasible, on the basis of the best available evidence, that no employee will suffer material impairment of health or physical capacity" [OSH Act § 6 (b)(5)]. The meaning of these contradictory phrases was for many years a source of controversy. Court decisions made clear that the "best available evidence" did not require proof of causation or even positive epidemiologic studies; animal data alone could support regulation of a toxic substance. The debate focused on whether OSHA had an obligation to weigh the economic costs of its standards. The agency acknowledged that it was required to consider technologic achievability and industry viability, but it denied that it was obliged to balance health benefits against economic costs.

Judicial challenges to OSHA standards have clarified OSHA's responsibilities. In a famous case, the U.S. Supreme Court overturned OSHA's benzene standard because the agency had not shown that prevailing worker exposure levels posed a "significant" health risk (*Industrial Union Department, AFL-CIO, v. American Petroleum Institute,* 1980). This prerequisite proved a major obstacle when OSHA attempted to establish standards for 428 air contaminants in a single proceeding in 1989. Although it found that OSHA's generic approach to regulation was permissible in theory, a court vacated the standards because OSHA failed to show that each individual contaminant posed a "significant risk" at current levels (*American Federation of Labor v. OSHA,* 1992). However, the Supreme Court earlier upheld OSHA's cotton dust standard, rejecting arguments that the agency was obligated to weigh the costs of individual standards for concededly hazardous substances (*American Textile Manufacturers Institute v. Donovan,* 1982).

Consumer Product Safety Commission

Of the four agencies discussed here, the CPSC has played the least important role in federal efforts to control toxic chemicals. The commission was created in 1972 by the Consumer Product Safety Act (CPSA) with authority to regulate products that pose an unreasonable risk of injury or illness to consumers. The commission is empowered to promulgate safety standards "to prevent or reduce an unreasonable risk of injury" associated with a consumer product. If no feasible standard "would adequately protect the public from the unreasonable risk of injury" posed by a consumer product, the commission may ban the product (CPSA § 8). In assessing the need for a standard or ban, the agency must balance the likelihood that a product will cause harm, and the severity of harm it will likely cause, against the effects of reducing the risk on the product's utility, cost, and availability to consumers.

The CPSC also administers the older Federal Hazardous Substances Act (FHSA). The FHSA authorizes the CPSC to regulate, primarily through prescribed label warnings, products that are toxic, corrosive, combustible, or radioactive or that generate pressure. The FHSA is unusual among federal health laws because it contains detailed criteria for determining toxicity. It defines "highly toxic" in terms of a substance's acute effects in specified tests in rodents; substances capable of producing chronic effects thus fall within the "toxic" category. The FHSA contains another unique provision [FHSA § 2(h)(2)] specifically addressing the probative weight of animal and human data on acute toxicity: "If the [commission] finds that available data on human experience with any substance indicates results different from those obtained on animals in the above-named dosages or concentrations, the human data shall take precedence."

The CPSC has prescribed labeling for products containing numerous substances that are acutely toxic. It has also acted to ban from consumer products several substances that pose a cancer risk, including asbestos, vinyl chloride as a propellant, benzene, tris(hydroxymethyl)aminomethane (TRIS), and formaldehyde (Merrill, 1981). Its ban of urea formaldehyde foam insulation was set aside by a reviewing court in an opinion that is remarkable for its unsophisticated but critical analysis of the agency's handling of toxicologic data (*Gulf South Insulation v. CPSC,* 1983).

The Labeling of Hazardous Art Materials Act of 1988 (LHAMA) amended the FHSA. The LHAMA authorizes the CPSC to require labeling of art materials that have "the potential for producing chronic adverse health effects with customary or reasonably foreseeable use." The LHAMA also requires a producer or repackager of an art material to submit the material to a toxicologist for review. The toxicologist must determine whether the material presents a chronic health hazard and must recommend appropriate labeling. The CPSC has issued guidelines, applicable to both the LHAMA and the FHSA, for determining whether a material presents a chronic health hazard (CPSC, 1992).

The CPSC's regulation of asbestos under the FHSA illustrates the overlap of regulatory jurisdictions of different agencies. In 1986, the CPSC issued an enforcement policy requiring accurate labeling of the hazards of asbestos for all asbestos-containing household products (CPSC, 1986). It characterized the labeling requirement as an "interim measure" because the EPA had proposed a ban of asbestos in household products under TSCA. However, as discussed earlier, a court later overturned the EPA's asbestos ban (*Corrosion Proof Fittings v. Environmental Protection Agency,* 1991). Neither the EPA nor the CPSC has since attempted to restrict asbestos-containing products.

REGULATORY CONTROLS OVER TOXICOLOGY

Previous sections of this chapter have surveyed legal contexts in which regulators draw on toxicologic data to decide whether and how to control environmental chemicals. Modern toxicology has developed, in substantial part, in response to the information needs of contemporary regulation. But government impinges on the discipline in more direct ways as well. Regulatory agencies often prescribe the specific objectives and design of studies that are conducted to satisfy regulatory requirements. In addition, pressure to protect animals used in research has produced laws and regulations that govern toxicologists themselves.

Different Ways Regulation Impinges on Toxicology

An agency's influence over the conduct of toxicologic studies depends on its regulatory responsibilities. An agency such as the FDA or the EPA, which must confirm the safety of new substances before marketing, can dictate the kinds of tests that manufacturers must conduct to gain approval. By contrast, an agency that has no premarket approval function has less leverage.

Statutory terms often do not reveal an agency's real power. For example, the FD&C Act does not in so many words authorize the FDA to prescribe the kinds of preclinical tests a manufacturer of human drugs must conduct; it merely says that no new drug may be marketed until the manufacturer has satisfied the FDA, "by all methods reasonably applicable," that it is "safe" [FD&C Act § 505(c)]. However, the agency's power to withhold approval when it has doubts about a drug's safety provides it the practical leverage necessary to demand whatever tests its scientific reviewers believe necessary. Some laws, notably the TSCA, explicitly accord power to prescribe testing; but if an agency has the ability to prevent marketing until safety is proved, doubts about its legal authority to prescribe testing requirements are academic. The important issues are the procedures by which its requirements are adopted, their scope and scientific support, and their legal effect.

The last issue is important for laboratory scientists and test sponsors as well as for lawyers. Two significant legal distinctions should be noted. The first is the distinction between the requirements that an agency imposes for testing of specific compounds and generic requirements prescribed for all compounds within a class (e.g., direct food additives). The FDA could impose its views of appropriate toxicologic testing without ever enunciating any general testing standards. When a compound's sponsor seeks approval, it could be told that the tests it had conducted were inadequate. Alternatively, an individual sponsor could solicit the agency's advice about what tests were necessary before it undertook testing. The first approach wastes resources, and the second—unless agency advice is broadly disseminated—fails to guide other potential sponsors and allows inconsistency in the treatment of similar compounds.

For these reasons, the FDA and EPA have moved increasingly toward establishing generic test standards or guidelines. Both agencies have issued guidelines for the design and conduct of studies of the health effects of compounds submitted for agency approval (EPA, 1993; FDA, 1993). In addition, the EPA has established guidelines for several of the tests that it may mandate by rule or consent agreement for individual chemicals under TSCA § 4 (EPA, 1993). Multinational bodies like the Organization for Economic Cooperation and Development have sought to secure multilateral adherence to standardized test guidelines and minimum testing requirements for new chemicals (Page, 1982).

This trend has focused attention on a second legal distinction: that between binding regulations and advisory guidelines. Any time a regulatory agency wants to provide guidance for private behavior, it confronts a choice between establishing standards that have the force of law and merely conveying its current best judgment of what conduct will satisfy the law. A regulation typically specifies what the law mandates; failure to comply (e.g., failure to perform a test or follow a specified protocol) constitutes a violation of law just as if the regulation had been enacted by Congress. A test guideline describes performance that will satisfy legal requirements; but failure to follow the guideline is not forbidden. The agency may accept another approach that employs, for example, a different set of studies or studies conducted using different protocols if it concludes that they meet the law's basic objectives.

Regulations ensure consistency and are more easily enforced than guidelines, but they are more rigid because they restrict the agency, and the procedures for their adoption are cumbersome. The design and conduct of toxicologic studies, it is often argued, should take into account the characteristics of the test compound, the endpoints to be evaluated, the resources available, and perhaps even laboratory capabilities. Accordingly, both the FDA and EPA have preferred to announce their standards as guidelines, permitting sponsors and scientists to consider alternative approaches.

It is increasingly common for U.S. agencies to specify the types of tests they require before they will consider the safety of a compound (e.g., tests for acute toxicity, subchronic effects, and chronic effects). Within each of these categories, an agency might set out more detailed requirements, essentially enumerating its "base set" data demands. As noted above, an agency may also describe methods for executing particular tests, for instance, a bioassay for carcinogenesis. It is these descriptions that in the United States usually take the form of guidelines.

Both the FDA and the EPA have adopted another set of requirements that specify laboratory procedures for conducting tests required or submitted for regulatory consideration. These good laboratory practice (GLP) regulations prescribe essential but often mundane features of sound laboratory science, such as animal husbandry standards and record-keeping practices (EPA, 1999; FDA, 2000). All of these types of requirements are intended to contribute to sound regulatory decision making by ensuring the quality and integrity of toxicologic data submitted to support agency decisions.

FDA and EPA Testing Standards

It would serve little purpose here to detail existing agency requirements for the design and conduct of toxicologic studies; they change frequently enough that any summary would soon be outdated. This chapter thus only attempts to acquaint the reader with the principal federal programs that specify standards for toxicity testing. The discussion focuses on the FDA and the EPA.

Food and Drug Administration The FDA exercises premarketing approval authority over several classes of compounds, of which the most important, for present purposes, are new human drugs and direct additives to food.

Toxicologic Testing Requirements for Human Drugs In 1962, Congress expressly authorized the FDA to exempt investigational drugs from the premarket approval requirement so that they could be shipped for use in clinical testing, subject to conditions the agency believed appropriate to protect human subjects [FD&C Act § 505(i)]. One condition that the FDA established was that an investigational drug first must have been evaluated in preclinical studies. This requirement appears in current regulations that amplify, in the text and in referenced guidelines, the types of tests that are to be performed and the design they should follow (FDA, 1994). Almost invariably, a drug's sponsor will consult agency personnel to get a precise understanding of what sorts of toxicologic studies they expect. Preclinical studies of substances that are candidates for use as human drugs must meet the standards set by the FDA's GLP regulations (FDA, 1994). These regulations apply to all laboratories—university, independent, and manufacturer-owned—in which such studies are conducted. The work of the International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH) highlights the trend toward international agreement on test methods. In 1994 the ICH—comprising the European Union, Japan, and the United States—issued six draft guidelines on various toxicology testing methods for human drugs. The testing requirements applicable in the United States surely will evolve as the international community reaches consensus on the appropriate methodology.

Testing Requirements for Food Additives The Food Additives Amendment and the Color Additive Amendments require premarket approval of new additives to human food. Both laws assume that laboratory studies in animals will provide the principal data for assessing safety. Thus, a petitioner must submit "full reports of investigations made with respect to the safety for use of such additives, including full information as to the methods and control used" [FD&C Act § 409(c)].

The FDA's regulations contain only general statements about the need for and features of toxicologic studies. For many years, the agency maintained an advice-giving system in which it prescribed the type and design of tests to be performed. In 1982, the FDA first codified this "common law" in *Toxicological Principles for the Safety Assessment of Direct Food Additives and Color Additives Used in Food,* known thereafter as the "Red Book." The Red Book describes the types of tests the FDA believes necessary to evaluate an additive's safety. The agency's requirements, which are in the form of guidelines rather than regulations, are calibrated to the purposes for which the additive will be used, to estimated levels of human exposure, and to the results of sequential studies. The FDA later issued a draft revision, "Red Book II," under the same title as the original. Tests of food color and additives must also comply with the FDA's good laboratory practice regulations (FDA, 1993).

Environmental Protection Agency The EPA's premarket approval authority over pesticides places it, like the FDA, in a position to dictate the design and conduct of studies on such compounds. The 1976 Toxic Substances Control Act gave the EPA authority to mandate testing of other chemicals in use or scheduled for introduction and to specify, by regulation, test standards.

Toxicology Requirements for Pesticides The FIFRA clearly contemplates the submission of toxicologic studies, as well as other types of investigations, to support the EPA's evaluation of a pesticide [FIFRA § 136(b)]. The statute also requires the EPA to "publish guidelines specifying the kinds of information which will be required to support the registration of a pesticide and to revise such guidelines from time to time."

The EPA's regulations state broadly that pesticide registration depends on evaluation of "all available, pertinent data," which must satisfy the minimum requirements set forth in registration guidelines (EPA, 1993). The agency has issued regulations outlining the procedures for submission of registration petitions and their basic content (EPA, 1978, 1993). Animal studies of pesticides must also comply with EPA's own good laboratory practice regulations, which were inspired by the same

investigations that led the FDA to promulgate its standards for testing laboratories and impose similar requirements.

Testing of Industrial Chemicals The primary means by which the EPA may mandate health effects testing of new or existing industrial chemicals is Section 4(a) of the TSCA. That provision states that the administrator "shall by rule require that testing be conducted to develop data with respect to the health and environmental effects for which there is an insufficiency of data and experience" to permit assessment of whether a substance presents an unreasonable risk. This obligation to order testing is triggered by an administrative finding that a chemical presents a potential risk (based on the suspicion of toxicity) or that humans or the environment will be exposed to substantial quantities. The statute creates an Interagency Testing Committee (ITC) with members from EPA, OSHA, CEQ, NIOSH, NIEHS, NCI, NSF, and the Department of Commerce to recommend a list of chemicals that should be tested and in what order of priority. Once the ITC has recommended a chemical substance for testing, the EPA must either initiate testing or publish its reasons for not doing so, within 12 months.

This last requirement, coupled with the statute's formal procedures for adopting test rules, led the EPA initially to rely on negotiations with chemical producers to secure voluntary agreements for the conduct of tests it thought appropriate for chemicals identified by the ITC (GAO, 1982). The practice was challenged by public interest organizations, who were excluded from the negotiations, and ultimately it was declared unlawful (*Natural Resources Defense Council, Inc., v. United States Environmental Protection Agency,* 1984). The agency amended its regulations to recognize two forms of mandates for testing: test rules and enforceable testing consent agreements (EPA, 1993).

TSCA test rules are subject to judicial challenge. Manufacturers challenged a 1988 test rule for cumene, arguing that the EPA had failed to support its finding that the substance enters the environment in substantial quantities with the potential for substantial human exposure. Although the court ultimately upheld the rule, it ordered the agency to articulate standards governing the definition of "substantial" (*Chemical Manufacturers Association v. EPA,* 1990). Another court challenge to a test rule requiring neurotoxicity studies of ten widely used and intensively marketed organic solvents resulted in a settlement with the EPA. The settlement required the EPA to enter into consent agreements with reduced testing requirements for seven chemicals, to eliminate testing requirements for two, and to postpone its decision on one. Both test rules and testing consent agreements specify what types of tests are to be done. Their design is governed either by general "test methodology guidelines" that the EPA has issued for several types of tests or by the rule or the agreement itself. All toxicologic studies required by the EPA under the TSCA must comply with its GLP regulations.

Locating Testing Guidelines The EPA usually publishes toxicology testing guidelines that apply to a specific regulatory program in the *Code of Federal Regulations* (*C.F.R.*). For example, the TSCA testing guidelines appear at 40 *C.F.R.* Part 798. The health effects testing guidelines applicable to the FIFRA appear in the *Federal Register* or may be obtained directly from the agency.

The EPA occasionally issues generic guidelines applicable to several of its regulatory programs. In 1996 it released a draft revision of its cancer assessment guidelines (EPA, 1996). The revised guidelines offer a more flexible approach to the assessment of cancer risk. For example, they support the use of several types of data—including biological, pharmacokinetic, and tumor development data—for hazard identification.

Interagency Testing Criteria and Programs

The foregoing summary of regulatory programs that mandate toxicologic tests (see "FDA and EPA Testing Standards," above) suggests the possibility of inconsistencies in testing standards. In the late 1970s, the responsible regulatory agencies (OSHA and the CPSC as well as the FDA and the EPA) combined to form the Interagency Regulatory Liaison Group (IRLG) to secure agreement on the design of standard toxicologic tests. Though the IRLG has long since collapsed, both the FDA and the EPA, along with the White House Office of Science and Technology Policy, have continued to work to achieve internal consistency.

The National Toxicology Program (NTP) was established in 1978 as an administrative umbrella for coordinating the numerous federal efforts to improve test methods and to coordinate toxicologic studies then under way, primarily in the Department of Health and Human Services. NTP assumed responsibility for what had been the bioassay program of the National Cancer Institute (NCI). An NTP committee that includes representatives of all four regulatory agencies is responsible for selecting chemicals to be tested at public expense. Attention continues to be focused on improving health risk assessment research techniques.

Animal Welfare Requirements

Researchers who conduct studies funded by federal agencies must comply with the Animal Welfare Act (AWA), and some may also be subject to restrictions imposed by the Public Health Service (PHS). Recipients of grants from the Department of Education, the Department of Health and Human Services, the Department of Agriculture, or the EPA are subject only to the AWA. Those funded by the Department of Energy or by the PHS must also comply with PHS policies. Restrictions on animal use also appear in the GLP regulations adopted by the FDA and the EPA (Reagan, 1986).

Animal Welfare Act The AWA is administered by the Animal and Plant Health Inspection Service (APHIS), a part of the U.S. Department of Agriculture. The AWA, which protects only warm-blooded animals and excludes birds, rats, and mice, requires all covered research facilities to register with APHIS and agree to comply with applicable AWA standards. Each facility must file an annual report signed by a responsible official that shows that "professionally acceptable standards governing the care, treatment, and use of animals" were followed for the year in question. The report must include the following:

1. Assurances that alternatives to painful procedures were considered in the design of the studies conducted there.
2. A summary and brief explanation of all exceptions to the standards and regulations that were approved by the Institutional Animal Care and Use Committee, including the species and number of animals affected.
3. The common names and the numbers of animals used in three research categories: (a) research involving no pain, distress, or use of pain-relieving drugs; (b) research involving pain and distress and for which pain-relieving drugs were used; and (c) research involving pain or distress in which no pain-relieving drugs were used because of adverse effects on the procedures, results, or interpretation.
4. The common names and the numbers of animals bred, conditioned, or held for research purposes but not yet used.

Pursuant to the AWA, APHIS has established specific requirements for the humane handling, care, and transportation of dogs and cats, guinea pigs and hamsters, rabbits, nonhuman primates, marine mammals, and other warm-blooded animals. The regulations governing facilities address living space, heating, lighting, ventilation, and drainage. The health and husbandry provisions address feeding, watering, sanitation, veterinary care, grouping of animals, and the number and qualifications of caretakers (APHIS, 1994).

The APHIS has strengthened the content and broadened the scope of its regulations, which were amended in an attempt to achieve more consistency with those of the PHS while favoring flexible guidelines rather than strict standards. The 1991 amendments to the specifications for the humane handling, care, and treatment of dogs and nonhuman primates require research facilities to develop plans to ensure appropriate exercise for dogs as well as an environment that promotes the psychological well-being of nonhuman primates (APHIS, 1991). The APHIS also has clarified the question of whether horses and other farm animals are subject to its regulations (APHIS, 1990). Despite these initiatives, several animal welfare groups and individuals have sued the agency in an attempt to further strengthen the regulations. One lawsuit challenged the APHIS's exclusion of rats, mice, and birds from coverage under the AWA (*Animal Legal Defense Fund v. Madigan,* 1992). A second lawsuit challenged the regulations governing the exercise of dogs and the psychological well-being of nonhuman primates on the grounds that the discretionary standard failed to guarantee minimum requirements (*Animal Legal Defense Fund v. Secretary of Agriculture,* 1993). Both suits were dismissed on the ground that the petitioners—including researchers, members of institutional oversight committees, and animal welfare organizations—lacked standing to challenge the regulations. A more recent challenge to USDA regulations to protect nonhuman primates in biomedical research surmounted the government's claim that the plaintiffs lacked standing but proceeded to uphold the regulations on the merits (*Animal Legal Defense Fund, Inc., v. Glickman,* 2000).

The AWA requires each research facility to establish an Institutional Animal Care and Use Committee (IACUC), composed of three or more members, one of whom must be a veterinarian and one of whom must represent community interests and who may not be affiliated with the institution. In 1989, the APHIS expanded the responsibilities of the IACUC. At least one member of the IACUC must now review and approve the animal care and use components of all proposed research activities. Prerequisites to approval include the avoidance or minimization of discomfort, distress and pain; the use of pain-relieving drugs where appropriate; the consideration of pain-free alternatives; and euthanization when an animal would otherwise experience severe or chronic pain or distress that cannot be relieved.

The IACUC is also responsible for conducting semiannual inspections of the facility itself and of the program for humane care and use of animals. Committee reports are filed with the APHIS and with any federal agency funding the research.

Public Health Service Policy The PHS Policy on Humane Care and Use of Laboratory Animals by Awardee Institutions applies to research using all vertebrates, and thus has a broader reach than the AWA. The PHS policy requires each facility to submit an annual report, called an "Assurance," which is evaluated by the National Institutes of Health (NIH) Office for Protection from Research Risks (OPRR) to determine the sufficiency of animal care.

The PHS policy imposes two primary obligations on researchers: each institution must adopt a Program for Animal Care and Use, and it must establish an IACUC. The IACUC must be made up of at least five members, including a veterinarian, an animal research scientist, a nonscientist, and a person who is not affiliated with the facility in any other capacity. The IACUC must review all applications for research funding and review the institution's programs to ensure compliance with NIH standards. The Health Research Extension Act of 1985 requires that PHS-funded institutions provide training on methods to reduce animal suffering similar to that mandated by the AWA for its personnel. It also requires that researchers' grant applications justify any proposed use of animals (NRC, 1988).

Research facilities subject to either the AWA or PHS may wish to consult a National Academy of Sciences report that details suggestions for developing institutional compliance programs (National Research Council, 1991). Scientists working with no federal funding who expect their research to be submitted to the FDA or the EPA are not subject to the AWA or PHS policies, but they must comply with the animal protection provisions of those agencies' GLP regulations. These regulations prescribe adequate living conditions, detail requirements for veterinary treatment, and impose specific record-keeping requirements (EPA, 1999; FDA, 2000).

CASES

American Federation of Labor v. OSHA, 965 F.2d 962 (11th Cir. 1992).

American Textile Manufacturers Institute v. Donovan, 452 U.S. 490, 495 (1982).

Animal Legal Defense Fund v. Glickman, 204 F.3d 229 (D.C. Cir. 2000).

Animal Legal Defense Fund v. Madigan, 781 F. Supp. 797 (D.D.C. 1992), *vacated and remanded sub nom. Animal Legal Defense Fund v. Espy,* 23 F.3d 496 (D.C. Cir. 1994).

Animal Legal Defense Fund v. Secretary of Agriculture, 813 F. Supp. 882 (D.D.C. 1993), *vacated and remanded sub nom. Animal Legal Defense Fund v. Espy,* 29 F.3d 720 (D.C. Cir. 1994).

Chemical Manufacturers Association v. EPA, 899 F.2d 344 (5th Cir. 1990).

Chlorine Chemistry Council v. EPA, 206 F.3d 1286 (D.C. Cir. 2000).

Corrosion Proof Fittings v. Environmental Protection Agency, 947 F.2d 1201 (5th Cir. 1991).

Environmental Defense Fund, Inc., v. Environmental Protection Agency, 548 F.2d 998 (D.C. Cir. 1976).

Environmental Defense Fund, Inc., v. Ruckelhaus, 439 F.2d 584 (D.C. Cir. 1971).

Environmental Defense Fund, Inc., and National Audubon Society v. Environmental Protection Agency, 510 F.2d 1292 (D.C. Cir. 1975).

Gulf South Insulation v. CPSC, 701 F.2d 1137 (5th Cir. 1983).

Industrial Union Department, AFL-CIO, v. American Petroleum Institute, 448 U.S. 607 (1980).

Industrial Union Department, AFL-CIO, v. Hodgson, 499 F.2d 467 (D.C. Cir. 1974).

Les v. Reilly, 968 F.2d 985 (9th Cir. 1992).

Monsanto v. Kennedy, 613 F.2d 947 (D.C. Cir. 1979).

Natural Resources Defense Council, Inc., v. United States Environmental Protection Agency, 595 F. Supp. 1255 (S.D.N.Y. 1984).

Natural Resources Defense Council, Inc., v. United States Environmental Protection Agency, 824 F.2d 1146 (D.C. Cir. 1987).

NRDC v. Train, 8 E.R.C. 2120 (D.D.C. 1976).

Public Citizen v. Young, 831 F.2d 1108 (D.C. Cir. 1987).

Society of the Plastics Industry, Inc., v. OSHA, 509 F.2d 9301 (2d Cir. 1975).

APPENDIX

RECOMMENDED LIMITS FOR OCCUPATIONAL EXPOSURE TO CHEMICALS

John Doull

The occupational exposure levels in this listing were taken from the recommendations of the 1999–2000 chemical substances threshold limit values (TLVs) from the American Conference of Governmental Industrial Hygienists (ACGIH) and the 1993 OSHA permissible exposure levels (PELs). Values in the occupational exposure listings include the time-weighted average (TWA) for a normal 8-h workday and, when appropriate, short-term exposure limits (STELs) or ceiling (C) recommendations. The information in this listing is intended to illustrate the types of chemicals for which recommendations have been made and the ranges and types of values recommended for the agents. This listing does not include all of the information provided in the source documents and, since the values are reviewed and updated frequently, interested readers should contact the sponsoring organization to obtain the current information and supporting documentation for the values. This documentation also provides information on other adverse effects (fetotoxicity, carcinogenicity, etc.), recommendations for dealing with mixtures, and various other types of useful information.

Abbreviations used in the listing:

ppm, parts per million
m/M, milligrams per cubic meter
f/cc, fibers per cubic centimeter
A1, Confirmed human carcinogen
A2, Suspected human carcinogen
A3, Animal carcinogen
A4, Not classifiable
A5, Not suspected as a worker carcinogen
Skin, Danger of cutaneous absorption
SEN, Sensitizer
