The production of blood cells, or hematopoiesis, is a highly regulated sequence of events by which blood cell precursors proliferate and differentiate to meet the relentless needs of oxygen transport, host defense and repair, hemostasis, and other vital functions described previously. The bone marrow is the principal site of hematopoiesis. The spleen has little function in blood cell production in the healthy human but plays a critical role in the clearance of defective or senescent cells, as well in host defense. In the human fetus, hematopoiesis can be found in the liver, spleen, bone marrow, thymus and lymph nodes. The bone marrow is the dominant hematopoietic organ in the latter half of gestation and the only blood cell producing organ at birth (Moore, 1975). All marrow is active, or "red marrow," at birth (Hudson, 1965). During early childhood, hematopoiesis recedes in long bones and, in adults, is confined to the axial skeleton and proximal humerus and femur (Custer and Ahlfeldt, 1932). The marrow in the distal long bones becomes "yellow" or fatty. When demand for blood cell production is great, as with certain disease states, fatty marrow can be reactivated as sites of hematopoiesis (Fig. 11-1). This can be useful in toxicology studies as a marker of sustained hematopoietic stress, as exemplified in studies on the hematopathology of cephalosporin toxicity in the dog (Bloom et al., 1987). Under extreme conditions, embryonic patterns of hematopoiesis may reappear as *extramedullary hematopoiesis* (Young and Weiss, 1997).

Figure 11-1

Bone marrow schema. Several venous sinuses (SINUS), cut longitudinally, drain into the central longitudinal vein, cut in cross section. A branch of the nutrient artery (ARTERY) and an arterial capillary (ARTER CAPIL) are present. The circulation in the bone marrow, as in the other tissues of the body save the spleen, is "closed"; that is, there is endothelial continuity from artery into vein. Veins in bone marrow have in common with veins elsewhere the primary function of returning blood to the heart. Marrow veins, in addition, possess the distinctive function of receiving blood cells produced and stored in the marrow and carrying them to thymus or spleen, or into the general circulation, for further maturation, widespread distribution and function. The hematopoietic compartments of the bone marrow consist of hematopoietic cells in varying stages of differentiation supported by a fibroblastic stroma. They lie between the most proximal veins, termed venous sinuses or vascular sinuses. When hematopoiesis is rather quiet and few nascent blood cells cross the wall of vascular sinuses, moving from hematopoietic compartments into the sinus lumen, the wall of the sinus tends to be trilaminar, consisting of endothelium (end), wispy basement membrane (in stipple), and adventitial reticular cells (adv) that form an incomplete outermost layer and branch out into the hematopoietic compartment, forming a scaffolding enclosing and supporting the hematopoietic cells. Thus, adventitial reticular cells are both vascular, as the outermost wall of the vascular sinus, and stromal, branching into the perivascular hematopoietic space, holding the vascular sinus in place and supporting hematopoietic cells. Where hematopoietic cell traffic across the wall of the venous sinus is heightened, the adventitial cell cover is retracted and a larger expanse of endothelium, covered only by wisps of basement membrane, is exposed to the hematopoietic cells, facilitating their transmural cell passage. Where transmural cell passage is greatly reduced, adventitial cells accumulate fat and become rounded and bulky, now termed adipocytes, impeding hematopoietic cell passage, and occupying space in the hematopoietic compartment which, when they transform again to adventitial cells flattened upon veins, they yield to hematopoiesis. These fibroblastic stromal cells in the marrow of central bones can modulate readily to and from adventitial cell and adipocyte and retain their granulocyte inductive capacities in either form. In the distal limb and tail bones, where there is little hematopoiesis, they assume the adipocyte form in such large numbers that the marrow is grossly yellow. These adipocytes lose fat only in marked hematopoietic stress, as in spherocytic and other severe anemias where this marrow becomes hematopoietic and grossly red. In such stress, moreover, barrier cells may augment or replace adventitial reticular cells and even endothelial cells. Thus, adventitial cells/adipocytes, by their disposition and bulk, mechanically regulate hematopoiesis and blood cell delivery. In addition, they do so in a subtle manner, through paracrine secretion of several small-protein regulatory factors termed cytokines, which include interleukins. [Reprinted from Young and Weiss (1997) with permission from the authors and Elsevier Science.]

While the central function of bone marrow is hematopoiesis and lymphopoiesis, bone marrow is also one of the sites of the mononuclear phagocyte system (MPS), contributing monocytes that differentiate into a variety of MPS cells located in liver (Kupffer cells), spleen (littoral cells), lymph nodes, and other tissues. Conventional histologic and cytologic sampling of bone marrow reveals a very limited picture of an exceedingly complex tissue containing erythroid, granulocytic, megakaryocytic, MPS, and lymphoid precursors in varied stages of maturation; stromal cells; and vasculature all encased by bone (Fig. 11-1). Routine examinations of such specimens in our pathology and toxicology laboratories cannot possibly reveal the sophisticated interactions that mediate lineage commitment, proliferation, differentiation, acquisition of functional characteristics, and trafficking that results in the delivery of mature cells to the circulation, as required in sickness and in health. This exquisite and homeostatic regulation of blood cell production involves a complex interplay of developing cells with stromal cells, extracellular matrix components, and cytokines that make up the *hematopoietic inductive microenvironment,* or HIM (Young and Weiss, 1997). Our understanding of how the array of hematopoietic growth factors interact within the HIM is growing rapidly (Kaushansky, 2000). This knowledge, through DNA recombinant technology, continues to yield sophisticated tools and promising therapies that present new pharmacologic and toxicologic challenges.

TOXICOLOGY OF THE ERYTHRON

The Erythrocyte

Erythrocytes (red blood cells, or RBCs) make up 40 to 45 percent of the circulating blood volume and serve as the principal vehicle of transportation of oxygen from the lungs to the peripheral tissues. In addition, erythrocytes are involved in the transport of carbon dioxide from tissues to the lung and in the maintenance of a constant pH in blood despite the ever changing concentration of carbon dioxide (Hsia, 1998). Erythrocytes help modulate the inflammatory response through clearance of immune complexes containing complement components and through interaction with nitric oxide, a potent vasodilator (Hebert, 1991). An area of developing interest is the role of erythrocytes as a carrier and/or reservoir for drugs and toxins (Schrijvers et al., 1999). The effect of xenobiotics on erythrocytes has been extensively evaluated, both because of the ready access to the tissue and the frequency with which xenobiotics cause changes in this critical tissue.

Xenobiotics may affect the production, function and/or survival of erythrocytes. These effects are most frequently manifest as a change in the circulating red cell mass, usually resulting in a decrease (anemia). Occasionally, agents that affect the oxygen affinity of hemoglobin lead to an increase in the red cell mass (erythrocytosis), but this is distinctly less common. Shifts in plasma volume can alter the relative concentration of erythrocytes (and hemoglobin concentration) and can be easily confused with true anemia or erythrocytosis.

There are two general mechanisms that lead to true anemia—either decreased production or increased destruction of erythrocytes. Both mechanisms may be operative in some disorders, or a combination may arise due to the imposition of a second disorder on a compensated underlying problem. For example, patients with compensated congenital hemolytic anemias are very susceptible to additional insults, such as parvovirus infection, that may precipitate an acute drop in a previously stable red cell mass.

Evaluation of a peripheral blood sample can provide evidence for the underlying mechanism of anemia (Lee, 1999a). The usual parameters of a complete blood count (CBC)—including the red blood cell (RBC) count, hemoglobin concentration (Hbg) and hematocrit (also referred to as packed cell volume, or PCV)—can establish the presence of anemia. Two additional parameters that are helpful in classifying an anemia are the mean corpuscular volume (MCV) and the reticulocyte count. Increased destruction is usually accompanied by an increase in reticulocytes (young erythrocytes containing residual RNA), which are easily enumerated using appropriate stains. Two related processes contribute to the increased number of reticulocytes in humans. First, increased destruction is accompanied by a compensatory increase in bone marrow production, with an increase in the number of cells being released from the marrow into the circulation. Second, during compensatory erythroid hyperplasia, the marrow releases reticulocytes earlier in their life span and thus the reticulocytes persist for a longer period in the peripheral blood. Other readily performed parameters helpful in the evaluation of the human erythron include: erythrocyte morphology (e.g., megaloblastic changes, erythrocyte fragmentation, sickled RBCs); serum concentration of haptoglobin, lactic dehydrogenase (LD), free hemoglobin, vitamin B$_{12}$, folate, iron, and ferritin; direct and indirect red cell antiglobulin tests; and bone marrow morphology (Lee, 1999a).

Alterations in Red Cell Production

Erythrocyte production is a continuous process that is dependent on frequent cell division and a high rate of hemoglobin synthesis. Adult hemoglobin (hemoglobin A), the major constituent of the erythrocyte cytoplasm, is a tetramer composed of two a- and two b-globin chains, each with a heme residue located in a stereospecific pocket of the globin chain. Synthesis of hemoglobin is dependent on coordinated production of globin chains and heme moieties. Abnormalities that lead to decreased hemoglobin synthesis are relatively common (e.g., iron deficiency) and are often associated with a decrease in the MCV and hypochromasia (increased central pallor of RBCs on stained blood films due to the low hemoglobin concentration).

An imbalance between a- and b-chain production is the basis of congenital thalassemia syndromes and results in decreased hemoglobin production and microcytosis (Weatherall, 1997). Xenobiotics can affect globin-chain synthesis and alter the composition of hemoglobin within erythrocytes. This is perhaps best demonstrated by hydroxyurea, which has been found to increase the synthesis of g globin chains. The g globin chains are a normal constituent of hemoglobin during fetal development,

replacing the b chains in the hemoglobin tetramer (hemoglobin F, a $_2$g$_2$). Hemoglobin F has a higher affinity for oxygen than hemoglobin A and can protect against crystallization (sickling) of deoxyhemoglobin S in sickle cell disease (Steinberg, 1999).

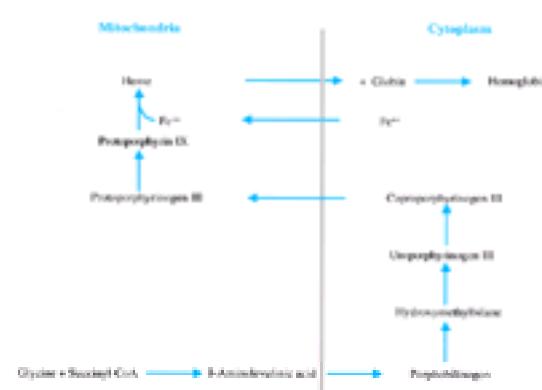
Synthesis of heme requires incorporation of iron into a porphyrin ring (Fig. 11-2) (Ponka, 1997; Dessypris, 1999). Iron deficiency is usually the result of dietary deficiency or increased blood loss. Any drug that contributes to blood loss, such as nonsteroidal anti-inflammatory agents, with their increased risk of gastrointestinal ulceration and bleeding, may potentiate the risk of developing *iron deficiency anemia.* Defects in the synthesis of porphyrin ring of heme can lead to *sideroblastic anemia,* with its characteristic accumulation of iron in bone marrow erythroblasts. The accumulated iron precipitates within mitochondria, causing the intracellular injury and the characteristic staining pattern of ringed sideroblasts evident on iron stains such as Prussian blue. A number of xenobiotics (Table 11-1) can interfere with one or more of the steps in erythroblast heme synthesis and result in sideroblastic anemia (Fiske et al., 1994; May and Fitzsimons, 1994; Bottomley, 1999).


Figure 11-2
The synthesis of heme involves a series of reactions that occur in the cytoplasm and mitochondria of erythroblasts. The initial step in the pathway is the mitochondria synthesis of d-aminolevulinic acid, a step that is commonly affected by xenobiotics, including lead. Ferrochelatase catalyzes the incorporation of ferrous iron into the tetrapyrrole protoporphyrin IX. Inhibition of the synthetic pathway leading to protoporphyrin IX, as occurs in the sideroblastic anemias, can cause an imbalance between iron concentration and ferrochelatase activity, resulting in iron deposition within mitochondria. Mitochondrial accumulation of iron is the hallmark lesion of the sideroblastic anemias.

Ethanol	Chloramphenicol
Isoniazid	Copper chelation/deficiency
Pyrazinamide	Zinc intoxication
Cycloserine	Lead intoxication

Table 11-1 Xenobiotics Associated with Sideroblastic Anemia

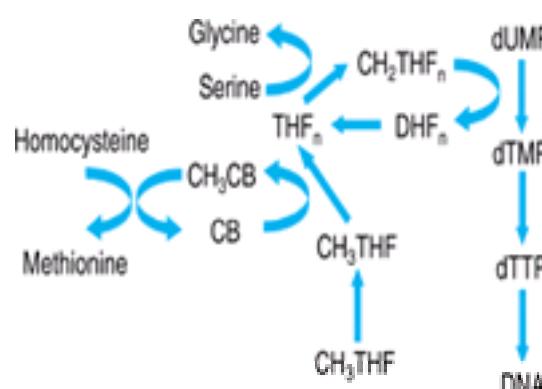
All of the hematopoietic elements of the marrow are dependent on continuous proliferation to replace the circulating cells. This requires active DNA synthesis and frequent mitoses. Folate and vitamin B$_{12}$ are necessary to maintain synthesis of thymidine for incorporation into DNA (Fig. 11-3). Deficiency of folate and/or vitamin B$_{12}$ results in *megaloblastic anemia,* with its characteristic morphologic and biochemical changes (Table 11-2), which commonly affect erythroid, myeloid, and megakaryocytic lineages. A number of xenobiotics may contribute to a deficiency of vitamin B$_{12}$ and/or folate (Table 11-3), leading to megaloblastic anemia (Tapp and Savarirayan, 1997; Lee, 1999b; Lee, 1999c).


Figure 11-3
Both tetrahydrofolate (THF) and cobalamin (CB, or vitamin B$_{12}$) are necessary for the synthesis of thymidine (dTMP) for incorporation into DNA. Folate enters the cell as a monoglutamate (CH$_3$THF) but is transformed to a polyglutamate within the cell, a step that helps prevent leakage of folate back across the cell membrane. However, CH$_3$THF cannot be conjugated with glutamate. CB is necessary for demethylation of the folate, allowing formation of conjugated (polyglutamate) folate (THF$_n$). In the absence of CB, folate levels within the cell drop, causing a functional deficiency of folate and impairing synthesis of thymidine.

MORPHOLOGY	BIOCHEMISTRY
Peripheral blood	Peripheral blood
Pancytopenia	Decreased B$_{12}$ and/or folate
Macrocytosis (↑MCV)	Increased LD
Oval macrocytes	Antiparietal cell antibodies
Hypersegmented neutrophils	Antibody to intrinsic factor
Variation in RBC shape	Increased serum iron
Bone marrow	Hypokalemia
Erythroid hyperplasia	
Megaloblastic anemia	
Giant band neutrophils	
Giant metamyelocytes	

Table 11-2 Laboratory Features of Megaloblastic Anemia

B12 DEFICIENCY	FOLATE DEFICIENCY
Paraminosalicylic acid	Phenytoin
Colchicine	Primidone
Neomycin	Carbamazepine
Ethanol	Phenobarbital
Omeprazole	Sulfasalazine
Hemodialysis	Cholestyramine
Zidovudine	Triamterene
Fish tapeworm	Malabsorption syndromes
	Antimetabolites

Table 11-3 Xenobiotics Associated with Megaloblastic Anemia

Many of the antiproliferative agents used in the treatment of malignancy predictably inhibit hematopoiesis, including erythropoiesis. The resulting bone marrow toxicity may be dose-limiting, as previously discussed. The development of recombinant forms of some of the cytokines that regulate hematopoiesis has helped shorten the duration of suppression, and new agents are being developed that may help protect against the marrow toxicity of these agents (Capizzi, 1999).

Drug-induced *aplastic anemia* may represent either a predictable or idiosyncratic reaction to a xenobiotic. This life-threatening disorder is characterized by peripheral blood pancytopenia, reticulocytopenia, and bone marrow hypoplasia (Young and Maciejewski, 1997; Young, 1999). Agents such as benzene and radiation have a *predictable* effect on hematopoietic progenitors, and the resulting aplastic anemia corresponds to the magnitude of the exposure to these agents. In contrast, idiosyncratic aplastic anemia does not appear to be related to the dose of the agent initiating the process. A long list of agents has been associated with the development of aplastic anemia (Table 11-4), many of which have been reported in only a few patients. The mechanism(s) of aplasia in affected patients is(are) still unknown. Immune mechanisms have long been thought to contribute to the development of the idiosyncratic form of drug-induced aplastic anemia. However, it has been difficult to obtain definitive evidence for humoral and/or cellular mechanisms of marrow suppression (Young, 2000).

Chloramphenicol	Organic arsenicals	Quinacrine
Methylphenylethylhydantoin	Trimethadione	Phenylbutazone
Gold	Streptomycin	Benzene
Penicillin	Allopurinol	Tetracycline
Methicillin	Sulfonamides	Chlortetracycline
Sulfisoxazole	Sulfamethoxypyridazine	Amphotericin B
Mefloquine	Ethosuximide	Felbamate
Carbamazine	Methylmercaptoimidazole	Potassium perchlorate
Propylthiouracil	Tolbutamide	Pyrimethamine
Chlorpropamide	Carbutamide	Tripelennamine
Indomethacin	Carbamazepine	Diclofenac
Meprobamate	Chlorpromazine	Chlordiazepoxide
Mepacrine	Chlorphenothane	Parathion
Thiocyanate	Methoxsalen	Dinitrophenol
Bismuth	Mercury	Chlordane
Carbon tetrachloride	Cimetidine	Metolazone
Acidothymidine	Ticlopidine	Isoniazid
Trifluoperazine	D-penicillamine	

Table 11-4 Drugs and Chemicals Associated with the Development of Aplastic Anemia

Pure red cell aplasia is a syndrome in which the decrease in marrow production is limited to the erythroid lineage. Pure red cell aplasia is an uncommon disorder that may be seen in a variety of clinical settings. A number of drugs have been implicated in the development of red cell aplasia, but many of these represent single case reports (Thompson and Gales, 1996; Marseglia and Locatelli, 1998; Misra et al., 1998; Blanche et al., 1999). As pure red cell aplasia also occurs sporadically, the linkage between drug exposure and pathogenesis of the aplasia remains speculative for some agents. The drugs most clearly implicated in this idiosyncratic reaction, and for which there are multiple case reports, include isoniazid, phenytoin, and azathioprine. The mechanism of drug-induced pure red cell aplasia is unknown, but some evidence suggests that it may be immune-mediated. It has been suggested that genetic variation may play a role in the susceptibility to the development of pure red cell aplasia (Marseglia and Locatelli, 1998). Patients with drug-induced red cell aplasia should not be reexposed to the purported offending agent.

Alterations in the Respiratory Function of Hemoglobin

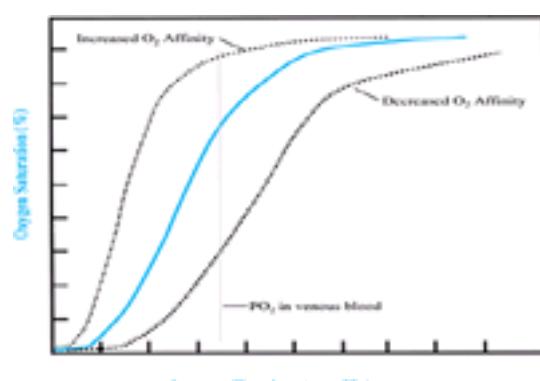
Hemoglobin is necessary for effective transport of oxygen and carbon dioxide between the lungs and tissues. The respiratory function of hemoglobin has been studied in detail, revealing an intricately balanced system for the transport of oxygen from the lungs to the tissues (Hsia, 1998). Electrostatic charges hold the globin chains of deoxyhemoglobin in a "tense" (T) conformation characterized by a relatively low affinity for oxygen. Binding of oxygen alters this conformation to a "relaxed" (R) conformation that is associated with a 500-fold increase in oxygen affinity. Thus the individual globin units show cooperativity in the binding of oxygen, resulting in the familiar sigmoid shape to the oxygen dissociation curve (Fig. 11-4). The ability of hemoglobin to safely and efficiently transport oxygen is dependent on both intrinsic (homotropic) and extrinsic (heterotropic) factors that affect the performance of this system.


Figure 11-4
The normal oxygen dissociation curve *(solid line)* has a sigmoid shape due to the cooperative interaction between the four globin chains in the hemoglobin molecule. Fully deoxygenated hemoglobin has a relatively low affinity for oxygen. Interaction of oxygen with one heme-iron moiety induces a conformational change in that globin chain. Through surface interactions, that conformational change affects the other globin chains, causing a conformational change in all of the globin chains that increases their affinity for oxygen. Homotropic and heterotropic parameters also affect the affinity of hemoglobin for oxygen. An increase in oxygen affinity results in a shift to the left in the oxygen-dissociation curve. Such a shift may decrease oxygen delivery to the tissues. A decrease in oxygen affinity results in a shift to the right in the oxygen dissociation curve, facilitating oxygen delivery to the tissues.

Homotropic Effects Perhaps one of the most important homotropic properties of oxyhemoglobin is the slow but consistent oxidation of heme iron to the ferric state to form methemoglobin. Methemoglobin is not capable of binding and transporting oxygen. In addition, the presence of methemoglobin in a hemoglobin tetramer has allosteric effects that increase the affinity of oxyhemoglobin for oxygen, resulting in a leftward shift of the oxygen dissociation curve (Fig. 11-4). The combination of decreased oxygen content and increased affinity may significantly impair delivery of oxygen to tissues when the concentration of methemoglobin rises beyond critical

levels (Hsia, 1998, Ranney and Sharma, 1995).

Not surprisingly, the normal erythrocyte has metabolic mechanisms for reducing heme iron back to the ferrous state; these mechanisms are normally capable of maintaining the concentration of methemoglobin at less than 1% of the total hemoglobin (Coleman and Coleman, 1996). The predominant pathway is cytochrome b_5 methemoglobin reductase, which is dependent on reduced nicotine adenine dinucleotide (NADH) and is also known as NADH-diaphorase. An alternate pathway involves a reduced nicotine adenine dinucleotide phosphate (NADPH) diaphorase that reduces a flavin that in turn reduces methemoglobin. This pathway usually accounts for less than 5 percent of the reduction of methemoglobin, but its activity can be greatly enhanced by methylene blue, which is reduced to leukomethylene blue by NADPH-diaphorase. Leukomethylene blue then reduces methemoglobin to deoxyhemoglobin.

A failure of these control mechanisms leads to increased levels of methemoglobin, or *methemoglobinemia.* The most common cause of methemoglobinemia is exposure to an oxidizing xenobiotic that overwhelms the NADH-diaphorase system. A large number of chemicals and therapeutic agents may cause methemoglobinemia (Table 11-5) (Coleman and Coleman, 1996; Khan and Kruse, 1999; Lukens, 1999; Nguyen et al., 2000). These agents may be divided into direct oxidizers, which are capable of inducing methemoglobin formation when added to erythrocytes in vitro or in vivo, and indirect oxidizers, which do not induce methemoglobin formation when exposed to erythrocytes in vitro but do so after metabolic modification in vivo. Nitrites appear to be able to interact directly with heme to facilitate oxidation of heme iron, but the precise mechanism that leads to methemoglobin formation is unknown for many of the other substances listed in Table 11-5.

THERAPEUTIC AGENTS	ENVIRONMENTAL AGENTS
Benzocaine	Nitrites
Lidocaine	Nitrates
Prilocaine	Nitrobenzenes
Dapsone	Aniline dyes
Amyl nitrate	Butyl nitrite
Isobutyl nitrite	Potassium chlorate
Nitroglycerine	Gasoline additives
Primaquine	Aminobenzenes
Sulfonamide	Nitrotoluenes
Phenacetin	Trinitrotoluene
Nitric oxide	Nitroethane
Phenazopyridine	
Metoclopramide	
Flutamide	
Silver nitrate	
Quinones	
Methylene blue	

Table 11-5 Xenobiotics Associated with Methemoglobinemia

The development of methemoglobinemia may be slow and insidious or abrupt in onset, as with the use of some topical anesthetics (Khan and Kruse, 1999; Nguyen et al., 2000). Most patients tolerate low levels (<10%) of methemoglobin without clinical symptoms. Cyanosis is often evident when the methemoglobin concentration exceeds 5 to 10%. Levels above 20% are generally clinically significant and some patients may begin to manifest symptoms related to tissue hypoxemia at methemoglobin levels between 10 and 20%. The severity of clinical manifestations increases as the concentration rises above 20 to 30%, with methemoglobin levels above 70% usually being fatal. Administration of methylene blue is effective in rapidly reversing methemoglobinemia through activation of the NADPH diaphorase pathway. The effect of methylene blue is dependent on an adequate supply of NADPH. Consequently, methylene blue is not effective in patients with glucose-6-phosphate dehydrogenase (G-6-PD) deficiency because of the decreased capacity to form NADPH (Coleman and Coleman, 1996).

Heterotropic Effects There are three major heterotropic effectors of hemoglobin function: pH, erythrocyte 2,3-bisphosphoglycerate (2,3-BPG, formerly designated 2,3-diphosphoglycerate) concentration, and temperature (Ranney and Sharma, 1995; Hsia, 1998). A decrease in pH (e.g., lactic acid, carbon dioxide) lowers the affinity of hemoglobin for oxygen; that is, it causes a right-shift in the oxygen dissociation curve, facilitating the delivery of oxygen to tissues (Fig. 11-4). As bicarbonate and carbon dioxide equilibrate in the lung, the hydrogen ion concentration decreases, increasing the affinity of hemoglobin for oxygen and facilitating oxygen uptake. Thus the buffering capacity of hemoglobin also serves to improve oxygen uptake and delivery.

The binding site for 2,3-BPG is located in a pocket formed by the two b chains of a hemoglobin tetramer. Binding of 2,3-BPG to deoxyhemoglobin results in stabilization of the "T" conformation, with reduced oxygen affinity (a shift to the right of the oxygen dissociation curve). The conformational change induced by binding of oxygen alters the binding site for 2,3-BPG and results in release of 2,3-BPG from hemoglobin. This facilitates uptake of more oxygen for delivery to tissues. The concentration of 2,3-BPG increases whenever there is tissue hypoxemia but may decrease in the presence of acidosis or hypophosphatemia. Thus hypophosphatemia may result in a left shift of the oxygen dissociation curve.

Clofibric acid and bezafibrate are capable of lowering the oxygen affinity of hemoglobin, analogous to 2,3-BPG, without damage to the erythrocyte or hemoglobin (Poyart et al., 1994). However, the association constant of bezafibrate for hemoglobin is too low for there to be a practical effect in vivo. Work continues on bezafibrate derivatives that may lower oxygen affinity and enhance tissue oxygenation. In contrast, some aromatic benzaldehydes have been shown to increase the oxygen affinity and shift the dissociation curve to the left. It was thought that these compounds may be useful in preventing the sickling of deoxyhemoglobin S in patients with sickle cell disease. However, these and other agents evaluated for their effect on hemoglobin oxygen affinity have not progressed into clinical usage (Poyart et al., 1994; Papassotirion et al., 1998).

The oxygen affinity of hemoglobin decreases as the body temperature increases (Hsia, 1998). This facilitates delivery of oxygen to tissues during periods of extreme exercise and febrile illnesses associated with increased temperature. Correspondingly, oxygen affinity increases during hypothermia, which may lead to decreased oxygen delivery under these conditions. This must be taken into consideration during surgical procedures during which there is induction of deep hypothermia.

The respiratory function of hemoglobin may also be impaired by blocking of the ligand binding site by the interaction with other substances, most notably carbon monoxide (Hsia, 1998). Carbon monoxide has a relatively low rate of association with deoxyhemoglobin but shows high affinity once bound. The affinity is about 200 times that of oxygen, and thus persistent exposure to a carbon monoxide concentration of 0.1% may lead to 50% saturation of hemoglobin. Binding of carbon monoxide also results in stabilization of the hemoglobin molecule in the high-affinity "R" conformation. Consequently, the oxygen dissociation curve is shifted to the left, further compromising oxygen delivery to the tissues. Carbon monoxide is produced at low levels by the body and equilibrates across the pulmonary capillary/alveolar bed. The major sources of significant exposure to carbon monoxide are smoking and burning of fossil fuels (including automobiles). Heavy smoking during pregnancy can result in significant levels of carboxyhemoglobin in fetal blood and diminished oxygenation of fetal tissues.

Methemoglobin can combine reversibly with a variety of chemical substances, including cyanide, sulfides, peroxides, fluorides, and azides (Coleman and Coleman, 1996; Lukens, 1999). The affinity of methemoglobin for cyanide is utilized in two settings. First, nitrites are administered in cyanide poisoning to form methemoglobin, which then binds free cyanide, sparing other critical cellular respiratory enzymes. Second, formation of cyanmethemoglobin by reaction of hemoglobin with potassium ferricyanide is a standard method for measurement of hemoglobin concentration.

Nitric oxide, an important vasodilator that modulates vascular tone, binds avidly to heme iron. An additional function of erythrocytes is related to this interaction, which can influence the availability of nitric oxide in parts of the circulation (Everse and Hsia, 1997; Hsia, 1998). Solutions of hemoglobin have been evaluated as a potential replacement for red blood cell transfusions. However, these trials have been halted due to the toxicity associated with administration of hemoglobin solutions. Vascular instability is one of the complications associated with infusion of hemoglobin solutions and is thought to be related to the scavenging of essential nitric oxide by the administered hemoglobin (Hess et al., 1993; Everse and Hsia, 1997).

Alterations in Erythrocyte Survival

The normal survival of erythrocytes in the circulation is about 120 days (Dessypris, 1999). During this period the erythrocytes are exposed to a variety of oxidative injuries and must negotiate the tortuous passages of the microcirculation and the spleen. This requires a deformable cell membrane and energy to maintain the sodium-potassium gradients and repair mechanisms. Very little protein synthesis occurs during this time, as erythrocytes are anucleate when they enter the circulation and residual mRNA is rapidly lost over the first 1 to 2 days in the circulation. Consequently, senescence occurs over time until the aged erythrocytes are removed by the spleen, where the iron is recovered for reutilization in heme synthesis. Any insult that increases oxidative injury, decreases metabolism, or alters the membrane

may cause a decrease in erythrocyte concentration and a corresponding anemia.

Anemia due to increased red cell destruction (hemolytic anemia) is usually characterized by reticulocytosis in the peripheral blood and erythroid hyperplasia of the bone marrow (Lee, 1999a). As reticulocytes tend to be somewhat larger than older erythrocytes, there may be a mild increase in the MCV. The presence of increased numbers of reticulocytes is often evident on the peripheral blood film in the form of polychromatophilic erythrocytes. The residual RNA present in these cells gives the cytoplasm a blue-gray cast on Wright-stained blood films. Depending on where erythrocyte destruction occurs, the concentration of haptoglobin may be decreased, serum LD may be increased, and serum free hemoglobin may be increased. The acquired hemolytic anemias are often divided into immune-mediated and non-immune mediated types.

Nonimmune Hemolytic Anemia

Microangiopathic Anemias Intravascular fragmentation of erythrocytes gives rise to the *microangiopathic hemolytic anemias* (Tabbara, 1992; Ruggenenti and Remuzzi, 1998). The hallmark of this process is the presence of schistocytes (fragmented RBCs) in the peripheral blood. These abnormal cellular fragments are usually promptly cleared from the circulation by the spleen. Thus their presence in peripheral blood samples indicates either an increased rate of formation or abnormal clearance function of the spleen. The formation of fibrin strands in the microcirculation is a common mechanism for RBC fragmentation. This may occur in the setting of disseminated intravascular coagulation, sepsis, the hemolytic-uremic syndrome, and thrombotic thrombocytopenic purpura. The erythrocytes are essentially sliced into fragments by the fibrin strands that extend across the vascular lumen and impede the flow of erythrocytes through the vasculature. Excessive fragmentation can also be seen in the presence of abnormal vasculature, as occurs with damaged cardiac valves, arteriovenous malformations, vasculitis, and widely metastatic carcinoma (Nesher et al., 1994; Rytting et al., 1996; Gordon and Kwaan, 1999). The high shear associated with malignant hypertension may also lead to RBC fragmentation.

Other Mechanical Injuries March hemoglobinuria is an episodic disorder characterized by destruction of RBCs during vigorous exercise or marching (Sagov, 1970; Abarbanel et al., 1990). The erythrocytes appear to be destroyed by mechanical trauma in the feet. Sufficient hemoglobin may be released to cause hemoglobinuria. The disorder should be distinguished from other causes of intermittent hemoglobinuria such as paroxysmal nocturnal hemoglobinuria. The introduction of improved footgear for athletes and soldiers has significantly decreased the incidence of this problem.

Major thermal burns are also associated with a hemolytic process. The erythrocyte membrane becomes unstable as the temperature increases. With major burns there can be significant heat-dependent lysis of erythrocytes. Small RBC fragments break off, with resealing of the cell membrane. These cell fragments usually assume a spherical shape and are not as deformable as normal erythrocytes. Consequently, these abnormal cell fragments are removed in the spleen, leading to an anemia. The burden of RBC fragments may impair the phagocytic function of the spleen, contributing to the increased susceptibility to endotoxic shock following major burns (Schneiderkraut and Loeggering, 1984; Hatherill et al., 1986)

Infectious Diseases A wide variety of infectious diseases may be associated with significant hemolysis, either by direct effect on the erythrocyte or development of an immune-mediated hemolytic process (Berkowitz, 1991; Lee, 1999d). The most common agents that directly cause hemolysis include malaria, babesiosis, clostridial infections, and bartonellosis. Erythrocytes are parasitized in malaria and babesiosis, leading to their destruction. Clostridial infections are associated with release of hemolytic toxins that enter the circulation and lyse erythrocytes. The hemolysis can be severe with significant hemoglobinuria, even with apparently localized infections. *Bartonella bacilliformis* is thought to adhere to the erythrocyte, leading to rapid removal from the circulation. The hemolysis can be severe and the mortality rate in this disorder (Oroya fever) is high.

Oxidative Hemolysis Molecular oxygen is a reactive and potentially toxic chemical species; consequently the normal respiratory function of erythrocytes generates oxidative stress on a continuous basis. The major mechanisms that protect against oxidative injury in erythrocytes include NADH-diaphorase, superoxide dismutase, catalase, and the glutathione pathway (Coleman and Coleman, 1996; Everse and Hsia, 1997). As indicated previously, a small amount of methemoglobin is continuously formed during the process of loading and unloading of oxygen from hemoglobin. Formation of methemoglobin is associated with formation of superoxide free radicals, which must be detoxified to prevent oxidative injury to hemoglobin and other critical erythrocyte components. Under physiologic conditions, superoxide dismutase converts superoxide into hydrogen peroxide, which is then metabolized by catalase and glutathione peroxidase (Fig. 11-5).

$$HgbFe^{++}O_2 \rightleftharpoons HgbFe^{++} + O_2 \quad (1)$$

$$HgbFe^{++}O_2 \rightleftharpoons HgbFe^{+++} + O_2^- \quad (2)$$

$$2O_2^- + 2H^+ \xrightarrow{\text{Superoxide Dismutase}} O_2 + H_2O_2 \quad (3)$$

$$2 H_2O_2 \xrightarrow{\text{Catalase}} H_2O + O_2 \quad (4)$$

$$H_2O_2 + GSH \xrightarrow{\text{Glutathione Peroxidase}} GSSH + H_2O \quad (5)$$

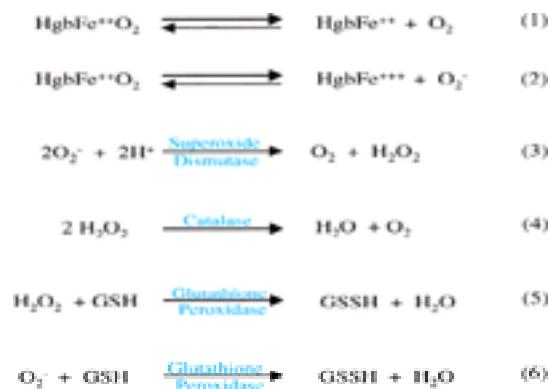
$$O_2^- + GSH \xrightarrow{\text{Glutathione Peroxidase}} GSSH + H_2O \quad (6)$$


Figure 11-5
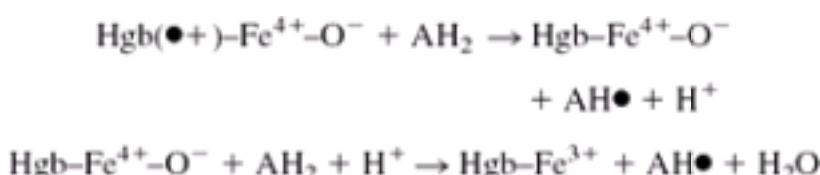
Oxygen normally exchanges with the ferrous iron of deoxyhemoglobin [Eq. (1)]. Oxygen can "capture" one of the iron electrons, resulting in the generation of methemoglobin (HgbFe^{3+}) and superoxide (O$_2$-) [Eq. (2)]. Superoxide must be detoxified or it can lead to oxidative injury within the cell. The pathways involved include superoxide dismutase [Eq. (3)], catalase [Eq. (4)], and glutathione peroxidase [Eqs. (5 and 6)]. A supply of reduced glutathione (GSH) is necessary to prevent excessive oxidative injury.


A number of xenobiotics, particularly compounds containing aromatic amines, are capable of inducing oxidative injury in erythrocytes (Table 11-6) (Yoo and Lessin, 1992; Jollow et al., 1995; Everse and Hsia, 1997; Nohl and Stolze, 1998). These agents appear to potentiate the normal redox reactions and are capable of overwhelming the usual protective mechanisms. The interaction between these xenobiotics and hemoglobin leads to the formation of free radicals that denature critical proteins, including hemoglobin, thiol-dependent enzymes, and components of the erythrocyte membrane. In the presence of hydrogen peroxide and xenobiotics such as hydroxylamine, hydroxamic acid, and phenolic compounds, a reactive ferryl (Fe^{+4}) hemoglobin intermediate may be formed according to the following reaction:

Acetanilide	Phenylhydrazine
Naphthalene	Nitrobenzene
Nitrofurantoin	Phenacetin
Sulfamethoxypyridazine	Phenol
Aminosalicylic acid	Hydroxylamine
Sodium sulfoxone	Methylene blue
Dapsone	Toluidine blue
Phenazopyridine	Furazolidone
Primaquine	Nalidixic acid
Chlorates	Sulfanilamide
Sulfasalazine	

Table 11-6 Xenobiotics Associated with Oxidative Injury

$$H_2O_2 + Hgb-Fe^{3+} \rightarrow H_2O + Hgb(\bullet+)-Fe^{4+}-O^-$$

In this intermediate, referred to as compound 1, tyrosine may donate the extra electron, turning it into a reactive free radical. Compound 1 may undergo further reaction with organic compounds (AH_2 in equations below) to yield additional free radicals according to the following reactions:

$$Hgb(\bullet+)-Fe^{4+}-O^- + AH_2 \rightarrow Hgb-Fe^{4+}-O^-$$
$$+ AH\bullet + H^+$$
$$Hgb-Fe^{4+}-O^- + AH_2 + H^+ \rightarrow Hgb-Fe^{3+} + AH\bullet + H_2O$$

Hemoglobin contains exposed free cysteines (b93) that are critical for the structural integrity of the molecule. Oxidation of these groups can denature hemoglobin and decrease its solubility. The oxidized, denatured hemoglobin species comprise what has been designated sulfhemoglobin. The denatured hemoglobin can form aggregates that bind to the cell membrane to form inclusions called *Heinz bodies,* a hallmark of oxidative injury to erythrocytes (Jandl, 1987). Heinz bodies can be visualized by use of phase-contrast microscopy or supravital stains such as crystal violet. These membrane-associated inclusions impair the deformability of the erythrocyte membrane and thus impede movement of erythrocytes through the microcirculation and the spleen. Heinz bodies are effectively removed from the erythrocyte by the spleen, so they are not often observed in peripheral blood samples from patients despite ongoing oxidative injury. However, the culling of Heinz bodies can alter the morphology of the affected cells, giving rise to what are called "bite" cells and "blister" cells, which may provide an important clue as to the ongoing process (Yoo and Lessin, 1992). These cells look as though a portion of the cytoplasm had been cut away. Heinz body formation can be induced by in vitro exposure to oxidizing agents and patients with oxidative hemolysis often show increased in vitro formation of Heinz bodies.

Oxidative denaturation of the globin chain decreases its affinity for the heme group, which may dissociate from the globin chain during oxidative injury. The ferric iron in the heme ring may react with chloride to form a complex called hemin. Hemin is hydrophobic and intercalates into the erythrocyte membrane from which it is removed by interaction with albumin. However, if the rate of hemin formation exceeds the rate of removal by albumin, hemin accumulates in the membrane, where it can cause rapid lysis of the erythrocyte (Everse and Hsia, 1997).

The generation of free radicals may also lead to peroxidation of membrane lipids (Jandl, 1987). This may affect the deformability of the erythrocyte and the permeability of the membrane to potassium. The alteration of the Na^+/K^+ gradient is independent of injury to the Na^+/K^+ pump and is potentially lethal to the affected erythrocyte. Oxidative injury also impairs the metabolic machinery of the erythrocyte, resulting in a decrease in the concentration of ATP (Tavazzi et al., 2000). Damage to the membrane can also permit leakage of denatured hemoglobin from the cell. Such free denatured hemoglobin can be toxic on its own. Free hemoglobin may irreversibly bind nitric oxide, resulting in vasoconstriction. Released hemoglobin may form nephrotoxic hemoglobin dimers, leading to kidney damage (Everse and Hsia, 1997).

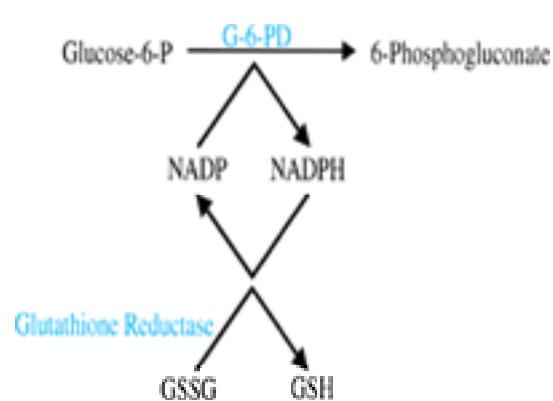
Oxidative injury thus results in a number of changes that decrease the viability of erythrocytes. Protection against many of the free radical-induced modifications is mediated by reduced glutathione. Formation of reduced glutathione is dependent on NADPH and the hexose monophosphate shunt (Fig. 11-6). Significant oxidative injury usually occurs when the concentration of the xenobiotic is high enough (either due to high exposure or decreased metabolism of the xenobiotic) to overcome the normal protective mechanisms, or, more commonly, when there is an underlying defect in the protective mechanisms.


Figure 11-6
The hexose monophosphate shunt in the erythrocyte is critical for generation of NADPH, which helps maintain an intracellular supply of reduced glutathione (GSH). With a deficiency of glucose-6-phosphate dehydrogenase (G-6-PD), the rate-limiting step in this pathway, the cellular levels of GSH are reduced. Such cells show increased susceptibility to oxidative injury. Acute exposure of such cells to an oxidizing agent can result in rapid hemolysis.

The most common enzyme defect associated with oxidative hemolysis is glucose-6-phosphate dehydrogenase (G-6-PD) deficiency, a relatively common sex-linked disorder characterized by alterations in the primary structure of G-6-PD that diminish its functional activity (Beutler, 1996; Weatherall, 1997). It is often clinically asymptomatic until the erythrocytes are exposed to oxidative stress. The stress may come from the host response to infection or exposure to xenobiotics. The level of G-6-PD normally decreases as the erythrocytes age. In the African type of G-6-PD deficiency, the enzyme is less stable than normal; thus the loss of activity is accelerated compared to normals. In the Mediterranean type of G-6-PD deficiency, the rate of loss of enzyme activity is even higher. Consequently, the older erythrocytes with the lowest levels of G-6-PD are most susceptible to hemolysis, with the degree of hemolysis affected by the residual amount of enzyme activity as well as the magnitude of the oxidative injury.

Erythrocyte reduced glutathione is rapidly depleted upon exposure to an oxidizing agent in patients with G-6-PD deficiency. This leads to the series of oxidative injuries described above with the development of intra- and extravascular hemolysis. Oxidative hemolysis is usually reversible if the process is promptly recognized and the offending agent is removed. Occasionally the hemolysis may be sufficiently severe to result in death or serious morbidity (e.g., renal failure).

Nonoxidative Chemical-Induced Hemolysis Exposure to some xenobiotics is associated with hemolysis without significant oxidative injury (Lee, 1999d). Arsenic hydride is a gas that is formed during several industrial processes. Inhalation of the gas can result in severe hemolysis, with anemia, jaundice, and hemoglobinuria. The mechanism of hemolysis in arsine toxicity is not understood. Lead poisoning is associated with defects in heme synthesis and a shortening of erythrocyte survival. The cause of the hemolysis is uncertain, but lead can cause membrane damage and interfere with the Na^+/K^+ pump. These effects may cause premature removal of erythrocytes from the circulation. Excess copper has been associated with hemolytic anemia. The pathogenesis may relate to inhibitory effects on the hexose monophosphate shunt and the Embden-Meyerhof pathway. Ingestion of excess chromium may result in a hemolytic anemia and thrombocytopenia, although the mechanism is not known (Cerulli et al., 1998). Significant hemolysis may also occur with biologic toxins found in insect and snake venoms (Gibly et al., 1998; Lee, 1999d).

Immune Hemolytic Anemia Immunologic destruction of erythrocytes is mediated by the interaction of IgG or IgM antibodies with antigens expressed on the surface of the erythrocyte (Parker and Foerster, 1999). In the case of autoimmune hemolytic anemia the antigens are intrinsic components of the patient's own erythrocytes. A large number of drugs have been associated with enhanced binding of immunoglobulin to the erythrocyte surface and shortened RBC survival.

A number of mechanisms have been implicated in xenobiotic-mediated antibody binding to erythrocytes (Parker and Foerster, 1999). Some drugs, of which penicillin is a prototype, appear to bind to the surface of the cell, with the "foreign" drug acting as a *hapten* and eliciting an immune response. The antibodies that arise in this type of response only bind to drug-coated erythrocytes. Other drugs, of which quinidine is a prototype, bind to components of the erythrocyte surface and induce a conformational change in one or more components of the membrane. This type of interaction can give rise to a confusing array of antibody specificities. Some of the antibodies recognize only the *drug-membrane component* complex; others are specific for the membrane component, but only when drug is present; while still others may recognize the membrane component in the presence or absence of the drug. A third mechanism, for which a-methyldopa is a prototype, results in production of a *drug-induced autoantibody* that cannot be distinguished from the antibodies arising in idiopathic autoimmune hemolytic anemia. The mechanism for induction of this group of antibodies is not understood. A variant of this type of response is the augmentation of autoimmune hemolytic anemia that may occur during therapy of some lymphoproliferative disorders. Autoimmune phenomena, including autoimmune hemolytic anemia, are known to occur in lymphoproliferative disorders such as chronic lymphocytic leukemia. Treatment of these disorders with some agents has been associated with worsening of the hemolytic anemia (Gonzalez et al., 1998). It has

been hypothesized that therapy further disrupts regulation of the autoimmune phenomenon, allowing increased antibody production.

Some xenobiotics are associated with *nonspecific deposition of proteins* on erythrocytes. This was first associated with cephalosporins but has also been seen with other agents, including cisplatin and the beta-lactamase inhibitors sulbactam and clavulanate (Garritty and Arndt, 1998). Immunoglobulin and complement proteins may be among the proteins deposited on the erythrocyte surface. These proteins may cause a positive direct antiglobulin test, suggesting a drug-induced antibody response. However, there is no evidence of a drug-dependent antibody in the patient's serum, and drug-treated erythrocytes may bind antibody from normal non-drug exposed serum. This form of antibody deposition is generally not associated with hemolysis, although the possibility of hemolysis related to this type of reaction has been raised (Garratty and Arndt, 1998).

The interaction of immunoglobulins with erythrocytes leads to hemolysis through one of two pathways (Parker and Foerster, 1999). The first involves activation of complement with formation of the membrane attack complex (C5b-9); this is the pathway responsible for immune-mediated *intravascular hemolysis.* The second is phagocytosis of erythrocytes that have been opsonized by IgG and/or complement components; this is the pathway responsible for immune-mediated *extravascular hemolysis.* Extravascular hemolysis is the more common of these two mechanisms. This is due in part to the orchestration of factors necessary to achieve lytic activation of complement on erythrocytes.

Lytic activation of complement depends on the isotype of the antibody, the titer of the antibody, the antigen density on the surface of the erythrocyte, and the integrity of erythrocyte defense mechanisms against complement activation. IgM antibodies are more efficient activators of complement than IgG antibodies due to their polyvalent composition. Indeed, complement-mediated lysis is the major mechanism for IgM-mediated hemolysis, as phagocytes do not have specific receptors for the Fc portion of IgM to mediate ingestion of IgM opsonized erythrocytes. High-titer antibodies and a high density of antigens are required to initiate sufficient complement activation to overcome the natural erythrocyte defense mechanisms. Two important regulators of complement activation that are present on erythrocytes are decay accelerating factor (CD55) and membrane inhibitor of reactive lysis (CD59). The importance of these regulators is evident in the enhanced hemolysis that occurs in when these proteins are missing, as in *paroxysmal nocturnal hemoglobinuria* (Nishimura et al., 1999).

Non-lytic activation of complement and binding of IgG results in opsonization of the erythrocyte. Such opsonized erythrocytes are removed by the phagocytic system, particularly in the spleen. The rate of phagocytosis is affected by the concentration of opsonins on the surface and by the presence of both complement components and IgG. Consequently, the higher the concentration of IgG on the surface of the erythrocyte, the greater the rate of phagocytosis.

The clinical phenotype of drug-induced hemolytic anemia is quite variable, due to the complexity of the interactions involved. In some patients with a high-titer antibody, exposure to the offending drug may lead to rapid intravascular hemolysis, with the potential for serious morbidity or even mortality. In other patients, erythrocyte survival is modestly reduced and reasonably well compensated for by erythroid hyperplasia in the bone marrow. In some cases, patients may have evidence of erythrocyte-associated IgG without any detectable effect on erythrocyte survival.

Drug-induced intravascular hemolysis is often a dramatic clinical event and may be associated with fever, chills, back pain, hypotension, a rapid fall in hemoglobin concentration, a decrease in serum haptoglobin, a marked increase in serum LD, and hemoglobinuria (Tabarra, 1992). The clinical picture of extravascular hemolysis depends on the rate of hemolysis but is usually less dramatic. Often there is evidence of reticulocytosis, polychromasia, spherocytosis, a moderate increase in serum LD, and an increase in serum bilirubin. Serologic studies usually show evidence of IgG and/or complement on the surface of erythrocytes, although it may be difficult to document that antibody binding is drug-dependent. The mainstay of therapy in patients with drug-induced hemolytic anemia is removal of the offending agent and avoidance of reexposure.

TOXICOLOGY OF THE LEUKON

Components of Blood Leukocytes

The leukon consists of leukocytes, or white blood cells. They include granulocytes, which may be subdivided into neutrophils, eosinophils and basophils; monocytes; and lymphocytes. Granulocytes and monocytes are nucleated ameboid cells that are phagocytic. They play a central role in the inflammatory response and host defense. Unlike the RBC, which resides exclusively within blood, granulocytes and monocytes merely pass through the blood on their way to the extravascular tissues, where they reside in large numbers.

Granulocytes are defined by the characteristics of their cytoplasmic granules as they appear on a blood smear stained with a polychromatic (Romanovsky) stain. Neutrophils, the largest component of blood leukocytes, are highly specialized in the mediation of inflammation and the ingestion and destruction of pathogenic microorganisms. The turnover of the neutrophil is enormous and increases dramatically in times of inflammation and infection, elevating the number of these cells released from the bone marrow. Eosinophils and basophils modulate inflammation through the release of various mediators and play an important role in other homeostatic functions. All these are influenced by humoral immunity, as discussed in greater detail in Chap. 12.

In the world of clinical and experimental toxicology, the neutrophil is the focus of concern when evaluating granulocytes as possible targets for drug and nontherapeutic chemical effects. Eosinophils and basophils are far more difficult to study, with changes in these populations most frequently associated with reactions to other target organ or systemic toxicity. Examples include the eosinophilia observed with the toxic oil syndrome that resulted from exposure to rapeseed oil denatured in aniline utilized in northwestern Spain (Kilbourne et al., 1991); and the eosinophilia-myalgia syndrome associated with L-tryptophan preparations contaminated with 1, 1-ethylidene-bis [tryptophan] (Varga et al., 1992).

Evaluation of Granulocytes

The most informative test to assess the neutrophil compartment is the blood neutrophil count. Accurate interpretation requires an understanding of neutrophil kinetics and the response of this tissue to physiologic and pathologic changes. In the blood, neutrophils are distributed between *circulating* and *marginated* pools, which are of equal size in man and in constant equilibrium (Athens et al., 1961; Athens et al., 1961). A blood neutrophil count assesses only the circulating pool, which remains remarkably constant (1800 to 7500 mL^{-1}) in a healthy adult human (Williams et al., 1995), considering that the number of neutrophils that pass through the blood to the tissues is estimated to be 62 to 400 × 10^7 cells/kg/day (Dancey, 1976). Mature (segmented) and a few immature (band) neutrophils can be identified on blood films stained with Wright or Giemsa stain. During inflammation, a "shift to the left" may occur, which refers to an increased number of immature (non-segmented) granulocytes in the peripheral blood, which may include bands, metamyelocytes, and occasionally myelocytes (Cannistra and Griffin, 1988). During such times, neutrophils may also show "toxic" granulation, Döhle bodies, and cytoplasmic vacuoles (Bainton, 1995). These morphologic changes may be prominent in sepsis or as a result of drug or chemical intoxication.

Neutrophil kinetics and response to disease will vary substantially among animal species. Thus, a thorough understanding of these features in any animal model used in investigative toxicology is required before informed interpretations can be made. In the human, clinically significant neutropenia occurs when the blood neutrophil count is less than 1000 mL^{-1}, but serious recurrent infections do not usually occur until counts fall below 500 mL^{-1} (Williams et al., 1995). In order to fully characterize such changes or understand the pathogenesis of the abnormality, bone marrow must be examined using marrow aspirates and biopsies. These provide information on rates of production, bone marrow reserves, abnormalities in cell distribution and occasionally specific clues as to etiology. In vitro stem cell assays may be used to assess the granulocyte progenitor cell compartment, which may include granulocyte-monocyte colony-forming cells (CFU-GM) performed in a semisolid medium, such as agar or methylcellulose, that contains appropriate growth factors. Normal human marrow specimens contain approximately 50 to 1000 CFU-GM per 10^6 nucleated cells cultured (Liesveld and Lichtman, 1997). Marrow neutrophil reserves can be assessed in vitro after administration of granulocyte colony stimulating factor, or G-CSF (Demirer and Bensinger, 1995), which stimulates increased production and release on neutrophil precursors. Glucocorticoids (Peters et al., 1972) and epinephrine (Babior and Golde, 1995) may also be used for this purpose but are rarely used in a clinical setting. The degree of proliferation in the granulocyte compartment can also be assessed using ^{3}H-thymidine suicide assays or DNA binding dyes with fluorescence-activated cell sorting analyses (Keng, 1986). Assessment of neutrophil function—including adhesion to endothelium, locomotion, chemotaxis, phagocytosis, and metabolic pathways critical to microbe killing—is discussed in Chap. 12.

Toxic Effects on Granulocytes

Effects on Proliferation As with other hematopoietic tissue, the high rate of proliferation of neutrophils makes their progenitor and precursor granulocyte pool particularly susceptible to inhibitors of mitosis. Such effects by cytotoxic drugs are generally nonspecific, as they similarly affect cells of the dermis, gastrointestinal tract, and other rapidly dividing tissues. Agents that affect both neutrophils and monocytes pose a greater risk for toxic sequelae, such as infection (Dale, 1995). Such

effects tend to be dose-related, with mononuclear phagocyte recovery preceding neutrophil recovery (Arneborn and Palmblad, 1982).

Various cytoreductive agents, such as the antimetabolites methotrexate and cytosine arabinoside, may inhibit DNA synthesis (i.e., the S phase of the mitotic cycle), or the G2 period, where RNA and protein synthesis proceed prior to the mitotic, or M phase, as is the case with daunorubicin (Minderman et al., 1994). Alkylating agents like cyclophosphamide, cisplatin, and the nitrosureas are toxic to resting and actively dividing cells, where maximum effects are usually seen 7 to 14 days after exposure. Cytokines may enhance these effects, perhaps through driving cells into S phase (Smith et al., 1994). Lindane, an insecticide used to treat seeds and soil, has been associated with leukopenia (Parent-Massin et al., 1994). It is cytotoxic for human CFU-GMs at concentrations observed in blood and adipose tissue from exposed human subjects. An example of agents affecting mature cells is methylmethacrylate monomer, which is used in orthopedic surgical procedures and is cytotoxic to both neutrophils and monocytes at clinically relevant concentrations (Dahl et al., 1994).

Effects on Function While there are a variety of disorders associated with defects in the parameters of neutrophil function discussed above, demonstrable in vivo effects associated with drugs and toxins are surprisingly few (Smolen and Boxer, 1995). Examples include ethanol and glucocorticoids, which impair phagocytosis and microbe ingestion in vitro and in vivo (Brayton et al., 1970). Iohexol and ioxaglate, components of radiographic contrast media, have also been reported to inhibit phagocytosis (Lillevang et al., 1994). Superoxide production, required for microbial killing and chemotaxis, has been reported to be reduced in patients using parenteral heroin as well as in former opiate abusers on long-term methadone maintenance (Mazzone et al., 1994). Chemotaxis is also impaired following treatment with zinc salts in antiacne preparations (Dreno et al., 1992).

Idiosyncratic Toxic Neutropenia Of greater concern are agents that unexpectedly damage neutrophils and granulocyte precursors—particularly to the extent of inducing *agranulocytosis,* which is characterized by a profound depletion in blood neutrophils to less than 500 mL $^{-1}$ (Pisciotta, 1997). Such injury occurs in specifically conditioned individuals, and is therefore termed "idiosyncratic." Mechanisms of idiosyncratic damage often do not relate to pharmacologic properties of the parent drug, which makes managing this risk a particular challenge to hematologists and toxicologists. Preclinical toxicology is rarely predictive of these effects, which are generally detected and characterized following exposure of a large population to the agent (Szarfman et al., 1997).

Idiosyncratic xenobiotic-induced agranulocytosis may involve a sudden depletion of circulating neutrophils concommitant with exposure, which may persist as long as the agent or its metabolites persist in the circulation. Hematopoietic function is usually restored when the agent is detoxified or excreted. Suppression of granulopoiesis, however, is more prevalent than peripheral lysis of neutrophils and is asymptomatic unless sepsis supervenes (Pisciotta, 1997). The onset of leukopenia in the former is more gradual but may be precipitous if lysis of circulating neutrophils also occurs. The pattern of the disease varies with the stage of granulopoiesis affected, which has been well defined for several agents that cause bone marrow toxicity (Table 11-7). Toxicants affecting uncommitted stem cells induce total marrow failure, as seen in aplastic anemia, which generally carries a worse prognosis than agents affecting more differentiated precursors (e.g., CFU-G). It is thought that, in the latter case, surviving uncommitted stem cells eventually produce recovery, provided that the risk of infection is successfully managed during the leukopenic episodes (Pisciotta, 1997).

Table 11-7 Stages of Granulocytopoiesis: Site of Xenobiotic-Induced Cellular Damage

Mechanisms of Toxic Neutropenia Toxic neutropenia may be classified according to mechanism as *immune-mediated* or *non–immune-mediated.* In immune-mediated neutropenia, antigen-antibody reactions lead to destruction of peripheral neutrophils, granulocyte precursors, or both. As with RBCs, an immunogenic xenobiotic can act as a hapten, where the agent must be physically present to cause cell damage, alternatively, may induce immunogenic cells to produce antineutrophil antibodies that do not require the drug to be present. Xenobiotic-induced immune-mediated damage may also be cell-mediated (Pisciotta, 1997).

Detection of xenobiotic induced neutrophil antibodies is considerably more difficult than those of RBCs or platelets. Several assays have been used, which can be grouped into four categories: those measuring endpoints of leukoagglutination, cytotoxic inhibition of neutrophil function, or immunoglobulin binding and those using cell-mediated mechanisms. Among the specific challenges these assays pose are the tendency of neutrophils to stick to each other in vitro, attract immunoglobulin nonspecifically to their surface, and reflect membrane damage through indirect and semiquantitative changes (Pisciotta, 1997). The reader is referred elsewhere for a more detailed discussion of assays for immune-mediated neutrophil damage (Minchinton and Waters, 1984 ; Hagen et al., 1993).

Non–immune-mediated toxic neutropenia often shows a genetic predisposition (Pisciotta, 1973). Direct damage may cause inhibition of granulopoiesis or neutrophil function. It may entail failure to detoxify or excrete a xenobiotic or its metabolites, which subsequently build up to toxic proportions (Gerson et al., 1983 ; Gerson and Melzer, 1992 ; Uetrecht, 1990). Some studies suggest that a buildup of toxic oxidants generated by leukocytes can result in neutrophil damage, as with the reactive intermediates derived from the interaction between clozapine, an atypical antipsychotic, and neutrophils. The resulting superoxide and hypochlorous acid production by the myeloperoxidase system are thought to contribute to clozapine-induced neutropenia (Uetrecht, 1992).

While many drugs and nontherapeutic agents have been associated with neutropenia (Young, 1994 ; Watts, 1999), the mechanism of this effect has been established in relatively few of these toxicants. Examples of agents associated with immune and non-immune neutropenia/agranulocytosis are listed in Table 11-8 .

Table 11-8 Examples of Toxicants That Cause Immune and Non-immune Idiopathic Neutropenia

LEUKEMOGENESIS AS A TOXIC RESPONSE

Human Leukemias

Leukemias are proliferative disorders of hematopoietic tissue that are monoclonal in origin and thus originate from individual bone marrow cells. Historically they have been classified as myeloid or lymphoid, referring to the major lineages for erythrocytes/granulocytes/thrombocytes or lymphocytes, respectively. Because the degree of leukemic cell differentiation has also loosely correlated with the rate of disease progression, poorly differentiated phenotypes have been designated as "acute," whereas well-differentiated ones are referred to as "chronic" leukemias. The classification of human leukemias proposed by the French-American-British (FAB) Cooperative Group has become convention, based on the above and other morphologic features (Bennett et al., 1985; Levine and Bloomfield, 1992; Bennett et al., 1982). It provides the diagnostic framework for classifying chronic lymphocytic leukemia (CLL), chronic myelogenous leukemia (CML), acute lymphoblastic leukemia (ALL), acute myelogenous leukemia (AML), and the myelodysplastic syndromes (MDS), along with various subtypes of these disorders. These early correlations imply that the biology and clinical features of these proliferative disorders relate to the stage of differentiation of the target cell, which is now being linked to individual gene alterations, as well as epigenetic factors such as cytokine stimulation. Evidence for these mechanisms is rapidly emerging and supports the notion that leukemogenesis is a multievent progression (Vogelstein et al., 1988; Williams and Whittaker, 1990; Varmua and Weinberg, 1993; Pedersen-Bjergaard et al., 1995). These studies suggest that factors involved in the regulation of hematopoiesis also influence neoplastic transformation. Such factors include cellular growth factors (cytokines), protooncogenes and other growth-promoting genes, as well as additional factors that govern survival, proliferation, and differen-tiation.

Mechanisms of Toxic Leukemogenesis

The understanding that certain chemicals and radiation can dysregulate hematopoiesis, resulting in leukemogenesis, is a relatively recent one. While suggested by Hunter as early as 1939, following his observations on benzene exposure and AML (Hunter, 1939), it was not until the introduction of radiation and chemotherapy as treatments for neoplasia that these agents became associated with blood dyscrasias that included (or led to) AML (Casciato and Scott, 1979; Foucar et al., 1979; Andersen et al., 1981). The notion emerged that myelotoxic agents, under certain circumstances, can be leukemogenic.

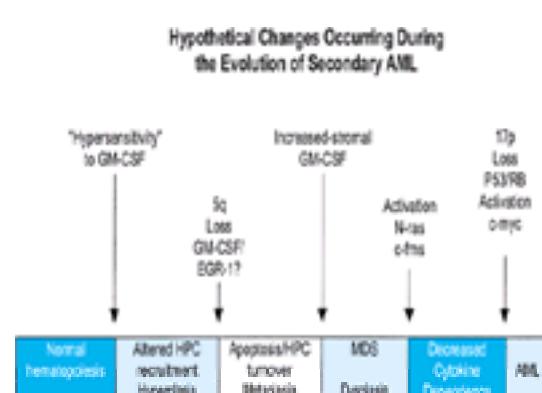
Curiously, AML is the dominant leukemia associated with drug or chemical exposure, followed by MDS (Casciato and Scott, 1979; Andersen et al., 1981; Irons, 1997). The evidence that this represents a continuum of one toxic response is compelling (Irons, 1997). This has also been linked to cytogenetic abnormalities, particularly the loss of all or part of chromosomes 5 and 7. Remarkably, the frequency of these deletions in patients who develop MDS and/or AML after treatment with alkylating or other antineoplastic agents ranges from 67 to 95 percent, depending on the study (Rowley et al., 1981; LeBeau, 1986; Pedersen-Bjergaard, 1984; Johansson et al., 1987; Bitter et al., 1987). Some of these same changes have been observed in AML patients occupationally exposed to benzene (Bitter et al., 1987; Mitelman et al., 1978; Mitelman et al., 1981; Golomb et al., 1982; Fagioli et al., 1992; Cuneo et al., 1992), who also show aneuploidy with a high frequency of involvement of chromosome 7 (Irons, 1997). The relatively low frequency of deletions in chromosomes 5 and 7 in de novo as compared with secondary AML suggests that these cytogenetic markers can be useful in discriminating between toxic exposures and other etiologies of this leukemia (Irons, 1997). These observations, together with the understandings on the pathogenesis of leukemia previously discussed, led Irons to propose a model for the evolution of toxic, or secondary, leukemogenesis, which is illustrated in Fig. 11-7 (Irons, 1997).


Figure 11-7
Hypothetical model for the evolution of s-AML involving 5q-. Schematic representation of one model for tumor progression consistent with frequently observed events in the development of AML secondary to drug or chemical exposure. Altered myeloid progenitor cell proliferation leads to increased division in the target cell population, which results in clonal loss of heterozygosity due to nondysjunction (e.g., 5q-). The resulting haploinsufficiency of a gene, such as GM-CSF, results in increased cell turnover, abnormal maturation, and ineffective hematopoiesis (i.e., MDS) in the abnormal clone. This is subsequently followed by activation of additional proto-oncogenes that result in progressive growth and survival independence in successive subclones and the development of overt AML. [Adapted from Irons (1997), with permission from Elsevier Science.]

Other forms of leukemia—including CML, CLL, ALL, and multiple myeloma—have shown weak correlations with occupational exposure or treatment with alkylating agents (Irons, 1997). The latter has been repeatedly associated with exposure to benzene, although a causal relationship has yet to be demonstrated (Bergsagel et al., 1999).

Leukemogenic Agents

Most *alkylating agents* used in cancer chemotherapy can cause MDS and/or AML, including cyclophosphamide, melphalan, busulfan, chlorambucil, and nitrosurea compounds such as carmustine, or BCNU (Casciato and Scott, 1979; Greene et al, 1986). Other oncolytic agents implicated include azathioprine, procarbazine, doxorubicin, and bleomycin (Carver et al., 1979; Valagussa et al., 1979; Vismans et al., 1980). The risk these agents pose varies considerably with the therapeutic regimen. The incidence of MDS/AML in patients treated with alkylating agents has been reported to be 0.6 to 17 percent, with an average of 100-fold relative risk. Moreover, treatment-related MDS is associated with a substantially higher rate of transformation to AML than is primary or spontaneous MDS (Bitter et al., 1987; Kantarjian et al., 1986).

Of the *aromatic hydrocarbons,* only benzene has been proven to be leukemogenic. Substituted aromatic hydrocarbons have long been suspected to be causative, due to the fact that preparations of xylene and toluene in the past contained as much as 20% benzene (Browning, 1965). There is no clinical or experimental evidence that substituted benzenes cause leukemia (Irons, 1997).

Treatment with *topoisomerase II inhibitors,* particularly the epipodophyllotoxins etoposide and teniposide, can induce AML, the clinical course of which has the following distinguishing characteristics: (1) the absence of a preleukemic phase, (2) a short latency period, (3) frequent involvement of an M4/5 subtype, and (4) balanced chromosome aberrations involving chromosomes 11q23 and 21q22 (Murphy, 1993). Similar cytogenetic features have been observed following treatment with doxorubicin or dactinomycin (intercalating topoisomerase II inhibitors) in conjunction with alkylating agents and irradiation (Sandoval et al., 1993).

Exposure to *high-dose g- or x-ray radiation* has long been associated with ALL, AML, and CML, as demonstrated in survivors of the atom bombings of Nagasaki and Hiroshima (Cartwright, 1992; Shimizu et al., 1989). Less clear is the association of these diseases with low-dose radiation secondary to fallout or diagnostic radiographs (Cartwright, 1992).

Other *controversial agents* include 1, 3-butadiene, nonionizing radiation (electromagnetic, microwave, infrared, visible, and the high end of the ultraviolet spectrum), and cigarette smoking, for which published studies on the relationship to leukemia incidence is confusing, contradictory, or difficult to interpret based on dose response (Irons, 1997).

TOXICOLOGY OF PLATELETS AND HEMOSTASIS

Hemostasis is a multicomponent system responsible for preventing the loss of blood from sites of vascular injury and maintaining circulating blood in a fluid state. Loss of blood is prevented by formation of stable hemostatic plugs mediated by the procoagulant arm of hemostasis. This procoagulant response is normally limited to sites of vascular injury by the multicomponent regulatory arm of hemostasis. The dynamically modulated balance between procoagulant and regulatory pathways permits a rapid, localized response to injury. The major constituents of the hemostatic system include circulating platelets, a variety of plasma proteins, and vascular

endothelial cells. Alterations in these components or systemic activation of this system can lead to the clinical manifestations of deranged hemostasis, including excessive bleeding and thrombosis. The hemostatic system is a frequent target of therapeutic intervention as well as inadvertent expression of the toxic effect of a variety of xenobiotics. This section briefly reviews the inadvertent effects of xenobiotics on hemostasis and the toxic effects of agents used to manipulate the hemostatic system.

Toxic Effects on Platelets

The Thrombocyte Platelets are essential for formation of a stable hemostatic plug in response to vascular injury. Platelets initially adhere to the damaged wall through binding of von Willebrand factor (vWF) with the platelet glycoprotein Ib/IX/V (GP Ib/IX/V) receptor complex (Sadler, 1998; Andrews et al., 1999). Ligand binding to GP Ib/IX/V or interaction of other platelet agonists (e.g., thrombin, collagen, ADP, thromboxane A$_2$) with their specific receptors initiates biochemical response pathways that lead to shape change, platelet contraction, platelet secretion of granule contents, activation of the GP IIb/IIIa receptor and externalization of phosphatidylserine (Solum, 1999; Ware and Coller, 1999). Activation of the GP IIb/IIIa receptor permits fibrinogen and other multivalent adhesive molecules to form crosslinks between nearby platelets, resulting in platelet aggregation (Plow, 1999). Xenobiotics may interfere with the platelet response by causing thrombocytopenia or interfering with platelet function; some agents are capable of affecting both platelet number and function.

Thrombocytopenia Like anemia, thrombocytopenia may be due to decreased production or increased destruction. Thrombocytopenia is a common side effect of intensive chemotherapy, due to the predictable effect of antiproliferative agents on hematopoietic precursors, including those of the megakaryocytic lineage. Thrombocytopenia is a clinically significant component of idiosyncratic xenobiotic-induced aplastic anemia. Indeed, the initial manifestation of aplastic anemia may be mucocutaneous bleeding secondary to thrombocytopenia. A few agents—including thiazide diuretics, diethylstilbestrol, recombinant GM-CSF, and procarbazine—have been associated with isolated suppression of thrombopoiesis. The mechanisms by which this occurs are not known (George, 1999).

Exposure to xenobiotics may cause increased immune-mediated platelet destruction through any one of several mechanisms (Table 11-9) (Aster, 1999). Some drugs function as haptens, binding to platelet membrane components and eliciting an immune response that is specific for the hapten. The responding antibody then binds to the hapten on the platelet surface, leading to removal of the antibody-coated platelet from the circulation. This type of antibody interaction can often be blocked in vitro by excess soluble drug that binds to the antibody and prevents its interaction with the platelet surface (George et al., 1998; Rizvi et al., 1999).

MECHANISM	INCITING AGENT	ANTIGEN TARGET	PLATELET EFFECT	CLINICAL EFFECT
Hapten-directed antibody	Penicillin	Drug	Opsonization ↑Clearance	Bleeding
Acquired antibody to drug-induced epitope	Quinidine	Drug-GP Ib/IX/V Drug-GP IIb/IIIa	Opsonization ↑Clearance +/− Function	Bleeding
Natural antibody to drug-induced epitope	Abciximab	GP IIb/IIIa	Opsonization ↑Clearance	Bleeding
Immune complex	Heparin	PF 4–heparin complex	Platelet activation Platelet aggregation ↑Clearance	Thrombosis
Thrombotic thrombocytopenic purpura (TTP)	Ticlopidine	vWF-cleaving protease	Platelet activation Platelet aggregation ↑Clearance	Microvascular thrombosis Microangiopathic hemolytic anemia
Hemolytic-uremic syndrome	Mitomycin	Unknown	Platelet activation Platelet aggregation ↑Clearance	Microvascular thrombosis Microangiopathic hemolytic anemia Renal failure

Table 11-9 Mechanism of Immune-Mediated Thrombocytopenia

A second mechanism of immune thrombocytopenia is initiated by xenobiotic-induced exposure of a neoepitope on a platelet membrane glycoprotein. This elicits an antibody response, with the responding antibody binding to this altered platelet antigen in the presence of drug, resulting in removal of the platelet from the circulation by the mononuclear phagocytic system. The epitope specificity can be quite selective, as there is often little or no cross-reactivity between drugs having a very similar structure (e.g., quinine and quinidine). This type of interaction is not inhibited in vitro by excess soluble drug, as the antibody target is a platelet-dependent epitope. Quinidine is a prototype of this type of mechanism and can induce antibodies directed at GP Ib/IX/V, GP IIb/IIIa and/or platelet endothelial cell adhesion molecule-1 (PECAM-1) (George et al., 1998; Aster, 1999; Rizvi et al., 1999).

The diagnosis of drug-dependent antiplatelet antibodies can be quite difficult. A number of assays have been described for measurement of platelet-associated immunoglobulin, but the sensitivity and specificity of these assays have not been established. Therefore, these assays are not used in routine clinical practice. Consequently, the diagnosis is usually established by observing the resolution of thrombocytopenia following discontinuation of the offending drug. In most cases, the platelet count returns to normal within 5 to 10 days of drug discontinuation. Although a large number of agents have been implicated in the development of immune thrombocytopenia, the supporting evidence in many cases is weak (George et al., 1998; Rizvi et al., 1999).

Thrombocytopenia is an uncommon but serious complication of inhibitors of GP IIb/IIIa such as abciximab (Nurden et al., 1999; Tcheng, 2000). The mechanism appears to be related to exposure of epitopes on GP IIb/IIIa that react with naturally occurring antibodies. Because the reaction is dependent on antibodies formed prior to exposure to drug, it may occur shortly after the first exposure to the drug. This mechanism appears to be similar to the mechanism underlying EDTA-dependent platelet clumping and satellitosis resulting in pseudothrombocytopenia. In the latter situation, anticoagulation with EDTA results in chelation of calcium and a conformational change in GP IIb/IIIa that allows antibody to bind and mediate platelet clumping or binding to neutrophils (platelet satellitosis). Ligand binding is known to alter the conformation of GP IIb/IIIa. The GP IIb/IIIa inhibitors bind at the ligand binding site and also cause a conformational change in GP IIb/IIIa, permitting naturally occurring antibodies to bind to and initiate clearance of platelets by the mononuclear phagocytic system. Thus, exposure of epitopes that react with naturally occurring antibodies represents a third mechanism of immune-mediated platelet destruction.

Heparin-induced thrombocytopenia (HIT) represents a fourth mechanism of immune-mediated platelet destruction. This disorder is due to the development of antibodies that react with a multi-molecular complex formed by the interaction between heparin and a protein, usually platelet factor 4 (PF 4) (Amiral and Meyer, 1998; Warkentin et al., 1998; Visentin, 1999; Warkentin, 1999). When the relative concentration of heparin to PF 4 is appropriate, formation of this complex is associated with exposure of a neoepitope on PF 4 (or another target protein) and development of an IgG response to the neoepitope. The IgG then binds to the PF 4-heparin complex to form an immune complex that binds to the platelet Fc receptor, FcgRIIa. Clustering of platelet FcgRIIa by the immune complex activates biochemical signaling pathways mediated by the cytoplasmic domain of FcgRIIa. This results in platelet activation and aggregation. During the process of platelet activation, platelet microparticles that promote thrombin generation are released. Consequently, HIT is associated with both thrombocytopenia and an increased risk of arterial and venous thrombosis. Other drug-antibody complexes (e.g., streptokinase-IgG) may trigger platelet activation and thrombocytopenia through a similar mechanism (Deckmyn et al., 1998; McRedmond et al., 2000).

Thrombotic thrombocytopenic purpura (TTP) is a syndrome characterized by the sudden onset of thrombocytopenia, a microangiopathic hemolytic anemia, and multisystem organ failure, which often includes neurologic dysfunction. The syndrome tends to occur following an infectious disease but may also occur following administration of some pharmacologic agents. The pathogenesis of TTP appears to be related to the ability of unusually large vWF multimers to activate platelets, even in the absence of significant vascular damage. Although these large multimers are normally secreted into blood by endothelial cells, they are normally processed into smaller multimers by a protease present in plasma. Acquired TTP is associated with the development of an antibody that inhibits this protease, permitting the very large vWF multimers to persist in the circulation (Furlan et al., 1998; Tsai and Lian, 1998). Consequently, these multimers bind to platelet GP Ib/IX/V and induce platelet activation and aggregation. The organ failure and hemolysis in TTP is due to the formation of platelet-rich microthrombi throughout the circulation. The development of TTP or TTP-like syndromes has been associated with drugs such as ticlopidine, clopidogrel, cocaine, mitomycin, and cyclosporine (Durand and Lefevre, 1991; Bennett et al., 1998; Bennett et al., 1999; Steinhubl et al., 1999; Volcy et al., 2000).

The hemolytic uremic syndrome (HUS) is a disorder characterized by clinical features similar to those of TTP, with microangiopathic hemolytic anemia, thrombocytopenia, and renal failure (Ruggenenti and Remuzzi, 1998; van de Kar and Monnens, 1998). Neurologic complications tend to be less severe, while renal failure often dominates the clinical picture. Sporadic cases of HUS have been linked to infection with verocytotoxin-producing *Escherichia coli,* but they may also occur during therapy with some drugs, including mitomycin. In contrast to TTP, the vWF-cleaving protease is normal in patients with HUS (Furlan et al., 1998). In the past it was difficult to distinguish between TTP and HUS, but it is now clear that these two syndromes represent distinct disorders. The pathogenesis of the thrombocytopenia and microangiopathic changes in HUS is still uncertain, but there is experimental evidence suggesting that it is related to endothelial cell injury, with

subsequent platelet activation and thrombus formation.

Desmopressin, a vasopressin analog, is an example of nonimmune-mediated increased platelet destruction. Desmopressin induces a two- to fivefold increase in the plasma concentration of vWF and factor VIII. It is commonly used in the treatment of patients with von Willebrand's disease and other mild bleeding syndromes. Desmopressin has been associated with the development or accentuation of thrombocytopenia in some patients with type 2B von Willebrand disease. The thrombocytopenia in such cases is related to the release of an abnormal vWF from endothelial cells. The abnormal vWF has enhanced affinity for GP Ib/IX/V and the interaction of the vWF with its receptor leads to platelet clearance from the circulation (Mannucci, 1998).

Toxic Effects on Platelet Function Platelet function is dependent on the coordinated interaction of a number of biochemical response pathways. A variety of drugs and foods have been found to inhibit platelet function, either in vivo or in vitro (George and Shattil, 1991; Schafer, 1995; Baker and Hankey, 1999; Quinn and Fitzgerald, 1999). Major drug groups that affect platelet function include nonsteroidal anti-inflammatory agents, b-lactam-containing antibiotics, cardiovascular drugs, particularly beta blockers, psychotropic drugs, anesthetics, antihistamines, and some chemotherapeutic agents. The effect of these agents can vary between individuals, perhaps due to subclinical variations in underlying platelet function. For example, about 5 percent of the population appears to be significantly more sensitive to the platelet inhibitor action of aspirin than the remainder of the population. In addition, exposure to medications having a modest antiplatelet effect may unmask an unrecognized subclinical intrinsic platelet function disorder. Therefore it is important to fully evaluate the onset of mucocutaneous bleeding when it occurs in patients exposed to agents that might affect platelet function.

Xenobiotics may interfere with platelet function through a variety of mechanisms. Some drugs inhibit the phospholipase A_2/cyclooxygenase pathway and synthesis of thromboxane A_2 (e.g., nonsteroidal anti-inflammatory agents). Other agents appear to interfere with the interaction between platelet agonists and their receptors (e.g., antibiotics, ticlopidine, clopidogrel). As the platelet response is dependent on rapid increase in cytoplasmic calcium, any agent that interferes with translocation of calcium may inhibit platelet function (e.g., calcium channel blockers). Occasionally, drug-induced antibodies will bind to a critical platelet receptor and inhibit its function. The functional defect induced by such antibodies may potentiate the bleeding risk associated with the xenobiotic-induced thrombocytopenia. In some cases, the mechanism of inhibition is not known.

The effect of xenobiotics on platelet function can be studied following in vitro exposure of platelets to the agent of interest. However, evaluation following in vivo exposure is preferred, as metabolites of the parent compound may contain the platelet inhibitory activity. The most common method of assessing platelet function is turbidometric platelet aggregation using platelet-rich plasma, but alternate techniques are available, including the PFA 100 analyzer, flow cytometry, and whole-blood impedance aggregometry (Schmitz et al., 1998; Harrison et al., 1999; Michelson and Furman, 1999).

Toxic Effects on Fibrin Clot Formation

Coagulation Fibrin clot formation is the result of sequential activation of a series of serine proteases that culminates in the formation of thrombin (Mann, 1999). Thrombin is a multifunctional enzyme that converts fibrinogen to fibrin; activates factors V, VIII, XI, XIII, protein C, and platelets; and interacts with a variety of cells (e.g., leukocytes and endothelial cells), activating cellular signaling pathways. The coagulation cascade is initiated when blood is exposed to tissue factor, a membrane protein not normally found in circulating blood but present in most extravascular tissues. The reactions of the coagulation cascade require a negatively charged phospholipid surface for interaction of the enzymes with their substrates. This surface is usually provided by the activated platelet after translocation of phosphatidylserine to the external membrane leaflet. The requirement for phospholipid helps to localize thrombin formation to sites of vascular damage where platelets are being activated.

The most common toxic effects of xenobiotics on fibrin clot formation are related to a decreased level of one or more of the critical proteins necessary for this process. The decrease in clotting factor activity may be due to decreased synthesis of the protein(s) or increased clearance from the circulation. Decreased synthesis is most often a reflection of hepatocellular damage or interference with vitamin K metabolism, as discussed below, whereas increased clearance is usually associated with the development of an antibody to a specific coagulation factor.M

Decreased Synthesis of Coagulation Proteins The majority of proteins involved in the coagulation cascade are synthesized in the liver. Therefore, any agent that impairs liver function may cause a decrease in production of coagulation factors. The common tests of the coagulation cascade, the prothrombin time (PT) and activated partial thromboplastin time (aPTT), may be used to screen for liver dysfunction and a decrease in clotting factors. These assays are often performed as part of the safety evaluation of a new chemical entity. The half-life of clotting factors in the circulation varies significantly, with factor VII having the shortest half-life. Therefore, with acute toxicity (e.g., acetaminophen overdose), the effect on blood coagulation may be first seen as a decrease in the level of factor VII. Such a decrease would lead to prolongation of the PT with a normal aPTT. With a more chronic process, either the PT or aPTT or both may be affected.

Factors II, VII, IX, and X are dependent on vitamin K for their complete synthesis (Nelsestuen et al., 2000). Anything that interferes with vitamin K metabolism may lead to a deficiency of these factors and a bleeding tendency. This may occur with agents that interfere with absorption of vitamin K from the intestine or with agents that interfere with the reduction of vitamin K epoxide (Table 11-10). The combination of antibiotic therapy and limited oral intake is a common cause of acquired deficiency of vitamin K-dependent proteins among hospitalized patients (Chakraverty et al., 1996). The "super rodenticides" are another cause of acquired vitamin K deficiency (Chua and Friedenberg, 1998; Berry et al., 2000). These agents have a very prolonged half-life in vivo; thus the coagulation defect may persist for weeks or months following exposure. Rodenticide exposure may occur accidentally, as part of a Munchausen syndrome, in association with a suicide attempt, or as part of a homicide attempt. At times it may be important to distinguish between a true vitamin K deficiency and interference with the reduction of vitamin K epoxide. This is most readily accomplished by measuring the level of vitamin K and vitamin K epoxide in serum or plasma. In the case of vitamin K deficiency, vitamin K and vitamin K epoxide are both decreased; whereas in the case of inhibition of vitamin K reduction, vitamin K epoxide is significantly increased. Specific rodenticides may be measured using HPLC techniques, but it is important to specify which active agent (e.g., brodifacoum) should be measured, as the assays may not show cross-reactivity between agents.

Warfarin and analogues	Intravenous α-tocopherol
Rodenticides (e.g., brodifacoum)	Dietary deficiency
	Cholestyramine resin
Broad-spectrum antibiotics	Malabsorption syndromes
N-methyl-thiotetrazole cephalosporins	

Table 11-10 Conditions Associated with Abnormal Synthesis of Vitamin K–Dependent Coagulation Factors

Increased Clearance of Coagulation Factors Idiosyncratic reactions to xenobiotics include the formation of antibodies that react with coagulation proteins. These antibodies bind to the coagulation factor, forming an immune complex that is rapidly cleared from the circulation and resulting in deficiency of the factor. The antibody is often reversible over time if the initiating agent is withdrawn. However, during the acute phase, these patients may have life-threatening bleeding. The factors that are most often affected include factor VIII, factor V, factor XIII, vWF, prothrombin, and thrombin (Table 11-11) (Muntean et al., 1997; Sallah, 1997; Tefferi and Nichols, 1997; Bossi et al., 1998; Knobl and Lechner, 1998; van Genderen and Michiels, 1998; Pruthi and Nichols, 1999). In addition to causing increased clearance from the circulation, these antibodies often inhibit the function of the coagulation factor. This allows analysis of the antibody through evaluation of its interaction with a normal coagulation factor in vitro.

COAGULATION FACTOR	XENOBIOTIC
Thrombin	Topical bovine thrombin
	Fibrin glue
Factor V	Streptomycin
	Penicillin
	Gentamicin
	Cephalosporins
	Topical bovine thrombin
Factor VIII	Penicillin
	Ampicillin
	Chloramphenicol
	Phenytoin
	Methyldopa
	Nitrofurazone
	Phenylbutazone
Factor XIII	Isoniazid
	Procainamide
	Penicillin
	Phenytoin
	Practolol
Von Willebrand Factor	Ciprofloxacin
	Hydroxyethyl starch
	Valproic acid
	Griseofulvin
	Tetracycline
	Pesticides

Table 11-11 Relationship between Xenobiotics and the Development of Specific Coagulation Factor Inhibitors

Lupus anticoagulants are antibodies that interfere with in vitro phospholipid-dependent coagulation reactions (Roubey, 1999). Although it was once hypothesized that these antibodies were directed against phospholipid, it is now evident that lupus anticoagulants are directed against phospholipid binding proteins, including prothrombin and b_2-glycoprotein 1. These antibodies usually do not cause a deficiency of any specific coagulation factor. However, in vivo, these antibodies can potentiate procoagulant mechanisms and interfere with the protein C system. Consequently, these antibodies have been associated with an increased risk of thrombosis (Roubey, 1998). The development of lupus anticoagulants has been seen in association with a variety of medications (Table 11-12) (Triplett and Brandt, 1988; List and Doll, 1989; Vargas-Alarcon et al., 1997).

Chlorpromazine	Antibiotics
Procainamide	Phenytoin
Hydralazine	Viral infections
Quinidine	

Table 11-12 Xenobiotics Associated with the Development of Lupus Anticoagulants

Toxicology of Agents Used to Modulate Hemostasis

Patients with bleeding or thrombotic problems are commonly encountered in clinical practice. A variety of agents are available to treat such patients, ranging from recombinant hemostatic proteins to chemical entities that modulate the activity of the coagulation system. The major toxicologic reactions to plasma-derived products are infectious diseases (e.g., hepatitis C) and allergic reactions, which can be severe. The use of some products, such as activated concentrates of vitamin K-dependent proteins (e.g., Autoplex and FEIBA), has been associated with the development of disseminated intravascular coagulation and/or thrombosis in some patients (Mannucci, 1998).

Oral Anticoagulants Oral anticoagulants (warfarin) interfere with vitamin K metabolism by preventing the reduction of vitamin K epoxide, resulting in a functional deficiency of reduced vitamin K (Freedman, 1992; Hirsh et al., 1998). These agents are widely used for prophylaxis and therapy of venous and arterial thrombosis. The therapeutic window for oral anticoagulants is relatively narrow, and there is considerable interindividual variation in the response to a given dose. The consequence of insufficient anticoagulant effect is an increased risk of thromboembolism, while the consequence of excessive anticoagulation is an increased risk of bleeding. A number of factors affect the individual response to oral anticoagulants. For these reasons, therapy with these agents must be routinely monitored to maximize both safety and efficacy. This is routinely performed with the PT, with results expressed in terms of the international normalized ratio (INR). The INR represents the PT ratio that would have been obtained had an international standard PT reagent been used to perform the PT (Hirsh et al., 1998).

Oral anticoagulants are readily absorbed from the gastrointestinal tract and bind avidly to albumin in the circulation. Warfarin and the related coumarin derivatives consist of racemic mixtures of *R*- and *S*-enantiomers. The two enantiomers differ in terms of their potency and metabolism, with the *S*-enantiomer of warfarin being more potent and having a shorter half-life than the *R*-enantiomer. The *S*-enantiomer is metabolized primarily by the cytochrome P450 isoenzyme CYP2C9 while the *R*-enantiomer is metabolized primarily by CYP1A2 and CYP3A4 (Kaminsky and Zhang, 1997). Genetic polymorphisms of CYP2C9 have been described that influence the activity of this enzyme. A C_{472}® T base substitution in the gene results in an Arg ® Cys substitution at amino acid 144, while an A $_{1061}$® T results in an Ile ® Leu substitution at amino acid 359. Three distinct alleles involving these polymorphisms have been identified in clinical studies (Furuya et al., 1995; Bhasker et al., 1997; Miners and Birkett, 1998; Steward et al., 1998; Aithal et al., 1999). The Arg144/Ile359 allele (CYP2C9*1) represents the wild type, with a frequency in the Caucasian population of about 0.79 to 0.86. The Cys144/Ile359 allele (CYP2C9*2) has a frequency of about 0.08 to 0.12 and the Arg144/Leu359 allele (CYP2C9*3) has a frequency of about 0.03 to 0.09. Patients who are heterozygous for CYP2C9*2 or CYP2C9*3 require significantly less warfarin for maintenance in the therapeutic range than patients who are homozygous for CYP2C9*1. In addition, the heterozygotes for Cys144 or Leu359 have a higher frequency of overdosage during the initiation of therapy and a higher rate of bleeding during the first several weeks of therapy. A patient homozygous for CYP2C9*3 was found to be exceedingly sensitive to the effect of warfarin, requiring less than 0.5 mg/day for effective therapy, about one-tenth the amount of drug required for the average patient (Steward et al., 1998).

Genetic variation in the vitamin K-dependent proteins may also affect the response to warfarin. Mutation of Ala-10 in the propeptide of factor IX has been associated with a marked decrease in factor IX and recurrent bleeding during oral anticoagulant therapy (Quenzel et al., 1997; Oldenburg et al, 1998). Ala-10 is a highly conserved amino acid in the region of the molecule that serves as a recognition site for the vitamin K-dependent carboxylase. Recombinant factor IX variants with Glu replacing Ala-10 have been constructed; these variants were found to be resistant to carboxylation in vitro . The factor IX levels are normal in the absence of oral anticoagulants in the patients with the mutation, but they are severely depressed when the PT is in the therapeutic range during oral anticoagulant therapy. This is because the PT is insensitive to the concentration of factor IX. Despite the PT being in the "therapeutic range" these patients are at increased risk of bleeding.

A number of xenobiotics, including foods, have been found to affect the response to oral anticoagulants (Freedman and Olatidoye, 1994; Wells et al., 1994; Harder and Thurmann, 1996; Takahashi et al., 1999). Perhaps the most common mechanism for interference with oral anticoagulants is mediated by inhibition of CYP2C9. The half-life of the *S*-enantiomer is significantly prolonged by such agents, leading to overdosage at what would ordinarily be a therapeutic dose. Other mechanisms of interference include induction of CYP2C9, which tends to diminish the effect of warfarin by shortening its half-life; interference with absorption of warfarin from the gastrointestinal tract; displacement of warfarin from albumin in plasma, which temporarily increases the bioavailability of warfarin until equilibrium is reestablished; diminished vitamin K availability, either due to dietary deficiency or interference with the absorption of this lipid-soluble vitamin; and inhibition of the reduction of vitamin K epoxide, which potentiates the effect of oral anticoagulants.

Just as other drugs interfere with the action of oral anticoagulants, administration of oral anticoagulants may affect the activity of other medications, particularly those that are metabolized by CYP2C9. Dicumarol administration prolongs the half-life of chlorpropamide and phenytoin, resulting in hypoglycemia in the case of chlorpropamide and an increased plasma drug concentration in the case of phenytoin. Bis-hydroxycoumarin, but not warfarin, potentiates the activity of tolbutamide, resulting in enhanced hypoglycemia (Harder and Thurmann, 1996).

Oral anticoagulants have been associated with the development of warfarin-induced skin necrosis (Sallah et al., 1997; Esmon et al., 1999). This disorder is due to the

development of extensive microvascular thrombosis in the affected skin. This uncommon toxic effect is believed to be due to a rapid drop in protein C following administration of the drug, resulting in impaired protein C function. As protein C has a much shorter half-life than prothrombin and factor X, the level of protein C drops more rapidly than that of these other coagulation factors once oral anticoagulant therapy is initiated. This effect is proportional to the dose of warfarin used to initiate therapy, with a more marked drop occurring at higher doses (Harrison et al., 1997). Thus the risk of developing warfarin-induced skin necrosis increases with the dose of warfarin used to initiate therapy, particularly when the initial dose exceeds 10 mg per day. Native prothrombin can interfere with the function of the protein C system in a concentration-dependent manner. During the early phases of anticoagulation, the ratio of prothrombin to protein C rises due to the differences in their half-lives. This causes further impairment of protein C function and may contribute to warfarin-induced skin necrosis (Esmon et al., 1999; Smirnov et al., 1999). Patients who are deficient in protein C or protein S at the start of therapy (e.g., congenital deficiency) are at a higher risk of developing this complication. In addition, the affected patients often have an underlying acute illness associated with ongoing activation of the procoagulant pathways.

Vitamin K is necessary for the synthesis of proteins other than the coagulation-related factors, including osteocalcin, a major component of bone. Perhaps because of this, long-term administration of warfarin has been associated with bone demineralization (Philip et al., 1995). This effect can be important in patients with borderline bone density. Administration of warfarin during pregnancy, particularly the first 12 weeks of pregnancy, is associated with congenital anomalies in 25 to 30 percent of exposed infants (Ginsberg and Hirsh, 1998). Many of the anomalies are related to abnormal bone formation. It is thought that warfarin may interfere with synthesis of proteins critical for normal structural development.

Heparin Heparin is a widely used anticoagulant for both prophylaxis and therapy of acute venous thromboembolism (Hirsh et al., 1998). In many hospitals, the majority of patients are exposed to this potent anticoagulant at some point during their hospitalization. The major complication associated with heparin therapy is bleeding, a direct manifestation of its anticoagulant activity. The risk of bleeding is related to the intensity of therapy, the patient's body mass and underlying condition, and the presence of other hemostatic defects (e.g., thrombocytopenia). The APTT is commonly used to monitor therapy with unfractionated heparin, but there are significant problems with standardization of this assay for monitoring purposes. An alternative to the APTT is determination of heparin concentration in plasma, using a functional assay based on the inhibition of thrombin or factor Xa (Olson et al., 1998).

As discussed in the section on platelets, heparin administration is also associated with the development of HIT. For unknown reasons, this complication occurs more frequently with heparin derived from bovine sources than with that derived from por-cine sources. The incidence of HIT is also significantly higher in patients receiving unfractionated heparin than it is in pa-tients receiving low-molecular-weight heparin (Warkentin et al., 1995).

Long term administration of heparin is associated with an increased risk of clinically significant osteoporosis (Ginsberg et al., 1990; Levine and Anderson, 1990). The mechanism underlying the development of osteoporosis in these patients is not known. Patients may suffer from spontaneous vertebral fractures and demineralization of long bones of the arms and legs. The risk of osteoporosis may be less with low-molecular-weight heparin as compared to unfractionated heparin.

Heparin administration may also cause a transient rise in serum transaminases (Dukes et al., 1984; Schwartz et al., 1985; Monreal et al., 1989; Guevara et al., 1993). The changes may suggest significant liver dysfunction. However, the rise is rapidly reversible upon discontinuation of heparin and may reverse even before heparin is discontinued. The elevation of serum transaminases has not been associated with chronic liver dysfunction. The mechanism of heparin-induced increase in transaminases is not known.

Fibrinolytic Agents Fibrinolytic agents are used in the treatment of acute thromboembolic disease with the goal of dissolving the pathogenic thrombus (Curzen et al., 1998; Collen, 1999). Each of these drugs works by converting plasminogen, an inactive zymogen, to plasmin, an active proteolytic enzyme. Plasmin is normally tightly regulated and is not freely present in the circulation. However, administration of fibrinolytic agents regularly results in the generation of free plasmin leading to systemic fibrin(ogen)olysis. The toxicology of the fibrinolytic agents can be divided into toxic effects of systemic plasmin activation and toxic effects of the activators themselves.

Systemic fibrinolysis is associated with the development of a complex coagulopathy characterized by a decrease in fibrinogen, factor V, factor VIII, a $_2$-antiplasmin; an increase in circulating fibrin split products; degradation of platelet GP Ib/IX/V and IIb/IIIa; degradation of endothelial cell glycoproteins; degradation of fibronectin and thrombospondin; and prolongation of the PT, APTT, and thrombin time. All of these effects potentiate the risk of bleeding. Anatomic locations that are frequently involved in bleeding complications include the cerebral circulation and sites of recent vascular access. As systemic plasmin can lyse physiologic as well as pathologic thrombi, reactivation of bleeding from sites of vascular access is not uncommon. Platelet inhibitors and heparin are commonly used in conjunction with fibrinolytic therapy to prevent recurrent thrombosis. As one might expect, the use of anticoagulants in the setting of systemic fibrinolysis may also contribute to the risk of bleeding.

Another complication associated with fibrinolysis is recurrent thrombosis at the site of pathologic thrombosis. While rethrombosis may be related to underlying damage to the vascular wall, there is some evidence that fibrinolytic therapy may contribute to this process. For example, plasmin, in appropriate concentrations can actually induce platelet activation (McRedmond et al., 2000). This process may be mediated by plasmin or streptokinase/plasminogen cleavage of the platelet thrombin receptor (protease activated receptor-1). Cleavage of the receptor is associated with activation of the platelet biochemical signaling pathways. There is sufficient "cross-talk" between the fibrinolytic system and the contact system of coagulation that one could also anticipate increased thrombin generation occurring as a result of fibrinolytic therapy (Schmaier et al., 1999).

Streptokinase is a protein derived from group C b-hemolytic streptococci and is antigenic in humans. Antibody formation to streptokinase occurs commonly in association with streptococcal infections as well as exposure to streptokinase. Acute allergic reactions may occur in 1 to 5 percent of patients exposed to streptokinase, and these allergic reactions may consist of minor symptoms such as hives and fever as well as major, life-threatening anaphylactic reactions. In addition, delayed hypersensitivity reactions associated with severe morbidity may occur (Siebert et al., 1992; Curzen et al., 1998). Allergic reactions also occur with other fibrinolytic agents containing streptokinase (e.g., anisoylated plasminogen-streptokinase complex) or streptokinase-derived peptides. The immune complex formed by IgG and streptokinase is capable of binding to and clustering platelet FcgRIIa, initiating platelet activation and aggregation (McRedmond et al., 2000).

Urokinase and recombinant plasma transminogen activator (t-PA) are generally not associated with allergic reactions. However, work is progressing on a number of genetically engineered forms of t-PA. Whether or not such mutant forms of t-PA are immunogenetic has not been firmly established.

Inhibitors of Fibrinolysis Inhibitors of fibrinolysis are commonly used to control bleeding in patients with congenital abnormalities of hemostasis, such as von Willebrand disease. Tranexamic acid and e-aminocaproic acid are small molecules that block the binding of plasminogen and plasmin to fibrin and other substrate proteins through interaction with lysine binding sites on plasmin(ogen). They are relatively well tolerated. However, there is some evidence that administration of these agents may increase the risk of thrombosis due to the inhibition of the fibrinolytic system (Mannucci, 1998). In a single case, intravenous infusion of e-aminocaproic in a patient with chronic renal failure was associated with acute hyperkalemia (Perazella and Biswas, 1999).

Aprotinin is a naturally occurring polypeptide inhibitor of serine proteases. It is usually derived from bovine material and consequently is immunogenic when administered to humans. Aprotinin is given by intravenous infusion, as it is inactive when given orally. Allergic reactions in response to aprotinin have been reported, ranging from minor cutaneous manifestations to anaphylactic reactions (Peters and Noble, 1999).

RISK ASSESSMENT

Assessing the risk that exposure to new drugs, chemical products, and other agents pose to humans—in terms of significant toxic effects on hematopoiesis and the functional integrity of blood cells and hemostatic mechanisms—can be logistically and intellectually challenging. This is due in part to the complexity of hematopoiesis and the range of important tasks that these components perform, as previously discussed. A central issue in drug and nontherapeutic chemical development is the *predictive value* of preclinical toxicology data and the expansive but inevitably limited preregistration clinical database for the occurrence of significant hematotoxicity upon broad exposure to human populations. Appropriately, this area of well-resourced applied toxicology is highly regulated yet provides unique and exciting opportunities for sophisticated, well-controlled research (Bloom, 1993).

Preclinical Risk Assessment

Animal Models and Hematologic Monitoring Most preclinical studies that assess the potential for candidate drugs or nontherapeutic chemicals to induce hematotoxicity in humans are performed in industry as part of the routine safety evaluation of these molecules. These studies are largely prescribed by government regulatory bodies of the various countries and regions, including the United States, the European Union, and Japan (Hall, 1992, 1997). The issues relating to the

assessment of blood as a target organ that confront the industrial toxicologist are largely similar to those of other target organs and include the selection of the appropriate animal model, how to best monitor for hematotoxicity, and the appreciation of species differences in responding to hematotoxic insults.

Selection of a species that is practical to study and predictive for hematotoxicity in humans is always a challenge. While this is driven in part by regulatory requirements (Hall, 1992), the selection is influenced by other considerations, including having a pharmacokinetic profile comparable to that of man; prior information on sensitivity of a particular species to a class of compounds; the ability to fully characterize effects on peripheral blood and bone marrow; and practical considerations, such as logistics and economics (Bloom, 1993). These become of particular importance in choosing a model to fully characterize the toxicity of an agent known to have an hematotoxic potential.

Of the commonly used animal species, rats and mice offer the advantage of their small size, which favorably impacts test compound requirements and number of subjects that can be economically housed and tested. Both have been well characterized hematologically (Jain, 1986; Smith, 1995; Valli and McGrath, 1997). Blood volume limitations, however, often prohibit the frequent, or serial, evaluation of blood and bone marrow required to characterize the progression of an hematotoxic effect. While this can be addressed in part through serial sacrifices, the inability to fully characterize individual animals poses a significant disadvantage.

Serial blood and bone marrow sampling is practical in larger species, such as the dog and monkey. These models offer the additional advantage of being hematologically more similar to humans as regards hematopoiesis and blood cell kinetics, which in the monkey extends to immunohematologic features (Ladiges, 1990; Shifrine et al., 1980). The latter species, however, presents more interanimal hematologic variability, particularly in wild-caught primates, due to temperament, vascular access, and other influences such as nutritional status and infection.

Tests used to assess blood and bone marrow in preclinical toxicology studies will vary with the phase or objective of the evaluation (acute, subacute, chronic), the intended use of the agent, and what is understood or suspected regarding the toxicologic profile of the xenobiotic. Ideally, the studies in aggregate should provide information on the effects of single- and multiple-dose exposure on erythrocyte parameters (RBC, Hbg, PCV, MCV, MCHC), leukocyte parameters (WBC and absolute differential counts), thrombocyte counts, screening coagulation tests (PT, aPTT), peripheral blood cell morphology, and bone marrow cytologic and histologic examinations (Bloom, 1993; Weingand et al., 1996). Additional tests should be employed in a problem-driven fashion, as required to better characterize findings from the aforementioned screening efforts or to more fully explore a class-specific effect or other hematotoxicologic potential of concern (Bloom, 1993). Examples of these tests are listed in Table 11-13. While much progress has been made in validating many of the more specialized assays in our principal animal models, additional validation that addresses laboratory- and species-specific preanalytic and analytic variables is often required.

Reticulocyte count
Heinz body preparation
Cell-associated antibody assays (erythrocyte, platelet, neutrophil)
Erythrocyte osmotic fragility test
Erythrokinetic/ferrokinetic analyses
Cytochemical/histochemical staining
Electron microscopy
In vitro hematopoietic clonogenic assays
Platelet aggregation
Plasma fibrinogen concentration
Clotting factor assays
Thrombin time
Bleeding time

Table 11-13 Examples of Problem-Driven Tests Used to Characterize Hematologic Observations in Preclinical Toxicology

Because hematologic features and response to disease can vary substantially among animal species, it is essential that the toxicologist fully understands the hematology of the animal model used for preclinical risk assessment. While complete and accurate reference data are helpful, they do not provide information on pathophysiology that may be species-specific and required to accurately interpret the preclinical data. Examples of these features include the relative influence of preanalytic variables (blood collection technique, nutritional status, sample stability), response to blood loss or hemolysis, stress effects on the leukogram, susceptibility to secondary effects associated with other target organ toxicity, etc. It is beyond the scope of this chapter to fully discuss the comparative hematology of laboratory animals, which is provided in several excellent reviews (Jain, 1986; Valli and McGrath, 1997; Smith, 1995).

Applications of in Vitro Bone Marrow Assays As with other target-organ risk assessment, in vitro methods for assessing potential hematotoxicity are attractive in that they are faster and less expensive than in vivo studies while providing data that often suggest or clarify the mechanism of a toxic effect. Drug- or chemical-induced bone marrow suppression can result from effects on specific hematopoietic stem cells or on the hematopoietic microenvironment. These effects can be distinguished and confirmed using short-term clonogenic assays and long-term functional assays, respectively (Deldar, 1994; Williams, 1988; Naughton et al., 1992). The former include burst-forming-unit erythroid (BFU-E), colony-forming-unit erythroid (CFU-E), colony-forming-unit granulocyte/monocyte (CFU-GM), colony-forming- unit megakaryocyte (CFU-MK), and colony-forming-unit granulocyte, erythroid, megakaryocyte, monocyte (CFU-GEMM), which have been developed for several laboratory animal species (Deldar and Parchment, 1997). It is therefore possible to examine effects on the myeloid, erythroid and megakaryocytic lineages in a fashion where concentrations of the agent are tightly controlled as is duration of exposure to it.

In vitro clonogenic assays are best used in a preclinical setting in combination with in vivo testing. Used in this way, the predictive value of these assays is enhanced. This has been particularly true for anticancer and antiviral drugs, where the in vitro component of risk assessment has been used for therapeutic index-based screening to identify less myelosuppressive analogs, structure-toxicity relationships, and new-drug lead candidates (Deldar and Stevens, 1993; Parchment et al., 1993). Other advantages of the in vitro hematopoietic stem cell assays include the opportunities they provide to test combinations of agents as well as their metabolites and effects of serum and other cell components, such as lymphocytes (Deldar and Parchment, 1997). Perhaps most important is the ability to test human hematopoietic cells directly in a preclinical setting, thus obviating extrapolation considerations. Concern for possible metabolic activation can be addressed by culturing the target cells in question with metabolizing systems in a cell-free extract (s9), with isolated hepatocytes, or with other CYP450-expressing cell types (Frazier, 1992).

Perhaps the most interesting use of these in vitro clonogenic assays in risk assessment has been their role in making practical interspecies comparisons regarding sensitivity to a particular agent or group of drugs or chemicals. Comparisons to the sensitivity of human cells can be made that have implications for the relative predictive value of various animal models for hematotoxicity in humans. Examples include the resistance of murine CFU-GM to the anticancer drug topotecan relative to that of the canine and human cells (Deldar, 1993). This is consistent with the early observations of Marsh, that the dog is a particularly predictive model for the myelosuppression associated with anticancer drugs in humans (Marsh, 1985). Thus, while some agents show comparable suppressive activity across species lines (doxorubicin, pyrazoloacridine, hepsulfan, cyclopentenyl cytosine), others, such as camptothecins, carboxyamidotriazole and fostriecin, show differences of as much as three log concentrations (Reagan et al., 1993; Horikoshi and Murphy, 1982; Du et al., 1991). A more detailed discussion on the application of in vitro hematopoietic clonogenic assays for preclinical screening and mechanistic studies is provided by Deldar and Parchment (1997).

While this discussion has focused on in vitro hematopoietic clonogenic assays in the context of risk assessment, these assays have also proven to be extraordinarily useful tools for investigating mechanisms of toxic cytopenia in humans (Deldar, 1994). Parchment and Murphy review the application of these to four categories of hematologic toxicity observed clinically: (1) the reversible cytopenia following acute exposure to a cytotoxic or cytostatic agent; (2) the permanent loss in the production of a mature blood cell type(s); (3) cytosis, or the dramatic increase in blood cell counts following single or repeated toxicant exposure; and (4) the progressive loss or one or more blood cell lineages during chronic exposure to a toxicant (Parchment and Murphy, 1997). In all these circumstances, in vitro and ex vivo hematopoietic clonogenic assays have proven useful in understanding the mechanism(s) of these toxic effects and formulating strategies for risk management and treatment.

Clinical Trials and Risk Assessment

As with preclinical risk assessment, most of the clinical research on hematotoxicity is driven by regulatory requirements and supported by the drug, cosmetic, and chemical industries. The challenges and opportunities this presents are similar to those in preclinical development with the following differences. Most clinical studies

involve actual patients with the targeted disease, in contrast to the inbred, healthy, well-defined animals employed in preclinical studies. This presents additional variables and challenges to manage. Second, the scale of clinical trials, the volume of data produced, and the resources required exceed by orders of magnitude those of preclinical studies. Third, many clinical trials involve research cooperative groups that represent a network of clinical scientists from academic medical centers, such as the Eastern Cooperative Oncology Group (ECOG), the AIDS Clinical Trial Group (ACTG), Thrombolysis in Myocardial Infarction (TIMI), and others. Most of the information on drug- or chemical-induced hematotoxicity in humans is collected through this industry-sponsored and highly regulated clinical research.

It is well understood that the ways in which drugs and nontherapeutic chemicals affect the hematopoietic system are influenced by both the nature of the agent and the response of the subject or target population. As discussed previously, many agents are known to induce dose-dependent hematotoxicity in a fashion that is highly predictable. Others cause toxicity in a small number of susceptible individuals, and these often include agents not otherwise hematotoxic in most individuals (Patton and Duffull, 1994). As previously discussed these *idiosyncratic reactions* present the biggest challenge as regards detection and characterization before human patients or populations are broadly exposed. They include aplastic anemia, thrombocytopenia, hemolysis and leukopenia, which may be immune-mediated (Salama and Muller-Eckhardt, 1992) or related to other mechanisms, such the generation of a toxic metabolite (Gerson et al., 1983), as previously discussed.

The chemical structure can be a risk factor if it is similar to that of other known toxicants. Patient or population-related risk factors include pharmacogenetic variations in drug metabolism and detoxification that lead to reduced clearance of the agent or production of novel intermediate metabolites (Gerson et al., 1993; Cunningham et al., 1974; Mason and Fisher, 1992), histocompatibility antigens (Frickhofen et al., 1990), interaction with drugs or other agents (West et al., 1988), increased sensitivity of hematopoietic precursors to damage (Vincent, 1986), preexisting disease of the bone marrow, and metabolic defects that predispose to oxidative or other stresses associated with the agent (Stern, 1989).

In drug development, the clinical evaluation of candidate molecules is usually performed in three phases: *Phase I* examines the effect of single and multiple increasing doses in small numbers of normal and/or patient volunteers. Pharmacokinetic properties are usually addressed, as well as the routes of excretion and metabolism; and the assessment of active and inactive metabolites. The emphasis is usually on safety assessment. *Phase II* includes controlled studies in the target patient population that examine both safety and efficacy. They explore dose response and usually provide the first indication of benefit versus risk. *Phase III* entails larger studies designed to confirm efficacy in an expanded patient population and evaluate less frequent adverse effects, such as the aforementioned idiosyncratic blood dyscrasias.

Development of demonstrably hematotoxic drugs is usually stopped in phase I or II unless the indications include life-threatening conditions, where toxicity is acceptable (e.g., anticancer drugs). Thus, drugs tested in phase III generally show an acceptable safety profile in most subjects at the doses used. Even phase III studies, however, are not usually powered to detect the low incidence of idiosyncratic hematotoxicity previously discussed (Levine and Szarfman, 1996). In order to detect one adverse event affecting 1 percent of an exposed patient population at a 95 percent confidence level, a trial must include approximately 300 subjects (O'Neill, 1988). Most clinical databases supporting new drug applications cannot be used to rule out events that occur below 1 per 500 exposures (Szarfman et al., 1997). Thus, rare, delayed or cumulative toxicity is often missed in preregistration clinical trials.

Detection of low-incidence hematotoxicity is usually achieved through postmarketing surveillance, such as the Med Watch program introduced by the FDA in 1993 (Szarfman et al., 1997). Other countries that practice comprehensive postmarketing surveillance include Canada, the United Kingdom, Sweden, Germany, France, Australia, and New Zealand. Adverse event data, including serious hematotoxicity, are provided to the WHO; this information is compiled by a computer-based recording system employing WHO terminology and system and organ classifications for adverse reactions (Edwards, 1990). Examples of iatrogenic blood dyscrasias detected through postmarketing surveillance include the hemolysis and thrombocytopenia associated with the antibiotic temafloxacin; the aplastic anemia linked to the antiepileptic felbamate; the hemolysis caused by the antidepressant nomifensine; and the agranulocytosis associated with the antiarrhythmic aprindine (Szarfman et al., 1997).

The WHO has also established criteria for grading hematotoxicity (WHO, 1997), which is summarized in Table 11-14. These have been particularly useful in establishing and communicating treatment strategies and guidelines for agents known to suppress hematopoiesis (cytoreductive oncolytic, immunosuppressive, and antiviral agents, etc.) and for which this limiting toxicity is used to establish maximum tolerated doses for individual patients.

HEMATOLOGICAL PARAMETERS (ADULTS)	GRADE 0	GRADE 1	GRADE 2	GRADE 3	GRADE 4
Hemoglobin (g dL⁻¹)	11.0	9.5–10.5	8.0–9.4	6.5–7.9	6.5
(mmol/L)	(6.5)	(6.5–6.7)	(4.95–5.6)	(4.0–4.9)	(4.0)
Leukocytes (1000 μL⁻¹)	4.0	3.0–3.9	2.0–2.9	2.0–1.9	1.0
Granulocytes (1000 μL⁻¹)	2.0	1.5–1.9	1.0–1.4	0.5–0.9	0.5
Platelets (1000 μL⁻¹)	100	75–99	50–74	25–49	<25
Hemorrhage/blood loss	None	Petechiae	Mild	Gross	Debilitating

SOURCE: WHO, 1979.

Table 11-14 WHO Grading Criteria for Subacute and Acute Hematotoxicity

Greater risk is acceptable with these agents due to the life-threatening conditions they are used to treat. Similar risk–benefit decisions are also made regarding the use of agents that cause blood dyscrasias in an idiosyncratic fashion, as previously discussed. Some are used to treat nonmalignant or life-threatening conditions, the risk of which is managed through rigorous laboratory monitoring. Examples include felbamate and ticlopidine, as discussed above, and the antischizophrenic drug clozapine, associated with agranulocytosis (Alvir et al., 1993). Postmarketing surveillance plays a critical role in measuring the effectiveness of such monitoring.

CHAPTER 12

TOXIC RESPONSES OF THE IMMUNE SYSTEM

Leigh Ann Burns-Naas, B. Jean Meade, and Albert E. Munson

Immunity, by definition, is a homeostatic condition in which the body maintains protection from infectious disease. It is a series of delicately balanced, complex, multicellular, and physiologic mechanisms that allow an individual to distinguish foreign material from "self" and to neutralize and/or eliminate the foreign matter. It is characterized by a virtually infinite repertoire of specificities, highly specialized effectors, complex regulatory mechanisms, and an ability to travel throughout the body. The immune system provides the means to initiate rapid and highly specific responses against a myriad of potentially pathogenic organisms. Indeed, the conditions of genetically determined immunodeficiency and of acquired immunodeficiency syndrome (AIDS) graphically highlight the importance of the immune system in the host's defense against microbial infection. In addition, evidence is rapidly building that the immune system plays a role in tumor identification and rejection (immune surveillance).

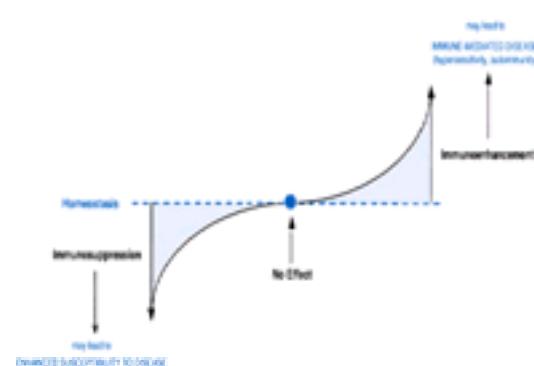
In light of the central role that the immune system plays in the maintenance of the health of the individual, the interaction of xenobiotics (pharmacologic agents, environmental contaminants, and other chemicals) with the various components of the immune system has become an area of profound interest. Indeed, in some instances, the immune system has been shown to be compromised (decreased lymphoid cellularity, alterations in lymphocyte subpopulations, decreased host resistance, altered specific immune function responses) in the absence of observed toxicity in other organ systems. Decreased immunocompetence (immunosuppression) may result in repeated, more severe, or prolonged infections as well as the development of cancer. Immunoenhancement may lead to immune-mediated diseases such as hypersensitivity responses or autoimmune disease (Fig. 12-1). Because of the potentially profound effects resulting from disruption of the delicately balanced immune system, there is a need to understand the cellular, biochemical, and molecular mechanisms of xenobiotic-induced immunomodulation. With the availability of sensitive, reproducible, and predictive tests, it is now apparent that the inclusion of immunotoxicity testing may represent a significant adjunct to routine safety evaluations for therapeutic agents, biological agents, and chemicals now in development.


Figure 12-1. Potential consequences of immunomodulation.

This chapter provides (1) an overview of basic concepts in immunology (structure, components, and functions), which are important to the understanding of the impact xenobiotics may have on the exposed individual; (2) a summary of selected cur-rent methods utilized to assess immune function; and (3) a brief review of current information on the immunomodulation (immunosuppression, hypersensitivity, and autoimmunity) induced by a variety of xenobiotics. This chapter is not meant to be an immunology textbook nor an exhaustive review of the mechan-isms of immunotoxicity of a myriad of xenobiotics. For detailed information on immunology, the reader is referred to two texts, the first edited by Paul (1999), the second edited by Roitt and colleagues (1993). For a more comprehensive review of immunotoxicology, the reader is referred to texts edited by Dean and colleagues (1994), Smialowicz and Holsapple (1996), and Lawrence (1997).

THE IMMUNE SYSTEM

Unlike most organ systems, the immune system has the unique quality of not being confined to a single site within the body. It comprises numerous lymphoid organs (Table 12-1) and numerous different cellular populations with a variety of functions. The bone marrow and the thymus contain microenvironments capable of supporting the production of mature T and B lymphocytes and myeloid cells, such as macrophages and polymorphonuclear cells from nonfunctional precursors (stem cells), and are thus referred to as primary lymphoid organs. With regard to T and B cells, key events that occur in both primary and secondary organs are (1) acquisition of the ability to recirculate and become localized in appropriate places in the periphery (homing capacity), (2) the ability to recognize antigen (rearrangement of the T-cell receptor and the B-cell antigen receptor germline genes), and (3) the ability to interact with accessory cells (through the expression of various cell surface molecules and the development of biochemical signaling pathways) to allow differentiation into both effector and memory cell populations.

CLASSIFICATION	LYMPHOID ORGANS
Primary	Bone marrow
	Thymus
Secondary	Spleen
	Lymph nodes
Tertiary	Skin-associated lymphoid tissue (SALT)
	Mucosal lamina propria (MALT)
	Gut-associated lymphoid tissue (GALT)
	Bronchial-associated lymphoid tissue (BALT)
	Cells lining the genitourinary tract

Table 12-1 Organization of the Immune System: Lymphoid Tissue

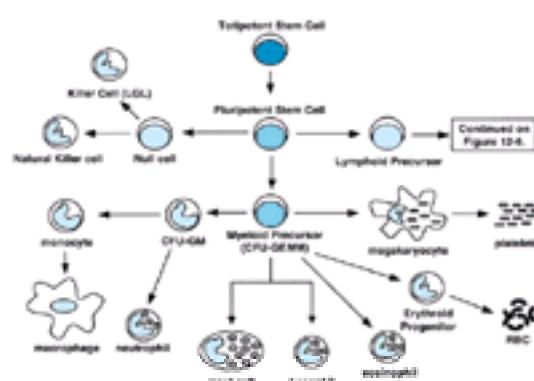
The bone marrow is the site of origin of the pluripotent stem cell, a self-renewing cell from which all other hematopoietic cells are derived (Fig. 12-2 and Fig. 12-6). During gestation, this cell is found in the embryonic yolk sac and fetal liver; subsequently, it migrates to the bone marrow. Within the bone marrow, the cells of the immune system developmentally "commit" to either the lymphoid or myeloid lineages. Cells of the lymphoid lineage make a further commitment to become either T cells or B cells. Because of their critical role in initiation and regulation of immune responses, T cell precursors are programmed to leave the bone marrow and migrate to the thymus, where they undergo "thymic education" for recognition of self and nonself. This is discussed in more detail under "Cellular Components" in the section below titled "Acquired (Adaptive) Immunity."


Figure 12-2. Development of the cellular components of the immune system.
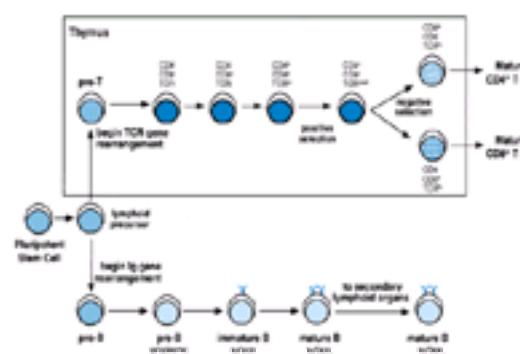

Figure 12-6. Development and differentiation of T and B cells.

Mature naive or virgin lymphocytes (those T and B cells that have never undergone antigenic stimulation) are first brought into contact with exogenously derived antigens within the highly organized microenvironment of the spleen and lymph nodes, otherwise known as the secondary lymphoid organs. These organs can be thought of as biological sieves. The spleen serves as a filter for the blood, removing both foreign antigens and any circulating dead cells and cellular debris. The lymph nodes are part of a network of lymphatic veins that filter antigens from the fluid surrounding the tissues of the body. Key events that occur within the secondary lymphoid organs are (1) specific antigen recognition in the context of the major histocompatibility complex (MHC) class II, (2) clonal expansion (proliferation) of antigen-specific cells, and (3) differentiation of antigen-stimulated lymphocytes into effector and memory cells.

Lymphoid tissues associated with the skin (skin-associated lymphoid tissue, or SALT) and mucosal lamina propria (mucosa-associated lymphoid tissue, or MALT) can be classified as tertiary lymphoid tissues. Tertiary lymphoid tissues are primarily effector sites where memory and effector cells exert immunologic and immunoregulatory functions. Although in a broad interpretation this would include essentially all tissues of the body, tertiary lymphoid tissues are associated primarily with the surfaces lining the intestines (gut-associated lymphoid tissue, or GALT), respiratory tract (bronchial-associated lymphoid tissue, or BALT), and the genitourinary tract, since these tissues have access directly to the external environment. For extensive reviews of respiratory, mucosal, and dermal immunology and immunotoxicology, the reader is referred to chapters in Smialowicz and Holsapple (1996) and in Lawrence (1997).

Innate Immunity

General Considerations Mammalian immunity can be classified into two functional divisions: innate immunity and acquired (adaptive) immunity (Table 12-2). Innate immunity acts as a first line of defense against infectious agents, eliminating most potential pathogens before significant infection occurs. It is characterized by being *nonspecific* and includes physical and biochemical barriers both inside and outside of the body as well as immune cells designed for specific responses. Unlike acquired immunity, there is no immunologic memory associated with innate immunity. Therefore, in a normal healthy adult, the magnitude of the immune response to a foreign organism is the same for a secondary or tertiary challenge as it is for the primary exposure.

CHARACTERISTIC	INNATE IMMUNITY	ACQUIRED IMMUNITY
Cells involved	Polymorphonuclear cells (PMN)	T cells
	Monocyte/macrophage	B cells
	NK cells	Macrophages
		NK cells
Primary soluble mediators	Complement	Antibody
	Lysozyme	Cytokines
	Acute phase proteins	
	Interferon-α/β	
	Other cytokines	
Specificity of response	None	Yes (very high specificity)
Response enhanced by repeated antigen challenge	No	Yes

Table 12-2 Innate verses Acquired Immunity

Externally, the skin provides an effective barrier, as most organisms cannot penetrate intact skin. Most infectious agents enter the body through the respiratory system, gut, or genitourinary tract. Innate defenses present to combat infection from pathogens entering through the respiratory system include mucus secreted along the nasopharynx, the presence of lysozyme in most secretions, and cilia lining the trachea and main bronchi. In addition, reflexes such as coughing, sneezing, and elevation in body temperature are also a part of innate immunity. Pathogens that enter the body via the digestive tract are met with severe changes in pH (acid) with-in the stomach and a host of microorganisms living in the intestines.

Cellular Components: NK, PMN, Macrophage Two general types of cells are involved in nonspecific (innate) host resistance: natural killer (NK) cells and professional phagocytes (Table 12-3). Like other immune cells, NK cells are derived from the bone marrow stem cell. It is not yet clear exactly how the NK lineage progresses; however, NK cells do possess several surface markers which have been used to define T cells, suggesting that the NK cell is a derivative of a lymphoid precursor cell. The vast majority of NK cells express CD16 (Fc receptor for IgG) on their surface. Although apparently derived from a similar lineage as the T cell, NK cells do not express cell surface CD3 (T cell receptor-associated protein complex) or either chain of the T-cell receptor (TCR). NK cells are located primarily in the spleen, blood, and peritoneal exudate, although they are occasionally found in lymph node tissue as well. For their part in innate immunity, NK cells can recognize virally infected and malignant changes on the surface of cells as well as the Fc portion of IgG on an antibody-coated target cell. The latter recognition is utilized in cell-mediated immunity. Using surface receptors, the NK cell binds and undergoes cytoplasmic reorientation so that cytolytic granules (perforins and enzymatic proteins) are localized near the target cell. These granules are then expelled onto the surface of the target cell. The result of this process is the induction of apoptosis (DNA fragmentation, membrane blebbing, and cellular disintegration) of the target cell.

Table 12-3 Characteristics of Selected Immune Cells

Phagocytic cells include polymorphonuclear cells (PMN; neutrophil) and the monocyte/macrophage. The precursors of the macrophage and PMN develop from pluripotent stem cells that have become committed to the myeloid lineage (Fig. 12-2). Evidence exists that there are bipotentiating reactive precursors for PMN and macrophage and that differentiation into one or the other is dependent upon the interaction with specific colony-stimulating factors (CSFs) such as macrophage-CSF (M-CSF), granulocyte-CSF (G-CSF), granulocyte-macrophage-CSF (GM-CSF), interleukin-3 (IL-3), and others (Unanue, 1993). Within the bone marrow, both cell types undergo several rounds of replication before entering the bloodstream where they circulate for about 10 h and then enter the tissues where they perform effector functions for about 1 to 2 days. PMNs are capable of passing through the cell membrane of the blood vessels and thereby represent a primary line of defense against infectious agents. They are excellent phagocytic cells and can eliminate most microorganisms. Their phagocytic activity is greatly enhanced by the presence of complement and antibody deposited on the surface of the foreign target. They are also important in the induction of an inflammatory response.

Macrophages are terminally differentiated monocytes. Upon exiting the bone marrow, monocytes circulate within the bloodstream for about 1 day. At that time, they begin to distribute to the various tissues where they can then differentiate into macrophages. Macrophages can be found in all tissues, most notably in the liver, lung, spleen, kidney, and brain. Within different tissues, mac-rophages have distinct properties and vary in extent of surface receptors, oxidative metabolism, and expression of MHC class II. This is likely due to the factors present within the microenvironment in which the monocyte differentiates. The liver macrophages, or Kupffer cells, are primarily responsible for particulate and microbial clearance from the blood. They express high levels of MHC class II, are actively phagocytic, and release several soluble mediators. Thus, they are the primary cells responsible for the acute phase response. Alveolar macrophages remove foreign particulate matter from the alveolar space. They are self-renewing and have a particularly long lifespan. These cells can be harvested by broncheoalveolar lavage and actively secrete proteases and bactericidal enzymes such as lysozyme. Splenic macrophages also phagocytose particulate material and polysaccharides from the blood and tissue. However, unlike other tissue macrophages, they are more diverse within the tissue and their level of expression of MHC class II and their stage of differentiation appears to be dependent upon where within the splenic architecture the macrophages are located. Mononuclear phagocytes within the central nervous system (CNS) are known as microglia and are responsible for antigen presentation in immunologic diseases of the CNS. Microglia have a very slow turnover time, and thus recruitment of monocytes to areas of inflammation within the CNS is also slow.

Should PMNs be unable to contain an infection, macrophages are then recruited to the site of infection. Although macrophages are phagocytic by nature, their bactericidal activity can be augmented by lymphokines produced by T cells that recognize a specific microbial antigen. Macrophages are unique cells within the immune system because they play roles in both the innate arm of immunity (as phagocytic cells) and the acquired arm (as antigen-presenting cells). They adhere well to glass or plastic, are recruited to sites of inflammation by chemotactic factors, can be activated by cytokines to become more effective killers, and can produce cytokines, such as IL (interleukin)-1, IL-6, and TNF (tumor necrosis factor), that act in a paracrine and autocrine fashion. Macrophages also play critical roles as scavengers in the daily turnover of senescent tissues such as red cell nuclei from maturing red cells, PMNs, and plasma cells. The importance of phagocytic cells to the organism can be seen in individuals with spontaneous or induced reduction in the numbers or activity of these cells. This condition is associated with repeated and sometimes fatal bacterial and fungal infections.

Soluble Factors: Acute-Phase Proteins and Complement In addition to the cellular components of innate immunity, there are several soluble components (Table 12-2). These are the acute-phase response and the complement cascade. Upon infection, mac-rophages (Kupffer cells, in particular) become activated and secrete a variety of cytokines, which are carried by the bloodstream to distant sites. This global response to foreign agents is termed the acute-phase response and consists of fever and large shifts in the types of serum proteins synthesized by hepatocytes, such as serum amyloid A, serum amyloid P, and C-reactive protein. These proteins increase rapidly to concentrations up to 100 times the normal concentration and stay elevated through the course of infection. These proteins can bind to bacteria and facilitate the binding of complement and the subsequent uptake of the bacteria by phagocytic cells. This process of protein coating to enhance phagocytosis is termed opsonization.

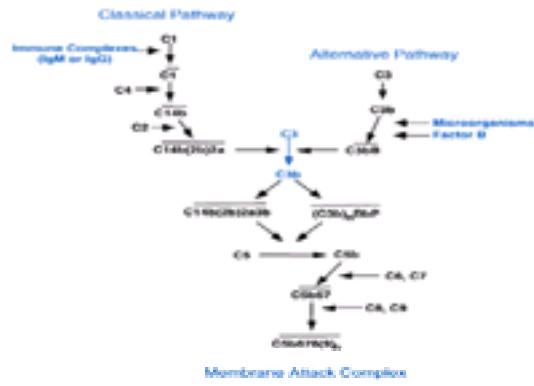
The complement system is a series of about 30 serum proteins whose primary functions are the modification of membranes of infectious agents and the promotion of an inflammatory response. The components of the complement cascade interact with each other and with other elements of both the innate and acquired arms of immunity. Complement activation occurs with each component sequentially, acting on others in a manner similar to the blood clotting cascade (Fig. 12-3). Early components of the cascade are often modified serine proteases, which activate the system but have limited substrate specificity. Several components are capable of binding to microbial membranes and serve as ligands for complement receptors associated with the membrane. The final components, which are related structurally, are also membrane-binding proteins that can enter into the membrane and disrupt membrane integrity (membrane attack complex). And finally, there are several regulatory complement proteins designed to protect the host from inadvertent damage.


Figure 12-3. The complement cascade.

Two pathways have been identified in the complement cascade. The classic pathway is involved when antibody binds to the microorganism. Because specific antibody defines the target, this is a mechanism by which complement aids effectors of the acquired side of immunity. The second, or alternative pathway, is used to assist the innate arm of immunity. For this cascade, it is not necessary for the host to have prior contact with the pathogen, since several microbial proteins can alone initiate this pathway. Whatever the mechanism of activation, the results are the same. The complement-coated material is targeted for elimination by interaction with complement receptors on the surface of circulating immune cells.

Acquired (Adaptive) Immunity

General Considerations If the primary defenses against infection (innate immunity) are breached, the acquired arm of the immune system is activated and produces a specific immune response to each infectious agent, which usually eliminates the infection. This branch of immunity is also capable of remembering the pathogen and can protect the host from future infection by the same agent. Therefore, the two key features which distinguish acquired immunity are *specificity* and *memory*. This means that in a normal healthy adult, the speed and magnitude of the immune response to a foreign organism is greater for a secondary challenge than it is for the primary challenge (Table 12-2). This is the principle exploited in vaccination.

Acquired immunity may be further subdivided into cell-mediated immunity (CMI) and humoral immunity. CMI, in its broadest sense, includes all immunologic activity in which antibody plays a minimal role. Humoral immunity is directly dependent upon the production of antigen-specific antibody by B cells and involves the coordinated interaction of antigen-presenting cells, T cells, and B cells. A more detailed discussion of both CMI and humoral immunity appears later.

Essential to the development of specific immunity is the recognition of antigen and the generation of an antibody that can bind to it. An antigen (sometimes referred to as an immunogen or allergen) is defined functionally as a substance that can elicit the production of a specific antibody and can be specifically bound by that antibody. Antigens are usually (but not absolutely) biological molecules that can be cleaved and rearranged for presentation. They may be either proteins, carbohydrates (often bacterial), lipids, nucleic acids, or human-engineered substances, and they must be foreign (nonself) or occult (hidden, sequestered). Generally, antigens are about 10 kDa or larger in size. Smaller antigens are termed *haptens* and must be conjugated with carrier molecules (larger antigens) in order to elicit a specific response. However, once a response is made, the hapten can interact with the specific antibody in the absence of the carrier.

Antibodies are produced by B cells and are also defined functionally by the antigen with which they react (i.e., anti-sheep red blood cell IgM, or anti-sRBC IgM). Because the immune system generates antibody to thousands of antigens with which the host may or may not ever come into contact, general antibody of unknown specificity is referred to as *immunoglobulin* (e.g., serum immunoglobulin or serum IgM) until it can be defined by its specific antigen (e.g., anti-sRBC IgM). A simple way to view this point is that an antibody is an immunoglobulin, but immunoglobulin is not necessarily antibody. There are five types of immunoglobulin that are related structurally (Table 12-4): IgM, IgG (and subsets), IgE, IgD, and IgA. All immunoglobulins are made up of heavy and light chains and of constant and variable regions. It is the variable regions that determine antibody specificity (Fig. 12-4). It is the variable region that interacts with antigen, while the Fc region mediates effector functions such as complement fixation (IgM and some IgG subclasses) and phagocyte binding (via Fc receptors). Antibodies subserve several functions in acquired immunity: (1) opsonization (coating of a pathogen with antibody to enhance Fc receptor-mediated endocytosis by phagocytic cells); (2) initiation of the classic pathway of complement-mediated lysis; (3) neutralization of viral infection by binding to viral particles and preventing further infection; and (4) enhancement of the specificity of effectors of CMI by binding to specific antigens on target cells, which are then recognized and eliminated by effector cells such as NK or cytotoxic T lymphocytes (CTL).

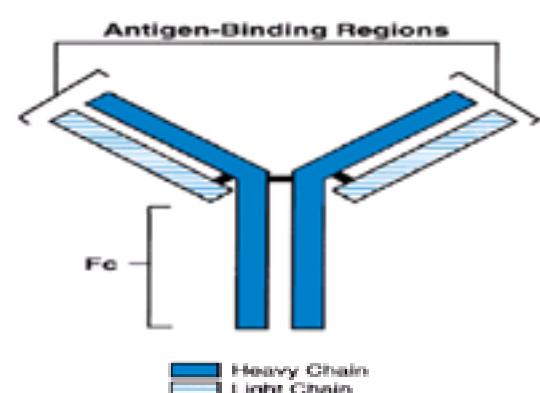
Table 12-4 Properties of Immunoglobulin Classes and Subclasses


Figure 12-4. Immunoglobulin structure.

During an immune response, the cells of the immune system must be able to communicate to coordinate all the activities that occur during the recognition and elimination of foreign antigens. Connecting all the cells of the immune system with each other as well as with other non-immune cell types within the body is a vast network of soluble mediators: the cytokines. Nearly all immune cells secrete cytokines, which may have local or systemic effects. Table 12-5 provides a brief summary of the sources and functions of cytokines of interest in the immune system. Although it would appear that many cytokines have related functions, these functions are not often identical, and a single cytokine may have multiple effects on a variety of cell types. Since cytokines work to tightly regulate immune responses, some induce

synthesis of other cytokines and inflammatory mediators, while others inhibit this process. Although the actual number of cytokines (lymphokines, monokines, chemokines, etc.) may not be altogether that large, the complexity of the network is magnified severalfold by the multitude of biological actions of each cytokine and the diversity of cells secreting each mediator.

Table 12-5 Cytokines: Sources and Functions in Immune Regulation

Cellular Components: APCs, T Cells, B Cells In order to elicit a specific immune response to a particular antigen, that antigen must be taken up and processed by accessory cells for presentation to lymphocytes. Accessory cells that perform this function are termed antigen-presenting cells (APCs) and include the macrophage, follicular dendritic cell (FDC), Langerhans dendritic cell, and B cells. A description of the macrophage is found in the section above titled "Cellular Components of Innate Immunity"; however, the macrophage also plays a critical role as an APC in acquired immunity. Unique among the APCs is the FDC. Unlike hematopoietic cells, the FDC is not derived from the bone marrow stem cell. It is found in secondary lymphoid organs and binds antigen-antibody complexes, but it does not internalize and process the antigen. Instead, the primary function of the FDC is in the persistence of antigen within the secondary lymphoid tissues and the presentation of antigen to B cells. This is believed to be critical for the maintenance of memory for B cells and the induction of high-affinity B cell clones. Although thought of more for its ability to produce immunoglobulin, the B cell can also serve as an APC, and in low antigen concentrations this cell is equally as competent as the macrophage in serving this function. The Langerhans dendritic cell is also a bone marrow–derived cell, but its lineage is distinct from that of the macrophage. It is found primarily in the epidermis, mucosal epithelium, and lymphoid tissues. The Langerhans dendritic cell can migrate into the lymphatic system, where it serves as an APC in the lymph nodes. This cell plays a primary role in contact sensitization.

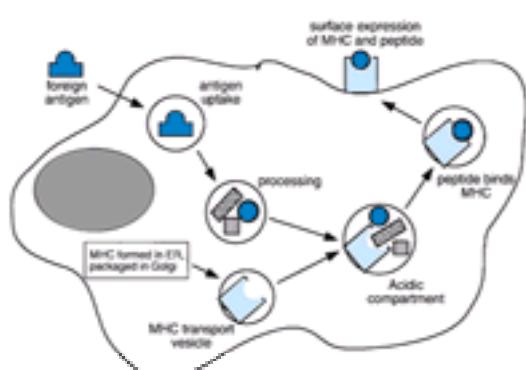
The interaction of APCs and lymphocytes is critical for the development of an immune response. With the exception of the FDC, APCs internalize the antigen either by phagocytosis, pinocytosis, or receptor-mediated endocytosis (via antigen, Fc, or complement receptors). Following internalization, antigen is processed (intracellular denaturation and catabolism) through several cytoplasmic compartments, and a piece of the antigen (peptide fragments about 20 amino acids in length) becomes physically associated with major histocompatibility complex (MHC) class II (Fig. 12-5). This MHC class II-peptide complex is then transported to the surface of the cell and can interact in a specific manner with lymphocytes. For most APCs, an immunogenic determinant is expressed on the surface of the APC within an hour after internalization, although this is slightly longer for B cells (3 to 4 h). In addition to processing and presentation, pieces of processed antigen may be expelled into the extracellular space. These pieces of processed antigen can then bind in the peptide groove of empty MHC class II on the surface of other APCs for the presentation of that peptide fragment to lymphocytes.


Figure 12-5. General schematic of antigen processing and presentation.

Not only are B lymphocytes capable of serving as APCs, but they are also the effector cells of humoral immunity, producing a number of isotypes of immunoglobulin (Ig) with varying specificities and affinities. Like other immune cells, the B cell develops in the bone marrow from the pluripotent stem cell and becomes committed to the B-cell lineage when the cell begins to rearrange its Ig genes (Fig. 12-6). If, after several attempts, the cell is unsuccessful at rearranging its Ig genes, it dies. Following Ig rearrangement, these cells express heavy chains in their cytoplasm and are termed pre-B cells. Expression of surface IgM and IgD indicates a mature B cell. Mature B cells are found in the lymph nodes, spleen, and peripheral blood. Upon antigen binding to surface Ig, the mature B cell becomes activated and, after proliferation, undergoes differentiation into either a memory B cell or an antibody-forming cell (AFC; plasma cell), actively secreting antigen-specific antibody. A broad description of several B-cell characteristics can be found in Table 12-3.

At a specified time following their commitment to the T-cell lineage, pre-T cells migrate from the bone marrow to the thymus where, in a manner analogous to their B-cell cousins, they begin to rearrange their TCRs (Fig. 12-6). This receptor consists of two chains (a and b, or g and d) and is critical for the recognition of MHC + peptide on APCs. At this time, the T cells begin to express the surface marker CD8. CD8 (and CD4) are coreceptors expressed by T cells and are involved in the interaction of the T cell with the APC. T cells bearing the g/d TCR subsequently lose expression of CD8 and proceed to the periphery. T cells with the a/bTCR gain surface expression of both the TCR and CD4 and are termed *immature double-positive cells* (CD4+/CD8+). These immature cells then undergo positive selection to eliminate cells that cannot interact with MHC. Following this interaction, TCR expression increases. Any of these T cells that interact with MHC + self peptide are then eliminated (negative selection). The double-positive cells then undergo another selection process whereby they lose expression of either CD4 or CD8 and then proceed to the periphery as mature single-positive cells (CD4 + or CD8+) with a high level of TCR expression. This rigorous selection process produces T cells that can recognize MHC + foreign peptides and eliminates autoreactive T cells. Generally, T cells that express CD8 mediate cell killing (CTL) or suppressor activity (T suppressor cells). Lymphocytes that participate in delayed hypersensitivity reaction (DHR) or that provide "B-cell help" in humoral responses (helper T cells; Th1 and Th2) express CD4 on their surface. A broad description of several T-cell characteristics can be found in Table 12-3.

Humoral and Cell-Mediated Immunity

The activation of antigen-specific T cells begins with the interaction of the T-cell receptor with MHC class II + peptide. This interaction is strengthened by the presence of co-receptors such as CD4, LFA-3, CD2, LFA-1, and ICAM-1 and involves the bilateral exchange of information, triggering a cascade of biochemical events that ultimately leads to the activation of not only the T cell but the APC as well. Although the macrophage or dendritic cell is traditionally thought of as the APC involved in humoral responses, B cells can also subserve this function. In fact, many believe that, in low antigen concentrations, the B cell serves as the primary APC because of the presence of the high-affinity Ig receptor on the surface of the B cell.

Upon activation and in the presence of IL-1 secreted by the APC, T cells begin to express high-affinity receptors for the major T-cell growth factor, IL-2. In addition, T cells begin to produce IL-2, which can act in an autocrine fashion (on IL-2 receptors on the same T cell) or paracrine fashion (IL-2 receptors on other T cells or on B cells). As T cells begin to undergo clonal expansion (proliferation), they secrete numerous lymphokines (cytokines secreted from lymphocytes; Table 12-5) which can influence (1) the strength of an immune response, (2) the down-regulation of the immune response, (3) the isotype of antibody secreted by the AFC, (4) the activation

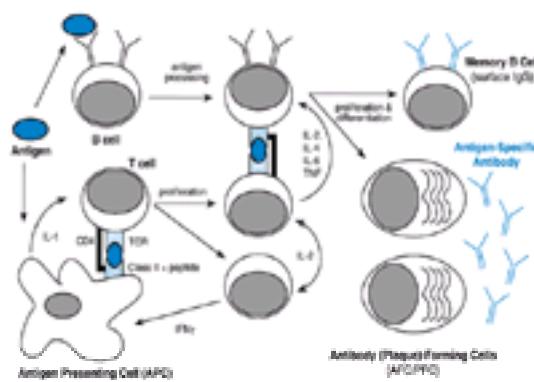
of cells involved in cell-mediated immunity, and (5) the modulation of activities of numerous immune and nonimmune cells. The next step in the generation of the humoral response is the interaction of activated T cells with B cells. This may be a direct interaction of the T cell with B cell (antigen-specific) or may simply involve the production of lymphokines (such as IL-2, IL-4, IL-6, and TNF-a and TNF-b), which lead to B-cell growth and differentiation into AFCs or memory B cells. A general diagram of the cellular interactions involved in the humoral immune response is given in Fig. 12-7. The production of antigen-specific IgM requires 3 to 5 days after the primary (initial) exposure to antigen (Fig. 12-8). Upon secondary antigen challenge, the B cells undergo isotype switching, producing primarily IgG antibody, which is of higher affinity. In addition, there is a higher serum antibody titer associated with a secondary antibody response.


Figure 12-7. Cellular interactions in the antibody response.
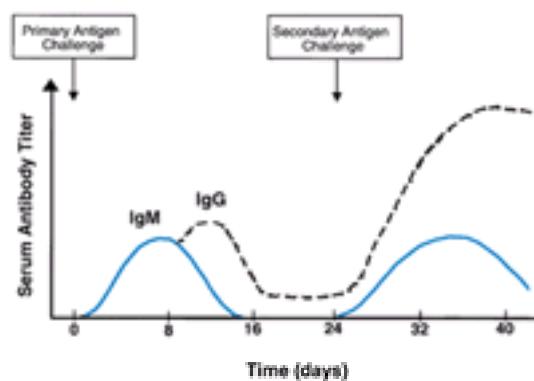

Figure 12-8. Kinetics of the antibody response.

Cell-mediated immunity (CMI), in its broadest sense, includes all immunologic activity in which antibody plays a minimal role. However, for purposes of discussion here, CMI is more specifically defined as the T-cell–mediated response such as DHR or CTL activity, antibody-dependent cellular cytotoxicity (ADCC) mediated by NK cells, and soluble factor–mediated macrophage cytotoxic responses. Whether an antigen will elicit a primarily cell-mediated or humoral response (or a combination of both) is dependent upon numerous factors. However, it should be noted that there is often an interplay between these two branches of acquired immunity. Cells are involved in the initiation of antibody responses and antibody is often an essential player in cell-mediated responses.

There are two general forms of cell-mediated immunity, referred to as delayed-type hypersensitivity and cell-mediated cytotoxicity. Delayed-type hypersensitivity is presented later in this chapter in the section titled "Immune-Mediated Disease." Cell-mediated cytotoxicity responses may occur in numerous ways: (1) MHC class I-dependent recognition of specific antigens (such as viral particles) by CTL, (2) the indirect antigen-specific recognition by the binding of antibody-coated target cells to NK cells via Fc receptors on the latter, and (3) receptor-mediated recognition of complement-coated foreign targets by macrophage. Let us consider the first two together, since their mechanisms of cytotoxicity are similar.

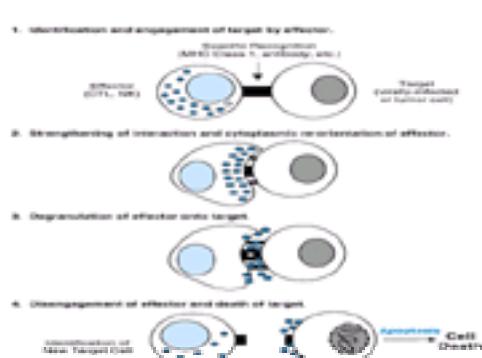
In cell-mediated cytotoxicity, the effector cell (CTL or NK) binds in a specific manner to the target cell (Fig. 12-9). The majority of CTLs express CD8 and recognize either foreign MHC class I on the surface of allogeneic cells, or antigen in association with self MHC class I (e.g., viral particles). In acquired immunity, NK recognition of target cells may be considered antigen-specific because the mechanism of recognition involves the binding of the Fc portion of antigen-specific antibody coating a target cell to the NK via its Fc receptors. Once the CTL or NK cells interact with the target cell, the effector cell undergoes cytoplasmic reorientation so that cytolytic granules are oriented along the side of the effector, which is bound to the target. The effector cell then releases the contents of these granules onto the target cell. The target cell may be damaged by the perforins or enzymatic contents of the cytolytic granules. In addition, the target is induced to undergo programmed cell death (apoptosis). Once it has degranulated, the effector cell can release the dying target and move on to kill other target cells.


Figure 12-9. Cell-mediated cytotoxicity.

Macrophages are the most promiscuous of the immune cells in that they play roles in both innate and acquired (both humoral and cell-mediated) immunity. Their role in cell-mediated cytotoxicity involves activation by T-cell–derived lymphokines (such as interferon-gamma, or IFN-g) and subsequent recognition of complement-coated target cells via complement receptors present on the surface of the macrophage. The result is enhanced phagocytic ability and the synthesis and release of hydrogen peroxide, nitric oxide, proteases, and TNF, all of which serve obvious cytolytic functions.

Neuroendocrine Immunology

There is overwhelming evidence that cytokines, neuropeptides, neurotransmitters, and hormones—as well as their receptors—are an integral and interregulated part of the central nervous system, the endocrine system, and the immune system. This blossoming area of immunology has been extensively reviewed elsewhere (Sanders, 1997; Weigent and Blalock, 1995), as has its new place in immunotoxicology (Fuchs and Sanders, 1994). Previous assumptions that the proteins secreted from these regulatory systems (nervous and endocrine) exerted unidirectional actions on the immune system have been shown to be erroneous, as the triad of influence these three systems exert over one another is bidirectional on all three sides (Fig. 12-10). Because receptors for neuropeptides, neurotransmitters, and hormones are present on lymphoid cells, it is reasonable to suspect that some chemicals may exert their immunomodulatory effects indirectly on the immune system by acting to modulate the activity of the nervous or endocrine systems. Some selected outcomes of neuroendocrine actions on immunity are described in Table 12-6.

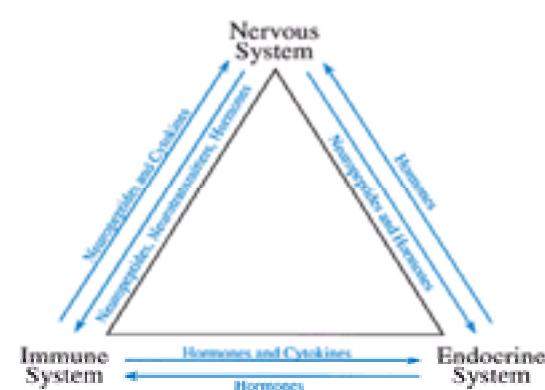
In addition, immune cells are capable of secreting and do secrete peptide hormones and neurotransmitters, which can have autocrine (immune system) and paracrine (endocrine and nervous systems) effects. Because the triad is bidirectional (and the cells of the endocrine and nervous systems possess receptors for several cytokines), the immune system can influence neuroendocrine responses. Due to the complexity of this subject, immune influence on neuroendocrine function is not considered in this chapter.


Figure 12-10. Triad of regulatory influence.

Table 12-6 Reported Influences of Neuroendocrine Factors on Immunity*

ASSESSMENT OF IMMUNOLOGIC INTEGRITY

For many years, toxicologists have been aware that xenobiotics can have significant effects on the immune system. However, it has only been in recent years that the subdiscipline of immunotoxicology has come into its own, with a battery of tests to evaluate immunocompetence. Among the unique features of the immune system is the ability of immune cells to be removed from the body and to function in vitro. This unique quality offers the toxicologist an opportunity to comprehensively evaluate the actions of xenobiotics on the immune system by providing an excellent system for dissecting the cellular, biochemical, and molecular mechanisms of action of multitudes of xenobiotics. While standard toxicologic endpoints such as organ weights, cellularity, and enumeration of cell subpopulations are important components in assessing immune injury, by far the most sensitive indicators of immunotoxicity are the tests that challenge the various immune cells to respond functionally to exogenous stimuli (reviewed in White, 1992). This section focuses on selected in vivo and in vitro tests currently used for evaluating immunotoxicity.

Methods to Assess Immunocompetence

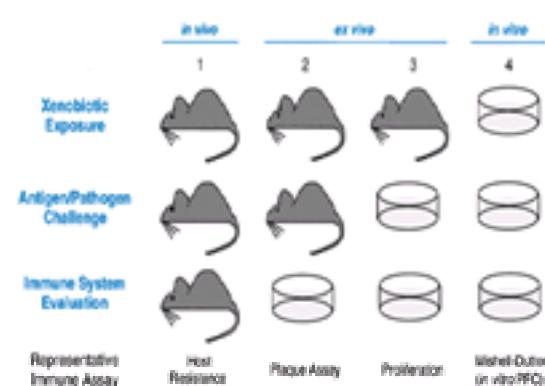
General Assessment Central to any series of studies evaluating immunocompetence is the inclusion of standard toxicologic studies, because any immunologic findings should be interpreted in conjunction with effects observed on other target organs. Standard toxicologic studies that are usually evaluated include body and selected organ weights, general observations of overall animal health, selected serum chemistries, hematologic parameters, and status of the bone marrow (ability to generate specific colony-forming units). In addition, histopathology of lymphoid organs—such as the spleen, thymus, and lymph nodes—may provide insight into potential immunotoxicants. Because of the unique nature of the immune system, there are several experimental approaches that may be taken to assess immunotoxicity and to evaluate the mechanisms of action of xenobiotics. These are depicted in Fig. 12-11 and vary with respect to in vivo or in vitro exposure, immunologic challenge, or immunologic evaluation (immune assay). As an example, the plaque-forming cell assay [Fig. 12-11 (2)] is an ex vivo assay where xenobiotic exposure and antigen challenge occur in vivo and the immune response is evaluated in vitro. In contrast [as depicted in Fig. 12-11 (4)], splenocytes can be removed from a naive animal, exposed to xenobiotic and antigen in vitro, and evaluated in vitro. An example of this would be the in vitro–generated PFC response (Mishell-Dutton assay; Mishell and Dutton, 1967).


Figure 12-11. Approaches to assessing the immunotoxicity of xenobiotics.

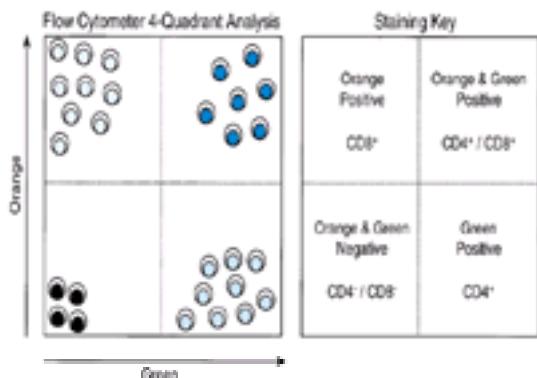
Using fluorescently labeled monoclonal antibodies to cell surface markers (Table 12-3) in conjunction with a flow cytometer, it is now possible to accurately enumerate lymphocyte subsets. Antibodies are available to the T-cell surface markers CD4, CD8, and CD3 (among others). Dual colored fluorochromes allow cells to be stained for two markers simultaneously. In this manner, the number of CD4$^+$ and CD8$^+$ cells can be determined simultaneously on a single sample of cells. In the thymus, this dual staining also helps determine the number of CD4$^+$/CD8$^+$ (double positive) and CD4$^-$/CD8$^-$ (double negative) cells residing in this organ (Fig. 12-12). This gives the researcher insight into which specific T-cell subsets are targeted and whether the xenobiotic may affect T-cell maturation. Antibodies available to surface immunoglobulin (Ig) and to B220 (the CD45 phosphatase on B cells) help determine the numbers of B cells. Surface markers can reveal significant alterations in lymphocyte subpopulations, and in many instances this is indicative of alterations in immunologic integrity. Indeed, an indicator of AIDS is the changes observed in CD4$^+$ T-cell numbers. Luster and coworkers (1992) have reported that, in conjunction with two or three functional tests, the enumeration of lymphocyte subsets can greatly enhance the detection of immunotoxic chemicals. However, it is important to keep in mind that although surface marker analysis can indicate shifts in lymphocyte populations, functional analysis of the immune system offers greater sensitivity for the detection of immunotoxicity.


Figure 12-12. Flow cytometry.

In this example, cells from the thymus are stained simultaneously with a fluorescent PE-conjugated (orange) antibody to CD8 and a fluorescent FITC-conjugated (green) antibody. When analyzed on a flow cytometer, the instrument is requested to display a four-quadrant analysis (*left*). Increasing fluorescent intensity (brightness) is indicated by the arrows on each axis. The key to this analysis is displayed on the right. Cells which possess only CD8 fluoresce orange (CD8 $^+$) and are displayed in the upper left quadrant (*light blue*). Cells that possess only CD4 fluoresce green (CD4 $^+$) and are displayed in the lower right quadrant (*medium blue*). Cells that possess both CD8 and CD4 fluoresce both orange and green (CD4 $^+$/CD8 $^+$; double positives) and are displayed in the upper right *quadrant* (*dark blue*). Cells that do not possess either CD8 or CD4 do not fluoresce (CD4 $^-$/CD8 $^-$; double negatives) and are displayed in the lower left quadrant (*black*). The instrument can then be requested to determine the percentage of cells in each quadrant. In a typical mouse thymus, there are approximately 8 to 13 percent CD4 $^+$, 2 to 5 percent CD8 $^+$, 80- to 85 percent CD4 $^+$/CD8 $^+$, and 2 to 5 percent CD4 $^-$/CD8 $^-$ cells.

Flow cytometry can be useful in immunotoxicology as a tool to assess mechanism of action beyond evaluation of surface markers. These include evaluation of the effects of chemicals in the cell cycle, intracellular free calcium, cellular viability assessment, induction of apoptosis, evaluation of p53, DNA strand breaks (TUNEL assay), membrane potential, intracellular pH, oxidative stress, and membrane lipophilicity (reviewed in Burchiel et al., 1997 and 1999). Flow cytometry has applications in cell sorting and high throughput screening, and there is interest in the utility of this tool in the refinement of certain cellular immune and hypersensitivity assays. A key to acceptance of flow cytometric methods for immunotoxicity assessment is assay validation. This concept is supported by one of the conclusions of a workshop focusing on the application of flow cytometry in immunotoxicity assessments. The workshop concluded that while immunophenotyping certainly has a place in the field of immunotoxicology (e.g., used in conjunction with functional tests to identify immunotoxic chemicals; as a method to assess mechanism of action), more research is needed in both the human and the animal before immunophenotyping alone is sufficiently validated for use in predicting chemical-induced effects on human health (ILSI, 1999).

Functional Assessment *Innate Immunity* As described earlier, innate immunity encompasses all those immunologic responses that do not require prior exposure to an antigen and that are nonspecific in nature. These responses include recognition of tumor cells by NK cells, phagocytosis of pathogens by macrophages, and the lytic activity of the components of the complement cascade.

To evaluate phagocytic activity, macrophages are harvested from the peritoneal cavity [peritoneal exudate (PE) cells] and are allowed to adhere in 24-well tissue culture plates. The cells are then incubated with chromated chicken red blood cells (^{51}Cr-cRBCs). Following incubation, the supernatant, containing ^{51}Cr-cRBCs that have not been bound by macrophages, is removed. The cRBCs which are bound to the macrophages, but which have not been phagocytized, are removed by a brief incubation with ammonium chloride. Finally, macrophages are lysed with NaOH and radioactivity in the lysate is counted to determine the amount of phagocytosis that occurred. A set of control wells is needed to determine DNA content for each set of wells. Data are presented as a specific activity for adherence and phagocytosis (adhered or phagocytized cpm/DNA content) since xenobiotics altering adherence will have a significant effect on the results.

Another method to evaluate phagocytosis, but which does not require radioactivity, begins similarly to the ^{51}Cr-cRBC assay. Peritoneal macrophages are allowed to adhere to each chamber of a tissue culture slide. After adherence, macrophages are washed and incubated with latex covaspheres. At the end of incubation, cells are fixed in methanol and stained in methylene chloride. Macrophages containing five covaspheres or more are counted as positive and data are expressed as a percentage of phagocytosis (the ratio of macrophages with ³5 covaspheres to total macrophages counted).

The previous macrophage assays are conducted in vitro after chemical exposure either in vivo or in vitro. If an in vivo assay of the ability of tissue macrophages to phagocytose a foreign antigen is required, the functional activity of the reticuloendothelial system can be evaluated. Intravenously injected radiolabeled sheep red blood cells (^{51}Cr-sRBCs) are removed by the tissue macrophage from the circulation and sequestered for degradation in organs such as the liver, spleen, lymph nodes, lung, and thymus. Clearance of the ^{51}Cr-sRBCs is monitored by sampling of the peripheral blood. When steady state has been attained, animals are euthanized and organs are removed and counted in a gamma counter to assess uptake of the ^{51}Cr-sRBCs.

Evaluation of the ability of NK cells to lyse tumor cells is achieved using the YAC-1 cell line as a tumor target for an in vitro cytotoxicity assay. YAC-1 cells are radiolabeled with ^{51}Cr and incubated (in 96-well microtiter plates) in specific effector-to-target ratios with splenocytes from xenobiotic-exposed and nonexposed animals. During an incubation step, splenic NK cells (effectors) lyse the ^{51}Cr-YAC-1 cells, releasing ^{51}Cr into the supernatant. At the end of the incubation, plates are centrifuged and the supernatant is removed and counted on a gamma counter. After correcting for spontaneous release (which should be <10 percent), specific release of ^{51}Cr is calculated for each effector-to-target ratio and compared to the specific release from control animals.

Acquired Immunity—Humoral The plaque-(antibody)forming cell (PFC or AFC) assay is a sensitive indicator of immunologic integrity for several reasons. It is a test of the ability of the host to mount an antibody response to a specific antigen. When the particulate T-dependent antigen (an antigen that requires T cells to help B cells make antibody) sheep erythrocytes (sRBCs) is used, this response requires the coordinated interaction of several different immune cells: macrophages, T cells, and B cells. Therefore, an effect on any of these cells (e.g., antigen processing and pre-sentation, cytokine production, proliferation, or differentiation) can have a profound impact on the ability of B cells to produce antigen-specific antibody. Other antigens, termed T cell-independent antigens, such as DNP-Ficoll or TNP-LPS (lipopolysaccharide), can be used that bypass the requirement for T cells in eliciting antibody production by B cells.

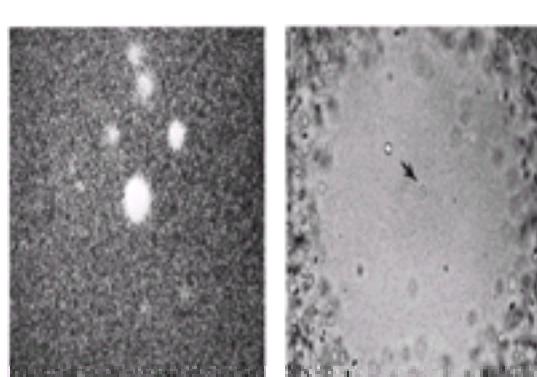
A standard PFC assay involves immunizing control and xenobiotic-exposed mice either intravenously or intraperitoneally with the sRBC. The antigen is taken up in the spleen and an antibody response occurs. Four days after immunization, spleens are removed and splenocytes are mixed with sRBC, complement, and agar. This mixture is plated onto petri dishes and covered with a cover slip. After the agar hardens the plates are incubated for 3 h at 37°C. During this time, B cells secrete anti-sRBC IgM antibody. When the IgM and complement coat the surrounding sRBCs, areas of hemolysis (plaques) appear which can be enumerated (Fig. 12-13). At the center of each plaque is a single B cell (antibody- or plaque-forming cell; AFC or PFC). Data are usually presented as IgM PFC (or AFC) per million splenocytes. IgG PFC can also be enumerated by slight modifications of this same assay. This isotype switching (from IgM to IgG) is important in secondary responses in which memory B cells respond more quickly to an antigen.


Figure 12-13. The plaque-forming cell (PFC) assay.

A. Demonstration of plaques (areas of hemolysis) that have formed within the lawn of sheep red blood cells, 310 magnification. *B.* 3100 magnification of a plaque from panel *A* showing the B cell evident in the center of the plaque. (From photos by Dr. Tracey L. Spriggs, with permission.)

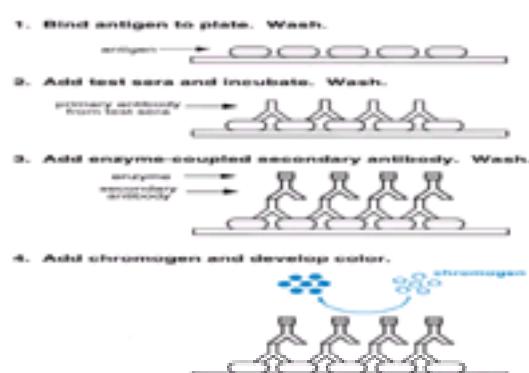
More recently, it has become evident that the PFC assay can be evaluated in vivo using serum from peripheral blood of immunized mice and an enzyme-linked immunosorbent assay (ELISA; Fig. 12-14). Although the optimal response is delayed by 1 to 2 days (compared to the PFC assay), this assay takes into account antigen-specific antibody secreted by B cells in the spleen as well as B cells residing in the bone marrow. Like the PFC assay, mice (or other experimental animals) are immunized with sRBCs and 6 days later peripheral blood is collected. Serum from each sample is serially diluted and incubated in microtiter plates that have been coated with sRBC membranes. The membranes serve as the antigen to which sRBC-specific IgM or IgG will bind. After incubation of the test sera and a wash step, an enzyme-conjugated monoclonal antibody (the secondary antibody) against IgM (or IgG) is added. This antibody recognizes the IgM (or IgG) and binds specifically to that antibody. After incubation and a wash step, the enzyme substrate (chromogen) is added. When the substrate comes into contact with the enzyme on the secondary antibody, a color change occurs which can be detected by measuring absorbance with a plate reader. Since this is a kinetic assay (color develops over time and is dependent upon concentration of anti-sRBC antibody in the test sera), it is important to establish control concentration–response curves so that data can be evaluated in the linear range of the curve. Data are usually expressed in arbitrary optical density (OD) units. Advantages of the ELISA over the PFC assay are the ability to conduct in vivo analyses and to attain a greater degree of flexibility, since serum samples can be stored frozen for analysis at a later date.


Figure 12-14. Schematic diagram of a standard enzyme-linked immunosorbent assay (ELISA).

One final assay measures the ability of B cells to undergo blastogenesis and proliferation, which are critical steps in the generation of an antibody response. This is achieved in micro-titer plates by stimulating splenocytes with a monoclonal anti-body to surface Ig (anti-Ig) in the presence of IL-4, or with the B-cell mitogen LPS. Proliferation is evaluated 2 to 3 days after stimulation by measuring uptake of ^{3}H-thymidine into the DNA of the cultured cells. Data are usually expressed as mean counts per minute for each treatment group. These studies are usually done in conjunction with T-cell proliferative responses described below.

Humoral Immunity—Cell-Mediated While there are numerous assays used to assess cell-mediated immunity, three primary tests are used routinely in the National Toxicology Program (NTP) test battery: the cytotoxic T-lymphocyte (CTL) assay, the delayed hypersensitivity response (DHR), and the T-cell proliferative responses to antigens (anti-CD3 + IL-2), mitogens (PHA and Con A), and allogeneic cell antigens (mixed lymphocyte responses; MLR).

The CTL assay measures the in vitro ability of splenic T cells to recognize allogeneic target cells by evaluating the ability of the CTLs to proliferate and then lyse the target cells. Splenocytes are incubated with P815 mastocytoma cells, which serve as target cells. These target cells are pretreated with mitomycin C so that they cannot proliferate themselves. During this sensitization phase, the CTLs recognize the targets and undergo proliferation. Five days after sensitization, the CTLs are harvested and incubated in microtiter plates with radiolabeled (^{51}Cr) P815 mastocytoma cells. During this elicitation phase, the CTLs that have acquired memory recognize the foreign MHC class I on the P815 cells and lyse the targets. At the end of the incubation, plates are centrifuged, the supernatant is removed, and radioactivity released into the supernatant is counted on a gamma counter. After correcting for spontaneous release, the percent cytotoxicity is calculated for each effector-to-target ratio and compared to that from control animals.

The DHR evaluates the ability of memory T cells to recognize foreign antigen, proliferate and migrate to the site of the antigen, and secrete cytokines which result in the influx of other inflammatory cells. Like the PFC response, this assay is conducted completely in vivo. The assay itself quantitates the influx of radiolabeled monocytes into the sensitization site. During xenobiotic exposure, mice are sensitized twice with keyhole limpet hemocyanin (KLH) subcutaneously between the shoulders. On the last day of exposure, mononuclear cells are labeled in vivo with an IV injection of ^{125}I-5-iododeoxyuridine (IUdR). One day later, mice are challenged intradermally in one ear with KLH. Twenty-four hours after challenge, animals are euthanized, the ears are biopsied, and radiolabeled cells are counted in a gamma counter. Data are expressed as a stimulation index which represents the cpm in the challenged ear divided by the cpm in the unchallenged ear.

T cells play a central role in cell-mediated immunity and the ability of T cells to undergo blastogenesis and proliferation is critical to this role. Several mechanisms exist to evaluate proliferative capacity. The mixed lymphocyte response (MLR) measures the ability of T cells to recognize foreign MHC class I on splenocytes from an MHC-incompatible mouse (allogeneic cells) and undergo proliferation. For example, splenocytes from B6C3F1 mice (responders) are incubated with splenocytes from mitomycin C-treated DBA/2 mice (stimulators). Proliferation is evaluated 4 to 5 days after stimulation by measuring uptake of ^{3}H-thymidine into the DNA of the cultured responder cells. Cells are collected from each well using a cell harvester and counted in a scintillation counter. Data may be expressed as either the mean cpm for each treatment group or as a stimulation index where the index is calculated by dividing the cpm of wells containing responders and stimulators by the cpm of wells containing responders alone.

General T cell proliferation can be evaluated in a manner similar to that described above for B cells (Table 12-3). Splenocytes are stimulated in microtiter plates with a monoclonal antibody to the CD3 complex of the T-cell receptor (anti-CD3) in the presence of IL-2, or with the T-cell mitogens concanavalin A (Con A) and phytohemagglutinin (PHA). Proliferation is evaluated 2 to 3 days after stimulation by measuring uptake of ^{3}H-thymidine into the DNA of the cultured T cells. Data are usually expressed as mean cpm for each treatment group. These studies are usually done in conjunction with B-cell proliferative responses described above.

Host Resistance Assays Host resistance assays represent a way of assaying how xenobiotic exposure affects the ability of the host to handle infection by a variety of pathogens. Although host resistance studies provide significant insight into the mechanisms by which an immunotoxicant is acting, these assays should not be a first or only choice for evaluating immunocompetence. An example of why this is true is the actions of the semiconductor material gallium arsenide (GaAs) on the immune system. Although GaAs produces profound immunosuppression of nearly all cell types evaluated, this compound was observed to confer varying degrees of protection to challenge with *Listeria monocytogenes* and *Streptococcus pneumoniae*. It was subsequently determined that the circulating blood arsenic concentrations were sufficient to inhibit growth of both of these organisms. In host resistance studies, it is also important to consider the following: (1) strain, route of administration, and challenge size of the pathogen; (2) strain, age, and sex of the host; (3) physiologic state of the host and the pathogen; and (4) time of challenge with the pathogen (prior to, during, or after xenobiotic exposure). All of these can have significant effects on the results from any individual study.

As with other immune function tests, no single host resistance model can predict overall immunocompetence of the host, primarily because each model uses different mechanisms for elimination of various pathogens. A representative list of host resistance models is shown in Table 12-7 as well as some of the cells involved in the immune response to these pathogens. Typically, three challenge levels of pathogen (approximating the LD$_{20}$, LD$_{50}$, and LD$_{80}$) for each concentration of xenobiotic are used in order to be able to detect both increases and decreases in resistance. Endpoint analyses are lethality (for bacterial and viral pathogens), changes in tumor burden, and increased or decreased parasitemia.

Table 12-7 Models of Host Resistance

Regulatory Approaches to the Assessment of Immunotoxicity

The NTP Tier Approach Luster and colleagues (1988) have described the selection of a battery of tests used by the National Toxicology Program to screen for potential immunotoxic agents. The result was a tier approach to assessing immunotoxicity and is summarized in Table 12-8. Tier I provides assessment of general toxicity (immunopathology, hematology, body and organ weights) as well as endline functional assays (proliferative responses, PFC assay, and NK assay). It was designed to detect potential immunotoxic compounds at concentrations that do not produce overt toxicity. Tier II was designed to further define an immunotoxic effect and includes tests for cell-mediated immunity (CTL and DHR), secondary antibody responses, enumeration of lymphocyte populations, and host resistance models. Subsequently, several testing configurations were defined that would minimize the number of immune tests needed, yet still provide a high degree of sensitivity for detecting potential immunotoxicants. These configurations are depicted in Table 12-9. The FDA has adopted a tier approach in its assessment of the immunotoxicity of food and color additives (*Redbook I*).

Table 12-8 Tier Approach for Immunotoxicology Testing

PFC	DHR	Surface markers
PFC	NK	DHR
PFC	NK	Thymus:body weight
PFC	DHR	Thymus:body weight
Surface markers	NK	DHR
Surface markers	DHR	T-cell mitogens
Surface markers	DHR	Thymus:body weight
Surface markers	DHR	LPS response

Table 12-9 Suggested Testing Configurations: Three Tests with 100 percent Concordance

Health Effects Test Guidelines After several years of international debate regarding inclusion of functional immunotoxicity assessments in regulatory studies (as opposed to relying on histopathology as an indicator of further testing needs), the Environmental Protection Agency published health effects test guidelines for immunotoxicity testing: TSCA 799.9780 (1997) and OPPTS 870.7800 (1998). These guidelines flow from the configurations depicted in Table 12-8, although conduct of 3 tests is not required by law. Assessment of immunotoxicity begins by exposure for a minimum of 28 days to the chemical followed by assessment of humoral immunity (PFC assay or anti-sRBC ELISA). If the chemical produces significant suppression of the humoral response, surface marker assessment by flow cytometry may be performed. If the chemical produces no suppression of the humoral response, an assessment of innate immunity (NK assay) may be performed. The tests do not represent a comprehensive assessment of immune function but are intended to complement assessment made in routine toxicity testing (hematological assessments, lymphoid organ weights, and histopathology). A phagocytosis assay on pulmonary macrophages obtained by broncheoalveolar lavage was included in TSCA 799.9135 (acute inhalation toxicity with histopathology) to address potential immunological changes in the lung associated with hazardous air pollutants. Although additional tests are not required, these guidelines should be viewed as just that–"guidelines," with both sound science and responsible management of chemicals being the larger guide to determining whether additional tests are needed. These documents are available on the EPA OPPTS Internet web site. In Europe, the OECD has not as yet adopted specific guidelines for immunotoxicity assessment. Instead, functional assessments are included in standard toxicology studies when desired or when suggested by expanded histopathological results on other standard toxicology studies.

Immunotoxicity Testing of Medical Devices Concern over the influence of medical devices on the immune system has grown over the past 10 years (reviewed in Rodgers et al., 1997). Many of these devices may have intimate and prolonged contact with the body. Possible immunologic consequences of this contact could be envisioned to include immunosuppression, immune stimulation, inflammation, and sensitization. In 1999, the Office for Device Evaluation in the Center for Devices and Radiological Health (CDRH) published a guidance document (Immunotoxicity Testing Guidance) to provide FDA reviewers and device manufacturers a systematic approach for evaluating potential adverse immunological effects of medical devices and constituent materials. Because of the complexity of the guidance, the reader is referred to the document itself, which may be located on the FDA CDRH Internet web site.

Animal Models in Immunotoxicology

The mouse has been the animal of choice for studying the actions of xenobiotics on the immune system for several reasons: (1) because there is a vast database available on the immune system of the mouse, (2) mice are less expensive to maintain than larger animals, and (3) a wider variety of reagents (cytokines, antibodies, etc.) are available for the mouse (Vos et al., 1994). Because of the need in the industrial setting to integrate immunotoxicologic assessments with routine toxicology testing, a worldwide effort has been under way to validate the rat as a model for immunotoxicology testing. With the exception of a few functional studies, the rat provides a near equal model to the mouse for assessing immunocompetence. Many reagents that are available for studying the human immune system can also be used in rhesus and cynomolgus monkeys.

Other experimental animals including the chicken and fish are being used to evaluate the immunotoxicity of xenobiotics (reviewed in IPCS, 1996). Development of

these animal models and the refinement in methods used to assess immunomodulation in these species is anticipated to grow as pressure continues to build regarding alternative animal models and environmental consciousness, and as the consumer market for poultry and farm-raised fish continues to expand. An understanding of the chicken immune system is well established. Because of the ease in handling the developing embryo, chickens may serve to aid the advancement of the field of developmental immunotoxicology.

There has been significant interest in the teleost immune system over the past 15 years, and equivalents of T, B, NK, and accessory cells have been identified. Fish B cells possess many biochemical and molecular qualities of their mammalian counterparts, and recently T-cell receptor alpha and beta genes have been characterized (reviewed in Miller et al., 1998). The immune systems of several species of fish have been reported to be sensitive to environmental stressors, including chemicals, which produce immunomodulation in mammalian species (reviewed in Zelikoff, 1994; Bly et al., 1997). As a result, teleosts may serve as early indicators of environmental exposure to immunotoxicants (Zelikoff, 1998; Zelikoff et al., 2000). Whether or not fish will eventually have efficacy as models in immunotoxicology risk assessment for the human population remains uncertain, and more effort will be required before the teleost models are at the current level of the rodent (reviewed in Gogal et al., 1999).

Relationship between Immunotoxicity Data in Animals and Humans

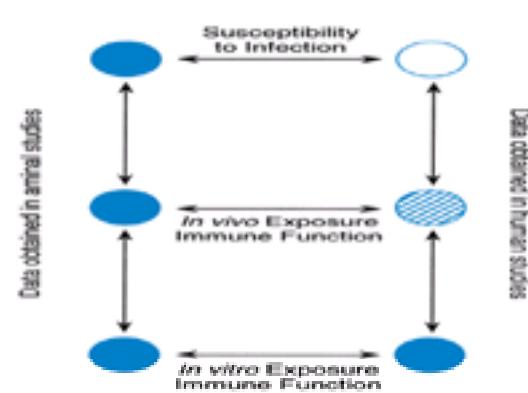
There is a clear association between suppression of immune function and an increased incidence of infectious and neoplastic disease in humans (reviewed in Biagini, 1998). Chemicals that produce immunotoxicity in animals have the potential to produce immune effects in the human population, and these effects may occur in the absence of observable disease (reviewed in Luster et al., 1994). While it would appear relatively straightforward, "the assessment [epidemiologically] of immunotoxicity in humans exposed to potentially immunotoxic chemicals is much more complicated than in experimental animals" (reviewed in IPCS, 1996). Because of this, there is a need and desire to extrapolate from animal data to human health effects. A parallelogram approach has been used to assess relationships between animal data and human data (Fig. 12-15; Selgrade et al., 1999; Van Loveren et al. 1995). In this approach, filled circles represent data which can be readily obtained in vivo or in vitro. Unfilled circles represent data which cannot be obtained experimentally. Data that may occasionally be obtained but must sometimes be extrapolated are represented by circles filled with blue lines. This approach has been used to extrapolate animal to human data in an initial quantitative assessment of risk for deleterious effects of UV radiation (Van Loveren et al. 1995). A dual parallelogram approach has also been used to propose that data for ozone suggest that effects of in vivo human exposure to phosgene on alveolar macrophage phagocytosis may be predicted based on effects of in vitro exposure and in vivo animal data (reviewed in Selgrade et al., 1995).


Figure 12-15. Parallelogram approach in immunotoxicology for relating animal data to human data. [Modified from Selgrade (1999), with permission.]

Evaluation of Mechanisms of Action

When we think of the ways chemicals can act on various organ systems we most often think of the direct effects of chemical exposure. Direct effects on the immune system may include chemical effects on immune function, structural alterations in lymphoid organs or on immune cell surfaces, or compositional changes in lymphoid organs or in serum (Table 12-10). Xenobiotics may exert an indirect action on the immune system as well. They may be metabolically activated to their toxic metabolites, may also have effects on other organ systems (e.g., liver damage) which then impacts the immune system, or may induce alterations in hormonal homeostasis.

Table 12-10 Possible Mechanisms of Chemically Induced Immune Modulation

As mentioned previously, a unique quality of the immune system is the ability to remove immune cells and have them function in vitro. This is particularly important in investigating the mechanisms of action of xenobiotics. For example, it can be determined whether a compound acts either directly or indirectly on immune cells by comparing in vivo to in vitro chemical exposure (refer to Fig. 12-11). Immunotoxic compounds that act indirectly will have no effect on an in vitro—generated immune response. Compounds that require metabolism to reactive metabolites will also have no effect on in vitro—generated immune responses following in vitro exposure. However, this metabolic requirement can be mimicked in vitro by incubating the chemical with a microsomal S9 preparation prior to in vitro exposure of splenocytes. The metabolically activated compound may then be capable of suppressing in vitro—generated immune responses.

Numerous methodologies are available to evaluate cellular and molecular mechanisms of action. Xenobiotic-induced effects on specific cell types of the antibody response can be determined using antigens that require several cell types, such as macrophage, T, and B cells (sRBC), macrophages, and B cells only (DNP-Ficoll), or B cells alone (LPS) for the production of antigen-specific antibody. In addition, splenocytes can be separated into the various cell populations such as adherent cells (primarily macrophages) and nonadherent cells (T and B cells), that can be individually exposed and then reconstituted in cell culture to yield an in vitro—generated immune response equal to that of unseparated cells. This separation/reconstitution analysis is an excellent way to determine specific cell targets of xenobiotic action. In addition, supernatants from in vitro—generated antibody responses can be transferred among themselves in an effort to assess xenobiotic action on soluble factors such as the cytokines, and ELISA methodology and quantitative PCR can be used to quantitate in vitro cytokine production and cytokine gene transcription, respectively, in response to various stimuli. Much of the progress in immunotoxicology research has been the result of the application of advances made in immunology and molecular biology and it is expected that this will continue as these areas of basic science progress by leaps and bounds.

IMMUNOMODULATION BY XENOBIOTICS

Immunosuppression

Halogenated Aromatic Hydrocarbons Few classes of xenobiotics have been as extensively studied for immunotoxicity as the halogenated aromatic hydrocarbons

(HAHs; reviewed by Kerkvliet and Burleson, 1994, and Holsapple, 1996). The prototypical and most biologically potent member of this family of chemicals, which includes the polychlorinated biphenyls (PCBs), the polybrominated biphenyls (PBBs), the polychlorinated dibenzofurans (PCDFs), and the polychlorinated dibenzodioxins (PCDDs), is 2,3,7,8-tetrachlorodibenzo- *p*-dioxin (TCDD; dioxin). Substantial evidence has accumulated that demonstrates the immune system to be a target for toxicity for these chemicals. Derived from a variety of animal models, primarily rodents, this evidence includes thymic atrophy, pancytopenia, cachexia, immunosuppression, and tumor promotion. There is also epidemiological evidence suggesting immunotoxicity by the HAHs can also occur in humans; however, significant immunosuppression has not been associated conclusively with specific alterations of human immune function.

Quite possibly the most important advance in recent years in the study of the HAHs has been the determination of a genetic basis for sensitivity to the toxic effects of this family of chemicals. Many of the biochemical and toxic effects of the HAHs appear to be mediated via HAH binding to an intracellular heterodimeric complex between the aryl hydrocarbon receptor (*Ah*-R) and the aromatic receptor nuclear transporter (ARNT; Hoffman et al., 1991). The *Ah*-R–ARNT complex translocates to the nucleus, binds to dioxin-responsive elements (DREs), and directs transcriptional activation (e.g., CYP1A1, PAI-2, *fos/jun*) and mRNA stabilization (e.g., TGFa, IL-1b) (Sutter et al., 1991; Sutter and Greenlee, 1992). In mice, allelic variation at the *Ah* locus has been described. These alleles code for *Ah*-Rs with differential binding affinities for TCDD. For example, the C57Bl/6 mouse represents a strain of mice (*Ah^{bt}*) which is exquisitely sensitive to TCDD (*TCDD responsive*), while the DBA/2 strain of mice (*Ah^{dc}*) is much less sensitive to the toxic effects of TCDD (*TCDD nonresponsive* or *TCDD low-responsive*). These allelic differences may ultimately explain the controversial differences in observed toxic responses between animal species and even between individual tissues within the same species.

Polychlorinated Biphenyls PCBs have seen extensive commercial use for over half a century. Their unique physical and chemical properties make PCB mixtures ideal for use as plasticizers, adhesives, and as dielectric fluids in capacitors and transformers. Mixtures of PCBs (e.g., Aroclors) have been commonly used to evaluate the immunotoxicity of PCBs and have been reported to suppress immune responses and decrease host resistance (reviewed by Kerkvliet, 1984). The first indication that PCBs produced immunotoxic effects was the observation of severe atrophy of the primary and secondary lymphoid organs in general toxicity tests and the subsequent demonstration of the reduction in numbers of circulating lymphocytes. Studies to characterize the immunotoxic action of the PCBs have primarily focused on the antibody response. This parameter is by far the one most consistently affected by PCB exposure and effects on antibody response have been demonstrated in guinea pigs, rabbits, mice, and rhesus monkeys. PCB-exposed monkeys exhibit chloracne, alopecia, and facial edema, all classical symptoms of HAH toxicity. In an extensive characterization of the effects of PCBs on nonhuman primates, Tryphonas and colleagues (1991a),(1991b) exposed rhesus monkeys to Aroclor 1254 for 23 to 55 months. The only immune parameter consistently suppressed was the PFC response to sRBC (both IgM and IgG). In addition, after 55 months of exposure, lymphoproliferative responses were dose-dependently suppressed and serum complement levels were significantly elevated. The observed elevation in serum complement has also been reported in PCDD-exposed children from Seveso, Italy (Tognoni and Bonaccorsi, 1982) and in B6C3F1-exposed mice (White et al., 1986).

The effects of PCBs on cell-mediated immunity (CMI) are far less clear and both suppression and enhancement have been reported. Exposure to Aroclor 1260 has been demonstrated to suppress delayed-type hypersensitivity (DTH) responses in guinea pigs, whereas exposure to Aroclor 1254 was reported to enhance lymphoproliferative responses in rats. In a similar study in Fischer 344 rats (Aroclor 1254), thymic weight was decreased, NK cell activity was suppressed, PHA-induced proliferative responses were enhanced, and there was no effect on the MLR proliferative response or CTL activity. Other investigators (Silkworth and Loose, 1978, 1979) have reported enhancement of graft–versus host reactivity and the MLR proliferative response. The augmentation of selected CMI assays may reflect a PCB-induced change in T cell subsets (as described above) and thus in immunoregula-tion.

Studies on host resistance following exposure to PCBs indicate that the host defenses against hepatitis virus (ducks) and to herpes simplex virus, *Plasmodium berghei, L. monocytogenes,* and *Salmonella typhimurium* (mice) are suppressed (reviewed by Dean et al., 1985). PCB-induced changes in tumor defenses have not been well defined and both augmentation and suppression have been reported. This probably reflects the variability in observed responses in CMI.

Polybrominated Biphenyls The polybrominated biphenyls (PBBs) have been used primarily as flame retardants (Firemaster BP-6 and FF-1). While it is assumed that their profile of activity is similar to that of the PCBs, few studies have actually evaluated the action of the PBBs on immunocompetence. In Michigan (in 1973) Firemaster BP-6 was inadvertently substituted for a nutrient additive in cattle feed, resulting in widespread exposure of animals and humans to PBBs. Studies conducted on livestock following the incident indicated little if any PBB-induced alterations in immunocompetence (Kately and Bazzell, 1978; Vos and Luster, 1989). Like CMI observations involving PCBs, CMI responses in PBB-exposed individuals are not conclusive, showing both a reduction in circulating numbers of T and B cells and a suppression of selected CMI parameters or no effect on CMI at all.

Polychlorinated Dibenzodioxins By far the majority of the investigations into the immunotoxic potential and mechanisms of action of the HAHs have focused on TCDD, primarily because this chemical is the most potent of the HAHs, binding the Ah-R with the highest affinity. The effects of TCDD on immune function have been demonstrated to be among the earliest and most sensitive indicators of TCDD-induced toxicity (reviewed by Holsapple et al., 1991a,1991b). TCDD is not produced commercially, except in small amounts for research purposes. Rather, it is an environmental contaminant formed primarily as a by-product of the manufacturing process that uses chlorinated phenols or during the combustion of chlorinated materials. It is usually associated with the production of herbicides such as 2,4,5-trichlorophenoxyacetic acid (2,4,5-T), and Agent Orange [a 1:1 combination of 2,4-dichlorophenoxyacetic acid (2,4-D) and 2,4,5-T]. Other sources include pulp and paper manufacturing (chlorine bleaching), automobile exhaust (leaded gasoline), combustion of municipal and industrial waste, and the production of PCBs.

Like other HAHs, exposure to TCDD results in severe lymphoid atrophy. Because thymus-derived cells play an integral role in tumor surveillance and host resistance, the earliest studies on TCDD-induced immunotoxicity focused on changes in cell-mediated immunity. Studies on CMI have shown that this branch of acquired immunity is sensitive to the toxic effects of TCDD. CTL development and activity has been shown by numerous investigators to be significantly decreased after exposure to TCDD, an effect which appeared to be age dependent (e.g., the younger the mice when exposed, the greater the sensitivity to TCDD). In addition to suppression of CTL function, TCDD exposure also results in decreases in PHA- and Con A–induced proliferative responses, DHR, and graft-versus-host responses. Enhanced proliferative responses in juvenile mice have also been observed (Lundberg et al., 1990).

Consistent with the observation that mice exposed perinatally or postnatally (developmentally younger animals) are more sensitive to the effects of TCDD, it has recently been determined that thymic involution is a result of TCDD-induced terminal differentiation of the thymic epithelium and, thus, T cells do not have a proper nutrient-filled microenvironment in which to develop (Greenlee et al., 1984, 1985). This conclusion is supported by previous observations that TCDD significantly decreased the number of immature T cells (CD4$^+$/CD8$^+$) in the thymus (Kerkvliet and Brauner, 1990).

Numerous investigations have demonstrated the PFC response to be exquisitely sensitive to the toxic effects of TCDD. This effect segregates with the *Ah* locus (Vecchi et al., 1983) and appears to be dependent upon duration and conditions of exposure (Hols-apple et al., 1991c). Although TCDD induces profound changes in the PFC assay, no changes have been observed in splenic cellularity (numbers of Ig$^+$, CD4$^+$, or Thy-1$^+$ cells) either before or after antigen challenge. In addition, in spite of suppression of antigen-induced antibody production, TCDD has been reported to enhance total serum immunoglobulin concentrations.

Although many labs have defined Th cells as unaffected by TCDD exposure, Kerkvliet has reported suppression of T-cell regulation of immune responses (Kerkvliet and Brauner, 1987; Kerkvliet et al., 1990). However, studies using separation/reconstitution or in vitro exposure techniques have elucidated the B cell as the primary immune cell target for TCDD. In addition, B-cell differentiation was identified as the stage affected. Consistent with these findings, TCDD has a selectively greater effect on immature B cells than on mature B cells. Additionally, the selective effect on B cells cannot be accounted for by induction of T $_s$ (suppressor T cells).

The information presented so far implicates an effect of TCDD on lymphocyte development/maturation either in the bone marrow, thymus, or after antigenic challenge. In support of this conclusion, TCDD exposure has been shown to suppress bone marrow cellularity and stem cell proliferation in rodent neonates exposed in utero. TCDD also appears to alter homing patterns of lymphocytes after perinatal or postnatal exposure in Fischer 344 rats and can alter development of granulocyte-macrophage colony-forming units (CFU-GM) at concentrations below those that induce thymic atrophy. Using fetal thymic or bone marrow equivalent cells from birds, it has been demonstrated that TCDD severely attenuates proliferation and development of CD4$^+$/CD8$^+$ cells and of B cells. These data support the conclusions of Greenlee and colleagues (1984),(1985) that TCDD alters the microenvironment in which lymphocytes develop.

The effects of TCDD on innate immunity are less well studied. TCDD has been shown to inhibit some functions of polymorphonuclear leukocytes (PMNs), including cytolytic and cytostatic activities. This inhibition has been postulated to be related to PMN development in the bone marrow. Results by several investigators have shown TCDD-induced alterations in serum C3, indicating soluble mediators of innate immunity may also be targeted (White and Anderson, 1985; White et al., 1986). There have been no observed effects on macrophage-mediated cytotoxicity, NK function, or interferon production. In host resistance models, TCDD exposure has been shown to increase susceptibility to several bacterial, viral, and tumor models.

There is little doubt that TCDD and related PCDDs are immunotoxic, particularly in mice. However, extrapolation to human exposure has proven to be difficult. There

are a few instances in which accidental human exposure to TCDD and related congeners has afforded the opportunity to study exposure-related human immunologic responses. In children exposed to PCDDs in Seveso, Italy (1976), nearly half of the exposed study group exhibited chloracne (a hallmark of human exposure to PCDDs) 3 years after the accident. Immune parameters measured at that time were unaffected. In a second study conducted 6 years later on different subjects, there was an increase in complement, which correlated with the incidence of chloracne, an increase in circulating T and B cells, and an increase in peripheral blood lymphocyte (PBL) mitogenic responses. A second incident occurred in 1971 in Times Beach, Missouri, when wastes containing TCDD were sprayed on roads to prevent dust formation. Both low-risk and high-risk individuals from this area were examined for DHR responses. Slight, but statistically nonsignificant alterations were observed in high-risk compared to low-risk individuals. In addition, there was a low-level increase in mitogenic responsiveness in high-risk persons. In a second study conducted 12 years later, no alterations were observed in DHR or mitogenic responses between exposed or control individuals. More recently, studies have been undertaken to evaluate the in vitro effects of TCDD on human cells. TCDD suppressed IgM secretion by human B cells in response to the superantigen toxic shock syndrome toxin-1 (TSST-1) and the proliferation and IgG secretion of human tonsillar B cells in response to LPS and cytokines.

Polychlorinated Dibenzofurans Like the PCDDs, polychlorinated dibenzofurans (PCDFs) are not produced commercially but are true environmental contaminants associated with the production of chlorophenoxy acids, pentachlorophenol, and other PCB mixtures. Although higher concentrations are required to achieve observable effects, the immunotoxic profile of the PCDFs is similar in nature to that described for TCDD. In fact, most of what is known regarding the immunotoxicity of the PCDFs in animal models has been learned during structure–activity relationship studies comparing TCDD to congeners of the dibenzofurans. TCDF (tetrachlorodibenzofuran) exposure in most species is associated with thymic atrophy and in guinea pigs it has been shown to suppress the DHR and lymphoproliferative responses to PHA and LPS. Suppression of the PFC response to SRBC after exposure to several PCDF congeners has also been reported.

Two important case studies of human immunotoxicology involved populations accidentally exposed to HAHs. There is evidence that the PCDFs were the primary contributors to the observed toxic effects. Greater than 1850 individuals in Japan (in 1968) and in excess of 2000 people in Taiwan (in 1979) were affected when commercial rice oil was found to be contaminated with HAHs. PCDFs were observed in the tissues of the exposed populations and subsequent studies on immune status revealed a decrease in total circulating T cells, decreased DHR, and enhanced lymphoproliferative responses to PHA and pokeweed mitogen (PWM). In addition, many of the exposed individuals suffered from recurring respiratory infections, suggesting that host resistance mechanisms had been compromised.

Polycyclic Aromatic Hydrocarbons The polycyclic aromatic hydrocarbons (PAHs) are a ubiquitous class of environmental contaminants. They enter the environment through many routes including the burning of fossil fuels and forest fires. In addition to being carcinogenic and mutagenic, the PAHs have been found to be potent immunosuppressants. Effects have been documented on humoral immunity, cell-mediated immunity, and on host resistance (reviewed by Ward et al., 1985, and White et al., 1986). The most extensively studied PAHs are 7,12-dimethylbenz[a]anthracene (DMBA) and benzo[a]pyrene (BaP).

The PAHs suppress the antibody response to a variety of T cell–dependent and T cell–independent antigens. In addition, mice exposed to BaP exhibit suppressed lymphoproliferative responses to mitogens but not alloantigens (Dean et al., 1983). In Dean's studies, host resistance to the PYB6 tumor and to *L. monocytogenes* were unaffected by BaP exposure, as was the DHR response and allograft rejection, suggesting that the T cell (and CMI) was only minimally affected by BaP. Since the PFC response to T cell–dependent and T cell–independent antigens is markedly suppressed by BaP exposure, it would appear that BaP may target the macrophage or the B cell.

In contrast to BaP, DMBA (the more potent PAH) significantly suppresses not only PFC responses but also NK activity, CTL responses, DHR responses, and alloantigen-induced lymphoproliferative responses as well. Therefore DMBA exposure seems to result in long-lasting immunosuppression of humoral immunity (HI), CMI, and tumor resistance mechanisms in mice. Suppression of the immunologic mechanism of tumor resistance by PAHs tends to correlate with their carcinogenic properties and may contribute to their carcinogenicity.

Although it is well established that the PAHs are immunosuppressive in nature, the mechanism or mechanisms by which they elicit this action have remained elusive until recently (reviewed by White et al., 1994). It is generally recognized that PAHs exert carcinogenic and mutagenic effects after being metabolized by P450 enzymes to more toxic metabolites. It has recently been shown that splenocytes from unexposed mice can metabolize exogenously added DMBA via P450 enzymes (Ladics et al., 1991). In addition, Ladics and colleagues (1992a), (1992b) demonstrated that macrophages were the primary cell capable of metabolizing PAHs, and that these cells were capable of generating 7,8-dihydroxy-9,10-epoxy-7,8,9,10-benzo[*a*]pyrene (BPDE), the reactive metabolite proposed to be the ultimate carcinogenic form of BaP. These data are consistent with other studies demonstrating the presence and inducibility of aryl hydrocarbon hydrolase (AHH) in cells of the macrophage lineage and with other data suggesting that the macrophage is the primary target and is functionally compromised (with respect to accessory cell help) following exposure to the PAHs.

Nitrosamines The nitrosamine family comprises the nitrosamines, nitrosamides, and *C*-nitroso compounds. Exposure to nitrosamines, especially *N*-nitrosodimethylamine (DMN, the most prevalent nitrosamine) comes primarily through industrial and dietary means, and minimally through environmental exposure. The toxicity and immunotoxicity of DMN have been extensively reviewed (Myers and Shook, 1996). Single or repeated exposure to DMN inhibits T-dependent humoral immune responses (IgM and IgG), but not T-independent responses. Other symmetrical nitrosamines, such as diethylnitrosamine (DEN), dipropylnitro-samine (DPN), and dibutylnitrosamine (DBN), demonstrated similar effects on humoral immunity but were not as potent as DMN. In fact, as the length of the aliphatic chain increased, the dose required to suppress the anti-sRBC PFC response by 50 percent (ED $_{50}$) also increased. In contrast, nonsymmetrical nitrosamines suppressed humoral immunity at comparable concentrations. Overall, the rank order of ED $_{50}$ values paralleled their LD $_{50}$ values. T cell–mediated lyphoproliferative responses (mitogens or mixed lymphocyte response) and delayed hypersensitivity response are also suppressed following DMN exposure. In vivo exposure to DMN followed by challenge with several pathogens did not produce a pattern of effects that was consistent (decreased resistance to *Streptococcus zooepidemicus* and influenza, no effects on resistance to herpes simplex types 1 or 2 or *Trichinella spiralis,* increased resistance to *L. monocytogenes*). In contrast, anti-tumor activity in DMN-exposed animals was consistently enhanced. DMN-exposed animals also have altered development of hematopoietic cells (increased macrophage precursors). Together these data suggest the macrophage (or its developmental precursors) as a primary target. Mechanistic studies have demonstrated that DMN alterations in cell-mediated immunity are associated with enhanced macrophage activity, increased myelopoietic activity, and alterations in TNF-a transcriptional activity. It has been postulated that DMN may cause the enhanced production of GM-CSF, which can have autocrine (enhanced tumoricidal and bactericidal activity) and paracrine (induced secretion of T cell–suppressing cytokines by macrophages) activities. Further work is needed to clarify the apparent selectivity of DMN for alteration in macrophage function.

Pesticides Pesticides include all xenobiotics whose specific purpose is to kill another form of life, usually insects or small rodents. These compounds can be divided into four classes: the organophosphates, organotins, carbamates, and organochlorines. While there is increasing evidence that certain pesticides can produce alterations in immune function in animal models (reviewed by Penninks et al., 1990; Barnett and Rodgers, 1994; and Voccia et al., 1999), studies following human exposure are limited and reveal no conclusive results (Thomas et al., 1990).

Organophosphates Occupational exposure to organophosphates has been linked to decreased PMN chemotaxis and increased upper respiratory infection. Overall, relatively little is known about the immunotoxic effects of organophosphates on the immune system. The most extensively studied of these are malathion, parathion, and methyl parathion. Prolonged exposure to low doses of malathion (a cumulative high dose) results in decreased humoral immunity. High doses, which have direct cholinergic effects, also suppress humoral immunity, but whether this is a direct effect of the chemical on the immune system or a stress response elicited by cholinergic effects is unclear. In contrast, acute oral exposure has been shown to enhance humoral immunity and mitogenic proliferative responses with no other immune-related effects. In vitro exposure of either human mononuclear cells or murine splenocytes to malathion results in decreased lymphoproliferative responses, suppressed CTL generation, and a decrease in the stimulus-induced respiratory burst in peritoneal cells. Moreover, after metabolism of malathion by liver S9 preparations, the metabolites of malathion were not immunosuppressive. In addition, separation and reconstitution studies revealed that the adherent population (i.e., the macrophage) is the primary cellular target for malathion. Malathion exposure also induces peritoneal mast cell degranulation and enhances macrophage phagocytosis. In light of the above findings and the fact that mast cell degranulation products can modulate leukocyte activity, it has been suggested that peritoneal mast cell degranulation following acute malathion exposure may subsequently lead to augmentation of leukocyte functions, thereby nonspecifically enhancing the generation of an immune response.

Parathion has attracted more attention than malathion, probably because it is more acutely toxic. This pesticide suppresses both humoral and cell-mediated immunity. Following exposure to methyl parathion, decreased germinal centers after antigen challenge, thymic atrophy, and suppressed DHR responses have been reported. Other experiments have shown suppression of lymphoproliferative responses as well as increased susceptibility to pathogens. In vitro exposure to parathion or paraoxon suppresses CMI in murine splenocytes, IL-2 production in rat splenocytes, and proliferative responses in human lymphocytes. Finally, exposure of human bone marrow cells to organophosphates may result in inhibition of CFU formation.

Organochlorines The organochlorines include chemicals such as chlordane, dichlorodiphenyltrichloroethane (DDT), Mirex, pentachlorophenol, aldrin, dieldrin, and hexachlorobenzene. These are among the longer-lived pesticides and they have an increased propensity for contamination of soil and ground water. The humoral

immune response to both T cell–dependent and T cell–independent antigens is suppressed following exposure to dieldrin, and macrophage functions from dieldrin-exposed animals are depressed. The apparent effect of dieldrin on macrophages correlates with the increased susceptibility of dieldrin-exposed animals to murine hepatitis virus, which targets macrophages (Krzystyniak et al., 1985).

Definitive immunosuppression produced by chlordane was first reported in 1982 by Spyker-Cranmer and colleagues. In utero exposure resulted in decreased DHR responses in mice with no deficit in antibody production to sRBC. This correlated with an increase in resistance to influenza infection because the DHR contributes to the pathology of the infection (Menna et al., 1985). As reported for dieldrin, the primary cellular target for chlordane appears to be the macrophage. Although peritoneal exudate cells from mice exposed to chlordane in utero showed normal cytotoxic responses, the response is delayed by 24 to 48 h. Preliminary evidence suggests that prenatal exposure inhibits myeloid progenitor development in bone marrow, but no cause–effect relationship between this and macrophage deficits has been determined. In contrast to observations from mice exposed in utero, exposure of adult mice to chlordane does not result in any changes to several immune parameters, including PFC response to sRBC, MLR, DHR, or mitogenic lymphoproliferation.

DDT is one of the oldest pesticides in use today and one of the first studied for its immunotoxic potential. DDT inhibited antiovalbumin serum antibody titers in rats exposed via the drinking water (Wasserman et al., 1969). In contrast, both rats and guinea pigs fed DDT exhibited no alterations in antitoxin antibody (Gabliks et al., 1973, 1975). These animals did, however, have a suppressed anaphylactic reaction as a result of decreased numbers of mast cells. Studies by Street (1981) indicated that chickens exposed to DDT or Mirex had suppressed levels of circulating IgM and IgG, although specific antibody titers were normal. In addition, DDT exposure resulted in decreased antigen-induced germinal centers, thymic atrophy, and suppressed CMI. While most studies on DDT have focused on humoral immunity, the effects of DDT on CMI, host resistance, and particularly macrophage function remain relatively unexplored.

Organotins Trisubstituted organotins such as TBTO are widely used as biocides and have recently been recognized as producing some immunotoxic effects. The action of these compounds on lymphoid tissue and immunity has been extensively reviewed (Penninks et al., 1990). The most outstanding action of TBTO is the induction of profound but reversible thymic atrophy. In addition, the developing immune system appears to be more sensitive to the effects of TBTO than does the immune system of the adult animal. Studies by Vos et al. (1984) demonstrated a decrease in cellularity in the spleen, bone marrow, and thymus. The decrease in splenic cellularity was associated with a concomitant loss of T lymphocytes. More specifically, oral TBTO exposure resulted in decreased serum IgG, increased serum IgM, and suppression of DHR responses to tuberculin and ovalbumin. In those studies, host resistance to *L. monocytogenes* was diminished. Cytotoxicity by adherent peritoneal cells was suppressed but there was no observed effect on NK cytotoxicity. In contrast, van Loveren et al. (1990) observed suppressed lung NK cytotoxicity in rats exposed orally to TBTO. In addition, the lymphoproliferative response of thymocytes to PHA, Con A, and PWM was significantly suppressed.

Carbamates Carbamate insecticides such as carbaryl (Sevin) and aldicarb have frequently been studied as immunotoxicants. Studies involving oral exposure of chickens to Sevin resulted in acute and sometimes prolonged suppression of germinal centers and antibody production. In addition, carbaryl exposure causes suppression of granulocyte phagocytosis, which may last for up to 9 months. However, other studies have found no indication of immunotoxicity except at near lethal concentrations. In an evaluation of humoral immunity following a 2-week exposure to carbaryl in rats, suppression of the IgM PFC response to sRBC was observed following inhalation exposure but not oral or dermal exposure (Ladics et al., 1994). Conflicting results have also been observed in animals exposed to aldicarb or methyl isocyanate, an intermediate in carbamate pesticide production. Deo and colleagues (1987) reported alterations in T cells and lymphoproliferative responses in humans accidentally exposed to methyl isocyanate. In contrast, mice exposed to the same compound showed no significant alterations in immune status (Luster et al., 1986). More recently, Pruett and coworkers (1992a) evaluated the immunotoxicity of sodium methyldithiocarbamate, a chemical widely used for the control of weeds, fungi, and nematodes in soil. These investigators observed decreased thymus weight, depletion of the CD4 $^+$/CD8$^+$ population of thymocytes, and profound suppression of NK activity following both oral and dermal exposure. Given the number of conflicting reports, currently there is insufficient evidence in either humans or animal models to indicate that carbamate pesticides pose a significant risk to the human population. However, the data by Ladics and colleagues (1994) suggest that immunotoxicologic studies on pesticides should consider relevant exposure routes, as carbaryl was not immunosuppressive by routes through which contact by the general population typically occurs (oral and dermal via residues in water and on food).

Pyrethroids Supermethrin has been demonstrated to decrease the plaque-forming cell response after a single oral administration. However, following repeated exposure (up to 3 mg/kg/day), only slight changes in circulating leukocytes and in nucleated cell numbers in the bone marrow were observed (Siroki et al., 1994). Rabbits administered cypermethrin orally for 7 weeks demonstrated decreased tuberculin skin reactions and a decrease in the antibody titer to *S. typhimurium* (Desi et al., 1985).

Other Pesticides Naphthalene is a bicyclic aromatic hydrocarbon that is used, among other things, as an insect repellent, insecticide, and vermicide. To date, no evidence for immunotoxicity has been demonstrated despite prolonged exposure (Shopp et al., 1984). Recently it has been suggested that this lack of effect may be related to the inability of splenocytes to metabolize naphthalene and/or to relatively low concentrations of metabolites that may be generated in the liver and diffuse to the spleen (Kawabata and White, 1990). Paraquat has been shown to decrease the percentage of circulating neutrophils as a result of their migration to the lungs and propanil can alter immune cell development (myeloid and erythroid progenitors). Thymic atrophy in response to propanil exposure has also been observed, although the contribution of induced glucocorticoids to this effect has not been ascertained (Voccia et al., 1999).

Metals Generally speaking, metals target multiple organ systems and exert their toxic effects via an interaction of the free metal with the target: enzyme systems, membranes, or cellular organelles. Although specific immunotoxic consequences of metal exposure are well documented in the literature (see reviews by Lawrence, 1985; McCabe, 1994; Burns et al., 1994e; and a text edited by Zelikoff and Thomas, 1998), this section focuses on the four best-studied immunotoxic metals: lead, arsenic, mercury, and cadmium. In considering the immunotoxicity of most metals, it is important to remember that at high concentrations, metals usually exert immunosuppressive effects; however, at lower concentrations, immunoenhancement is often observed (Koller, 1980; Vos, 1977).

Lead By far the most consistent finding in studies evaluating the effects of metals on immune responses is increased susceptibility to pathogens. For lead (Pb), decreased resistance to the bacterial pathogens *S. typhimurium, Escherichia coli,* and *L. monocytogenes* has been observed. Enhanced susceptibility to viral challenge has also been reported. Other investigators found no change in virally induced IFN production in Pb-exposed animals.

Studies on the specific effects of Pb on functional cell-mediated immunity have yielded no conclusive results, as reports range from significant suppression to no effect. Currently, these differences cannot be explained by differences in routes of exposure or dose. Suppression of humoral immunity, however, has been demonstrated. In rodents exposed to Pb, lower antibody titers have been observed. In addition, children environmentally exposed to Pb and infected naturally with *Shigella dysenteriae* had prolonged diarrhea, and occupationally exposed persons reported more colds and influenza and exhibited suppressed secretory IgA levels, suggesting Pb-induced suppression of humoral immunity. Pb-induced effects on myeloid cells include an increase in the number of myeloid progenitors in the bone marrow (CFU-GM) with a subsequent decrease in more mature cells. Following in vivo exposure to Pb, splenocytes displayed consistently suppressed IgM PFC responses to sRBC. Separation and reconstitution experiments indicated that this suppression is likely due to an effect on macrophage function.

In recent mechanistic studies (reviewed by McCabe, 1994), an alteration in the ability of the macrophage to process and present antigen to antigen-primed T cells confirmed the previous observation and suggested that Pb alters immune recognition. In contrast to other reports concerning the immunosuppressive action of Pb on PFC responses, enhancement of the in vitro–generated PFC response (in vitro exposure in Mishell-Dutton-type culture) has been reported which appeared to be the result of enhancement of B-cell differentiation. This effect may occur at the level of B-cell activation or cytokine responsiveness. And finally, in vitro addition studies indicate that Pb may have differential effects on Th1 and Th2 cells and can inhibit the production of IL-2. If the production or activity of other cytokines is observed to be suppressed or enhanced by metal exposure, it may be that metals can exert significant effects on immune regulation, which can result in either immunoenhancement or immunosuppression.

Arsenic The literature concerning arsenic (As)-induced immunomodulation is fraught with inconsistencies due to differences in speciation of As (which plays a significant role in arsenic toxicity), the route of administration, the concentrations used, and the various species and strains of animals utilized. As with many other metals, exposure to low concentrations of As often leads to enhanced immune responses while exposure to higher concentrations results in immunosuppression (reviewed by Burns et al., 1994e). Exposure of mice to sodium arsenite (NaAsO$_2$) in the drinking water or subcutaneously was shown to decrease resistance to viral pathogens. Other investigators have shown that exposure to arsenicals offers some degree of protection against tumor incidence, although tumors that did develop grew at a much faster rate. No alterations in CMI were observed in those investigations. Interestingly, host resistance studies, conducted after exposure to the semiconductor material gallium arsenide (GaAs), revealed that GaAs afforded modest protection against infection with both *S. pneumoniae* and *L. monocytogenes,* although resistance to the B16F10 melanoma was reduced. It was subsequently determined that the As concentrations in the blood of these animals was high enough to offer a chemotherapeutic effect against the bacterial pathogens (arsenicals were once widely used as chemotherapeutic agents before the development of drugs with higher efficacy and lower toxicity). These studies are important because they are among the first to demonstrate the intricate interplay between the host, the pathogen, and the xenobiotic.

In addition to these holistic immune alterations, As exposure has been shown to inhibit both the PFC response in animal models and peripheral blood lymphocyte proliferation in humans. Also, substantial mechanistic information exists regarding the immunotoxicity of intratracheally instilled GaAs. Exposure results in suppression of the PFC, CTL, DHR, and MLR responses. Following instillation, both arsenic and gallium can be detected in the blood and tissues for as long as 30 days, suggesting that the lung acts as a depot for prolonged systemic exposure to dissociated gallium and arsenic. Mechanistic studies revealed that all cell types involved in the generation of an antibody response (macrophage, T, and B cells) are affected by GaAs exposure. Decreased expression of Ia and ability to process and present the particulate antigen, sRBC, represent functional deficits of the macrophage, while inhibition of mitogen- or receptor-driven proliferation, expression of the IL-2 receptor, and production of cytokines during the antibody response represent functional deficits of the T cell. A criticism of the studies using GaAs has been that instillation of particulate matter causes a stress response resulting in increased levels of circulating corticosteroids, known to have potent immunosuppressive activity. Studies utilizing the glucocorticoid antagonist RU-486 showed that although GaAs in the lung did increase circulating corticosterone levels, elevated corticosterone was not responsible for suppression of the AFC response. Rather, GaAs exerted direct immunosuppressive effects independent of its ability to increase serum corticosteroid levels.

Mercury Both organic and inorganic mercury (Hg) has been shown to decrease immunologic responses. Specifically, Hg exposure suppresses the PFC response and increases susceptibility to encephalomyocarditis (EMC) virus in addition to decreasing polyclonal activation of lymphocytes by T-cell mitogens. It has also been reported that Hg can activate B cells and augment anaphylaxis by enhancing IgE production. Recently, interest in Hg has focused on the ability of this metal to induce type III hypersensitivity. Hg administration is used to induce glomerulonephritis in brown Norway rats (a model for induction of autoimmune disease; Sapin *et al.,* 1981).

Cadmium Like other metals, cadmium (Cd) exposure increases susceptibility to both bacterial and viral pathogens, although enhanced resistance to tumor and EMC virus has been reported. Exposure to Cd has also been demonstrated to modulate lymphocyte proliferative responses to mitogens and allogeneic cells. Greenspan and Morrow (1984) reported decreased macrophage phagocytic ability, which correlates with changes in host resistance. Humoral immunity (PFC response and serum antibody titer) and NK function have also been demonstrated to be suppressed by Cd exposure, while CTL activity appears to be enhanced.

Other Metals Organotin compounds are used primarily as heat stabilizers and catalytic agents (dialkyltin compounds) and as biocides (trisubstituted organotins). The immunotoxicity of the organotins has been extensively reviewed (Penninks et al., 1990). Since the trisubstituted organotins are examined elsewhere (see "Pesticides," above) discussion here is limited to the dialkyltins, di- *n*-octyltin dichloride (DOTC) and di- *r*-dibutyltin dichloride (DBTC). As in the case of tributyltin oxide (TBTO), the most outstanding action of the dibutyltins is the induction of profound but reversible thymic atrophy. Additionally, there is a preferential loss of CD4 $^+$ cells observed in the peripheral blood. The dialkylorganotins have also been observed to decrease resistance to *L. monocytogenes* and to suppress the DHR and allograft rejection responses. Suppression of the PFC response to sRBC and inhibition of T-cell mitogen responses was also observed, while no effect on B-cell mitogenesis or the PFC response to LPS occurred. These data suggest that the T cell may be a primary target for compounds like DOTC and DBTC. Like the trisubstituted organotins and the HAHs, the developing immune system appears to be more sensitive to the effects of these compounds than does the immune system of the adult.

Beryllium is known primarily for its ability to produce beryllium lung disease, a chronic granulomatous inflammation of the lung often observed in persons with occupational contact or environmental exposure to beryllium compounds. This metal produces a T-cell–mediated hypersensitivity and causes the in vitro transformation of PBL (from exposed but not unexposed patients) into large lymphoblasts (Hanifin et al., 1970). In addition, lymphocytes from beryllium oxide–exposed individuals produce migration inhibitor factor (MIF) that inhibits the migration of macrophages (Henderson et al., 1972).

Platinum compounds have been used in cancer chemotherapy and have been shown to suppress macrophage chemotaxis, to inhibit humoral immunity and lymphoproliferation, and to induce hypersensitivity responses. Gold salts, used therapeutically in rheumatic disease, may cause immune complex hypersensitivity and enhance allergic reactions. While nickel has been reported to enhance anaphylaxis, it also inhibits humoral immunity, NK activity, and impairs resistance to pathogenic challenge. Chromium at low doses enhances phagocytic ability and PFC responses but appears to suppress these responses at higher concentrations. Cobalt, a constituent of vitamin B_{12}, has been demonstrated to suppress PMN chemotaxis and host resistance to streptococcal infection and to inhibit the PFC response. Vanadium impairs the activities of macrophages and results in increased susceptibility to disease and bacterial challenge with *L. monocytogenes*.

Inhaled Substances Pulmonary defenses against inhaled gases and particulates are dependent upon both physical and immunologic mechanisms. Immune mechanisms primarily involve the complex interactions between PMNs and alveolar macrophages and their abilities to phagocytize foreign material and produce cytokines, which not only act as local inflammatory mediators but also serve to attract other cells into the airways.

Urethane Urethane (ethyl carbamate) was once widely used as a veterinary anesthetic until its carcinogenic potential was defined in 1948. Exposure to urethane produces severe myelotoxicity, resulting in suppression of NK-cell activity and antibody responses to sRBC (Luster *et al.*, 1982; Gorelik and Heberman, 1981). In addition, urethane exposure leads to increased frequency of spontaneous lung adenomas in susceptible mouse strains and impaired resistance to B16F10 melanoma cells and metastatic tumor growth in the lungs.

Tobacco Smoke Cigarette smoke has been implicated in acute respiratory illness and chronic obstructive lung disease, but the effect of exposure to mainstream cigarette smoke has yielded ambiguous results in humans and in animal models (reviewed by Sopori et al., 1994). In humans, the number of alveolar macrophages is increased three- to fivefold in smokers compared to nonsmokers. This may be a result of increased production of IL-1 by the resident alveolar macrophages, resulting in enhanced influx of other inflammatory cells (PMNs and peripheral blood mononuclear cells) into the lung. In addition to the increased numbers of macrophages, the macrophages present appear to be in an activated state, as evidenced by an increase in cytoplasmic inclusions, increased enzyme levels, altered surface morphology, and enhanced production of oxygen radicals. However, despite their apparent activated state, these macrophages seem to have decreased phagocytic and bactericidal activity. Although the primary site of exposure of the immune system to cigarette smoke is the lung, selected immune parameters have been shown to be altered in smokers. Decreased serum immunoglobulin levels and decreased NK-cell activity have been reported. Concentration-dependent leukocytosis (increased numbers of T and B cells) is well-defined in smokers when compared to nonsmokers. However, the question of whether there is a relationship between smoking and lymphocyte function is debatable.

Numerous immunologic studies conducted in animals exposed to cigarette smoke demonstrate suppression of antibody responses, biphasic lymphoproliferative capacity (enhanced, then suppressed with continued exposure), and enhanced susceptibility to murine sarcoma virus and influenza virus. Animal studies cannot precisely replicate human exposure conditions because of the route of exposure and the rapid chemical changes that occur in the components of tobacco smoke upon its generation.

Particles: Asbestos and Silica It is believed that alterations in both humoral and cell-mediated immunity occur in individuals exposed to asbestos and exhibiting asbestosis. Decreased DHR and fewer T cells circulating in the periphery as well as decreased T-cell proliferative responses have been reported to be associated with asbestosis (reviewed by Miller and Brown, 1985, and Warheit and Hesterberg, 1994). Autoantibodies and increased serum immunoglobulin levels have also been observed. Within the lung, alveolar macrophage activity has been implicated as playing a significant role in asbestosis-induced changes in immunocompetence. Fibers of asbestos that are deposited in the lung are phagocytized by macrophages, resulting in macrophage lysis and release of lysosomal enzymes and subsequent activation of other macrophages. Recently it has been hypothesized that the development of asbestosis in animal models occurs by the following mechanism. Fibers of asbestos deposited in the alveolar space recruit macrophages to the site of deposition. Some fibers may migrate to the interstitial space where the complement cascade becomes activated, releasing C5a, a potent macrophage activator and chemoattractant for other inflammatory cells. Recruited interstitial and resident alveolar macrophages phagocytize the fibers and release cytokines, which cause the proliferation of cells within the lung and the release of collagen. A sustained inflammatory response could then contribute to the progressive pattern of fibrosis which is associated with asbestos exposure.

The primary adverse consequence of silica exposure, like that to asbestos, is the induction of lung fibrosis (silicosis). However, several immune alterations have been associated with silica exposure in experimental animals, including decreased antibody- and cell-mediated immune parameters (reviewed in IPCS, 1996). Alterations in both T- and B-cell parameters have been reported, although T cell–dependent responses appear to be more affected than B cell–dependent responses. Dose and route of antigen exposure appear to be important factors in determining silica-induced immunomodulation. Silica is toxic to macrophages and PMNs, and exposure is correlated with increased susceptibility to infectious pathogens. The significance of these immunologic alterations for the pathogenesis of silicosis remains to be determined. The association of this disease with the induction of autoantibodies is covered elsewhere in this chapter.

Pulmonary Irritants Chemicals such as formaldehyde, silica, and ethylenediamine have been classified as pulmonary irritants and may produce hypersensitivity-like reactions. Macrophages from mice exposed to formaldehyde vapor exhibit increased synthesis of hydroperoxide (Dean et al., 1984). This may contribute to enhanced bactericidal activity and potential damage to local tissues. Although silica is usually thought of for its potential to induce silicosis in the lung (a condition similar to

asbestosis), its immunomodulatory effects have also been documented (Levy and Wheelock, 1975). Silica decreased reticuloendothelial system (RES) clearance and suppressed both humoral immunity (PFC response) and the cell-mediated response (CTL) against allogeneic fibroblasts. Both local and serum factors were found to play a role in silica-induced alterations in T-cell proliferation. Silica exposure may also inhibit phagocytosis of bacterial antigens (related to RES clearance) and inhibit tumoricidal activity (Thurmond and Dean, 1988).

Oxidant Gases It is becoming increasingly clear that exposure to oxidant gases—such as ozone (O_3), sulfur dioxide (SO_2), nitrogen dioxide (NO_2), and phosgene—alters pulmonary immunologic responses and may increase the susceptibility of the host to bacterial infections (reviewed by Selgrade and Gilmour, 1994). Infiltration of both PMNs and macrophages has been observed, resulting in the release of cellular enzyme components and free radicals, which contribute to pulmonary inflammation, edema, and vascular changes. Exposure to O_3 has been demonstrated to impair the phagocytic function of alveolar macrophages and to inhibit the clearance of bacteria from the lung. This correlated with decreased resistance to *S. zooepidemicus* and suggests that other extracellular bacteriostatic factors may be impaired following exposure to these oxidant gases. Short-term NO_2 exposure decreases killing of several bacterial pathogens and, like O_3, this decreased resistance is probably related to changes in pulmonary macrophage function. A role for the products of aracadonic acid metabolism (specifically, the prostaglandins) has recently been implied. This is supported by the facts that decreased macrophage functions are associated with increased PGE_2 production and that pretreatment with indomethacin inhibits O_3-induced pulmonary hyperresponsiveness and related inflammatory responses.

It is clear that exposure to oxidant gases can also augment pulmonary allergic reactions. This may be a result of increased lung permeability (leading to greater dispersion of the antigen) and to the enhanced influx of antigen-specific IgE-producing cells in the lungs. In studies involving O_3 exposure and challenge with *L. monocytogenes,* decreased resistance to the pathogen correlated not only with changes in macrophage activity, but with alterations in T cell–derived cytokine production (which enhances phagocytosis) as well. In support of an effect on T cells, other cell-mediated changes were observed: changes in the T- to B-cell ratio in the lung, decreased DHR response, enhanced allergic responses, and changes in T-cell proliferative responses. Together, these data suggest that in addition to altering macrophage functions, oxidant gases may also produce an imbalance in the Th1 and Th2 cell populations. Given the different patterns of lymphokine secretion by these T-cell subpopulations (Mosmann and Coffman, 1989) this is a very plausible explanation for some of the observed immune alterations.

Organic Solvents and Related Chemicals *Aromatic Hydrocarbons* There is limited but substantive evidence that exposure to organic solvents and their related compounds can produce immunosuppression (reviewed by Snyder, 1994). By far the best-characterized immunotoxic effects are those produced by benzene. In animal models, benzene induces anemia, lymphocytopenia, and hypoplastic bone marrow. In addition, it has recently been suggested that this myelotoxicity may be a result of altered differentiative capacity in bone marrow–derived lymphoid cells. Benzene (oral and inhaled) exposure alters both humoral and cell-mediated immune parameters including suppression of the anti-sRBC antibody response, decreased T- and B-cell lymphoproliferative responses (mitogens and alloantigens), and inhibition of CTL activity. Benzene exposure also appears to increase the production of both IL-1 and TNF-a and to inhibit the production of IL-2. With these dramatic effects on immune responses, it is not surprising that animals exposed to benzene exhibit reduced resistance to a variety of pathogens. More recently, nitrobenzene (an oxidizing agent used in the synthesis of aniline and benzene compounds) has been reported to also produce immunotoxic effects (Burns et al., 1994a), with the primary targets being the peripheral blood erythrocyte and the bone marrow.

Immunomodulating activity has also been observed for toluene, although most effects occur at significantly high concentrations. When compared with benzene, toluene has little to no effect on immunocompetence. However, it should be noted that toluene exposure effectively attenuates the immunotoxic effects of benzene (probably because of competition for metabolic enzymes).

In contrast to the parent toluene, the monosubstituted nitrotoluenes (*para-* and *meta*-nitrotoluene) do significantly alter the immune system (Burns et al., 1994b,1994c). Exposure to *p*-nitrotoluene has been demonstrated to suppress the antibody response to sRBC, to decrease the number of CD4 [+] splenic T cells, and to inhibit the DHR to keyhole limpet hemocyanin (KLH). In addition, host resistance to *L. monocytogenes* was impaired, suggesting the T cell as a primary target. Similarly, *m*-nitrotoluene suppresses the antibody response to sRBC, the DHR to KLH, T-cell mitogenesis, and host resistance to *L. monocytogenes,* again suggesting the T cell as the cellular target. The di-substituted nitrotoluene (2,4-dinitrotoluene; DAT) is also immunosuppressive (Burns et al., 1994d), with exposure resulting in suppressed humoral immunity, NK activity, and phagocytosis by splenic macrophages. Host resistance to bacterial challenge was also impaired. It would appear that DAT may perturb the differentiation and maturation of leukocytes.

Haloalkanes and Haloalkenes Carbon tetrachloride (CCl_4) is widely recognized as hepatotoxic. Recent studies have revealed that CCl_4 is also immunotoxic. Mice exposed for 7 to 30 days to CCl_4 (orally or intraperitoneally) exhibit a decreased T cell–dependent antibody response (sRBC), suppressed mixed lymphocyte responses (allogeneic cells), and lower lymphoproliferative capacity (T and B cells). This change in immune status, which primarily affects helper T-cell function, is associated with the serum of treated animals, suggesting specific cytokine involvement. In fact, the CCl_4-dependent induction and release of TGF-b [1] from the liver results in the indirect suppression of these T cell–mediated immunologic responses (Delaney et al, 1994; Jeon *et al.*, 1997). Induction or inhibition of liver P450 activity augmented and blocked, respectively, the immunotoxic actions of CCl_4, suggesting a requirement for metabolism in order for CCl_4 to be immunosuppressive. In contrast, Fischer 344 rats exposed orally for 10 days exhibited no immunotoxic effects, despite signs of liver toxicity. These differences may represent differences in the metabolic capabilities between these two species.

There is relatively little information on other solvents and related chemicals. Exposure to dichloroethylene (in drinking water for 90 days) has been reported to suppress the anti-sRBC antibody response in male CD-1 mice an to inhibit macrophage function in their female counterparts (Shopp et al., 1985). Similarly, exposure to trichloroethylene (in the drinking water for 4 to 6 months) was reported to inhibit both humoral and cell-mediated immunity and bone marrow colony-forming activity (Sanders et al., 1982). In those experiments, females were more sensitive than males. Exposure to 1,1,2-trichloroethane results in suppression of humoral immunity in both sexes. In addition, macrophage function was inhibited (males only; Sanders et al., 1985). Finally, inhalation of dichloroethane, dichloromethane, tetrachloroethane, and trichloro-ethene has been reported to suppress pulmonary host resistance to *Klebsiella pneumoniae* (Aranyi et al., 1986; Sherwood et al., 1987), suggesting that alveolar macrophages may be affected.

Glycols and Glycol Ethers Exposure to glycol ethers has been associated with adverse effects in laboratory animals, including thymic atrophy and mild leukopenia. Oral administration of ethylene glycol monomethyl ether (EGME) for 1 to 2 weeks (House et al., 1985; Kayama et al., 1991) or its meatabolite methoxyacetic acid (MAA) for 2 weeks (House et al., 1985), produced decreased thymic weight, thymic atrophy, and a selective depletion of immature thymocytes in mice. No alterations in humoral immunity, cell-mediated immunity, macrophage function, or host resistance to *L. monocytogenes* were observed (House et al., 1985). More recently, it has been suggested that perinatal exposure to EGME may produce thymic hypocellularity and inhibition of thymocyte maturation and that it may affect pro-lymphocytes in fetal liver (Holladay et al., 1994).

Oral studies (5 to 10 days) on the glycol ether 2-methoxyethanol (ME) have consistently shown a decrease in thymus weight in the rat (Williams et al., 1995; Smialowicz et al., 1991a). This decrease is often accompanied by alterations in lymphoproliferative responses, although suppression is seen in some cases and stimulation in others, with no clear reason for the differences in response. Alterations in spleen weight and splenic cell populations have also been observed, as well as suppression of TNP-LPS and anti-sRBC plaque-forming-cell responses. Similar results have been obtained following dermal exposure to 2-methoxyethanol (Williams et al., 1995). A decrease in IL-2 production has also been reported (Smialowicz et al., 1991a). Studies using the metabolites of 2-methoxyethanol (methoxyacetaldehyde and methoxyacetic acid) or specific metabolic pathway inhibitors have shown that methoxyacetaldehyde (MAAD) and methoxyacetic acid (MAA) are more immunotoxic than 2-methoxyethanol alone (MAAD>MAA>ME) (Smialowicz et al., 1991a,1991b; Kim and Smialowicz, 1997), suggesting a role for metabolism in the observed alterations in immunocompetence. Although there was no effect following 10-day oral exposures to 2-methoxyethanol (50 to 200 mg/kg/day) (Smialowicz et al., 1991a), subchronic exposure for 21 days to 2000 to 6000 ppm (males) or 1600 to 4800 ppm (females) did produce an enhanced NK response (Exon et al., 1991) in addition to suppression of the PFC response and a decrease in IFN-g production. In that study, it was also determined that 2-methoxyethanol produced greater immunotoxic effects than 2-butoxyethanol. 2-Butoxyethanol was observed to enhance NK activity, but only at the low doses.

Mycotoxins The immunotoxicity of mycotoxins, structurally diverse secondary metabolites of fungi that grow on feed, has been reviewed (IPCS, 1996). This class of chemicals comprises such toxins as aflatoxin, ochratoxin, and the tricothecenes, notably T-2 toxin and vomitoxin. As a class, these toxins can produce cellular depletion in lymphoid organs, alterations in T- and B-lymphocyte function, suppression of antibody responses, suppression of NK activity, decreased delayed hypersensitivity responses, and an apparent increase in susceptibility to infectious disease. T-2 toxin has also been implicated as a developmental immunotoxicant, targeting fetal lymphocyte progenitors leading the thymic atrophy often observed with these mycotoxins (Holladay et al., 1993). For ochratoxin, at least, the dose, the route of administration, and the species appear to be critical factors in results obtained in immunotoxicity studies. For the extensively studied tricothecenes, the mechanism of immunoimpairment may be related to inhibition of protein synthesis. The tricothecenes are currently considered among the most potent small-molecule inhibitors of protein synthesis in eukaryotic cells (IPCS, 1996).

Natural and Synthetic Hormones It is well established that a sexual dimorphism exists in the immune system. Females have higher levels of circulating immunoglobulins, a greater antibody response, and a higher incidences of autoimmune disease than do males. Males appear to be more susceptible to the development of sepsis and mortality associated with this following soft tissue trauma and hemorrhagic shock. Specific natural sex hormones in this dichotomy have been implicated. Immune effects of androgens and estrogens appear to be very tightly controlled within the physiologic range of concentrations, and profound changes in immune activity can result for very slight changes in concentrations of hormones.

Estrogens Diethylstilbestrol (DES) is a synthetic nonsteroidal compound possessing estrogenic activity. DES was used in men to treat prostatic cancer and in women to prevent threatened abortions, as an estrogen replacement, and as a contraceptive drug. Extensive functional and host resistance studies on DES (mg/kg/day range) have indicated that exposure to this chemical results in alterations in cell-mediated immunity and/or macrophage function and are believed to be mediated by the presence of the estrogen receptor on immune cells (Kalland, 1980; Luster et al., 1980; 1984a,1984b; Holsapple et al., 1983). Targeted sites of action include the thymus (thymic depletion, alteration in T-cell maturation process), T cells (decreased MLR, DTH, lymphoproliferative responses), and macrophage (enhanced phagocytic, anti-tumor, and suppressor function). Pre- and neonatal exposures (μg/kg/day dose range) have also demonstrated immunotoxic effects related to T-cell dysfunction. Delayed hypersensitivity and inflammatory responses associated with DES exposure in adult mice have been shown to be reversible upon cessation of exposure (Luster et al., 1980; Holsapple et al., 1983). However, effects from in utero and neonatal exposures appear to have more lasting, possibly permanent effects on immune responses (Luster et al., 1979; Kalland et al., 1979; Ways, 1980).

Exposure to 17b-estradiol in male rats (63 days of age) intraperitoneally for 15 days (1 to 50 mg/kg/day) did not alter spleen weight, spleen cellularity, or the humoral immune response to sRBC (Ladics et al., 1998). As observed with other estrogenic agents, thymic weight was decreased following exposure. Serum androgens and luteinizing hormone and male accessory organ weights were depressed, while serum estradiol and prolactin were increased. Dietary exposure (2.5 to 50 ppm) of male and female rats for 90 days resulted in decreased spleen weights and alterations in hematologic elements suggestive of bone marrow effects. Body weights were also affected. No histological alterations were noted. Decreases in splenic T- and B-cell populations were observed at the higher concentrations. These data suggest the possibility that exposure to 17b-estradiol may have resulted in altered normal immune cell trafficking and distribution, the mechanism of which is not clear. This hypothesis is supported by recent data indicating the observed anti-inflammatory effects of estrogens may be related to combination of alterations in homing and the acti-vation of inflammatory cells and their production of TNF-a and IFN-g (Salem et al., 2000).

While it appears that estrogens can affect the maturation and function of the thymus and its components, it has recently been observed that estrogen receptor knockout mice have significantly smaller thymi than do their wild-type littermates, apparently due to the lack of the estrogen receptor-alpha (ERa) (Staples et al., 1999). In addition, it has been suggested that the effects of estrogens on the thymus appear to be mediated not only through ERa but also through another pathway.

Androgens Oxymetholone is a synthetic androgen structurally related to testosterone and used in the past in the treatment of pituitary dwarfism and as an adjunctive therapy in osteoporosis. Its current use is limited to treatment of certain anemias. Oxymetholone was administered orally to male mice daily for 14 consecutive days (50 to 300 mg/kg/day). In male mice, oxymetholone exposure resulted in a minimal decrease in cell-mediated immunity (MLR and CTL response) but did not alter the ability of the animals to resist infection in host resistance assays. In contrast, anabolic androgenic steroids have been shown to significantly inhibit the sRBC PFC response and to increase the production of pro-inflammatory cytokines from human peripheral blood lymphocytes.

Exposure to flutamide, an androgen receptor antagonist, in male rats (63 days of age) intraperitoneally for 15 days (0.25 to 20 mg/kg/day) did not alter spleen weight or the humoral immune response to sRBC (Ladics et al., 1998). Relative thymic weight and total spleen cellularity were minimally increased. Serum androgens, estrogens, luteinizing hormone, and follicle-stimulating hormone were increased, while male accessory organ weights were depressed.

No comprehensive studies evaluating the effects of testosterone on immune parameters have been conducted. However, it is clear that testosterone is capable of contributing to the suppression of immune function—in particular, cell-mediated responses and macrophage activity. There are numerous reports in the clinical literature that males are more susceptible than females to infection following soft tissue trauma and hemorrhagic shock (reviewed in Catania and Chaudry, 1999). Treatment of males with agents that block testosterone (e.g., flutamide) can prevent the trauma- and hemorrhage-induced depression of immunity. Similarly, treatment of females with dihydrotestosterone prior to trauma-hemorrhage results in depression of CMI similar to that of males. Furthermore, gonadectomized mice of either sex have elevated immune responses to endotoxin, which can be attenuated in either sex by the administration of testosterone. The mechanisms in these cases, including influences of the neuroendocrine system, are not clear. Other investigators have reported that, like estrogenic agents, testosterone and other androgens are capable of influencing host defense by altering lymphocyte trafficking in the body and altering the ability of the macrophage to participate in immune responses.

Glucocorticoids The immunosuppressive actions of corticosteroids have been known for years. Following binding to an intracellular receptor, these agents produce profound lymphoid cell depletion in rodent models. In nonhuman primates and humans, lymphopenia associated with decreased monocytes and eosinophils and increased PMNs are seen. Corticosteroids induce apoptosis and T cells are particularly sensitive. In addition, these agents inhibit macrophage accessory cell function, the production of IL-1 from the macrophages, and the subsequent synthesis of IL-2 by T cells. In general, corticosteroids suppress the generation of CTL responses, MLR, NK activity, and lymphoproliferation. While it is clear that these drugs inhibit T-cell function, their effects on B cells are not completely clear. Corticosteroids inhibit humoral responses, but this appears to be due to effects on T cells, as antigen-specific antibody production by B cells to T-independent antigens does not appear to be affected by corticosteroid treatment.

Mifepristone (RU-486) is a potent competitive antagonist of both progesterone receptor and glucocorticoid type 1 receptor binding. While use of mifepristone has focused on termination of pregnancy, it may find use as a contraceptive, anti-cancer agent, or inducer of labor. No significant studies could be located examining the immunotoxicity of mifepristone. However, in studies utilizing this compound as a glucocorticoid type 1 receptor antagonist to demonstrate the role of corticosteroids in chemical-induced immunomodulation, some insights can be gleaned. Acute oral administration of mifepristone to mice at 100 mg/kg did elevate circulating levels of corticosterone, presumably by preventing binding to the type 1 glucocorticpoid receptor and thus altering the feedback loop. However, the chemical did not alter humoral immunity or the weights and cellularity of lymphoid organs. Similarly, no effects on thymic or splenocyte cellular subpopulations have been observed.

Therapeutic Agents Historically speaking, very few drugs used today as immunosuppressive agents were actually developed for that purpose. In fact, if one looks closely enough, nearly all therapeutic agents possess some degree of immunomodulatory activity (Descotes, 1986). The recent explosion of knowledge regarding the function and regulation of the immune system (at the cellular, biochemical, and molecular levels) has provided investigators with a relatively new avenue for specific drug development. The following discussion focuses on those drugs used primarily for modulating the immune system: the immunosuppressants (corticosteroids are considered above), AIDS therapeutics, and the recombinant cytokines. Extensive reviews of these drugs can be found elsewhere (Spreafico et al., 1985; Rosenthal and Kowolenko, 1994; Talmadge and Dean, 1994).

Immunosuppressive Drugs Originally developed as an antineoplastic agent, cyclophosphamide (Cytoxan, CYP) is the prototypical member of a class of drugs known as alkylating agents. Upon entering the cell, the inactive drug is cleaved into phosphoramide mustard, a powerful DNA alkylating agent that leads to blockade of cell replication. Clinically, CYP has found use in reducing symptoms of autoimmune disease and in the pretreatment of bone marrow transplant recipients. Experimentally, this drug is often used as a positive immunosuppressive control in immunotoxicology studies because it can suppress both humoral and cell-mediated immune responses. There appears to be preferential inhibition of B-cell responses, possibly due to decreased production and surface expression of immunoglobulins. CMI activities that are suppressed include the DHR, CTL, graft-versus-host (GVH) disease, and the MLR.

Azathioprine (AZA), one of the antimetabolite drugs, is a purine analog that is more potent than the prototype, 6-mercaptopurine, as an inhibitor of cell replication. Immunosuppression likely occurs because of the ability of the drug to inhibit purine biosynthesis. It has found widespread use in the inhibition of allograft rejection, although it is relatively ineffective in attenuating acute rejection reactions. It can also act as an anti-inflamma-tory drug and can reduce the number of PMNs and monocytes. Clinical use of the drug is limited by bone marrow suppression and leukopenia. AZA inhibits humoral immunity, but secondary responses (IgG) appear more sensitive than primary respons-es (IgM). A large range of CMI reactivities are also reduced by AZA treatment, including DHR, MLR, and GVH disease. Although T-cell functions are the primary targets for this drug, inhibition of NK function and macrophage activities has also been reported.

Cyclosporin A (Sandimmune, CsA) is a cyclic undecapeptide isolated from fungal organisms found in the soil. Important to its use as an immunosuppressant is the relative lack of secondary toxicity (e.g., myelotoxicity) at therapeutic concentrations (Calne et al., 1981). However, hepatotoxicity and nephrotoxicity are limiting side effects. CsA acts preferentially on T cells by inhibiting the biochemical signaling pathway emanating from the T-cell receptor (TCR). The result is inhibition of IL-2 gene transcription and subsequent inhibition of T-cell proliferation. More specifically, CsA interacts with an intracellular molecule cyclophillin, an intracellular protein with peptidyl proline isomerase activity (although this enzymatic activity probably has nothing to do with the immunosuppressive effect of CsA). The CsA–cyclophillin complex inhibits the serine/threonine phosphatase activity of a third molecule, calcineurin. Calcineurin is proposed to dephosphorylate the cytoplasmic subunit of NF-AT (nuclear factor of activated T cells) and allow the transport of NF-AT into the nucleus, where it can couple with nuclear components and induce the

transcription of the IL-2 gene. Inhibition of calcineurin phosphatase activity by the CsA–cyclophillin complex then prevents nuclear translocation of NF-AT and the resulting IL-2 gene transcription.

FK506 is a cyclic macrolide which is structurally distinct from CsA, but which possesses a nearly identical mechanism of action. Like CsA, FK506 binds intracellularly to proteins with peptidyl proline isomerase activity, the most abundant of which is FK506 binding protein-12 (FKBP12). The FK506–FKBP12 complex also binds to and inhibits calcineurin activity, thereby inhibiting IL-2 gene transcription. Clinically, FK506 inhibits T-cell proliferation, lacks myelotoxicity (although, like CsA, it does cause nephrotoxicity), and induces transplantation tolerance. In addition, the minimum effective dose appears to be approximately tenfold lower than that of CsA.

Rapamycin (RAP) is also a cyclic macrolide which is structurally related to FK506. However, the mechanism by which it produces inhibition of proliferation is strikingly distinct. Unlike CsA and FK506, RAP does not inhibit TCR-dependent signaling events and IL-2 gene transcription. Rather, this compound inhibits IL-2–stimulated T-cell proliferation by blocking cell-cycle progression from late G_1 into S phase (Morice et al., 1993; Terada et al., 1993). Like FK506, RAP binds to the intracellular protein FKBP12. But this RAP–FKBP12 complex does not bind calcineurin. Moreover, until very recently, the actual target protein or proteins of this complex have remained elusive. Now it is clear that the RAP–FKBP12 complex binds to the mammalian target of rapamycin, mTOR (Sabers et al., 1995), also referred to as FRAP-1 and RAFT-1 (Brown et al., 1994; Sabatini et al., 1994). This protein, originally identified as two proteins (TOR-1 and TOR-2) in rapamycin-resistant yeast mutants (Kunz et al., 1993), has homology to the lipid kinase domain of the p110 catalytic subunit of phosphatidylinositol 3-kinase (PI3K, a biochemical signaling molecule) and VPS34 (a yeast PI3K). The function of the TOR proteins in cellular regulation (specifically cell-cycle progression) remains unknown at this time. Unlike both CsA and FK506, RAP does not appear to be nephrotoxic.

Leflunomide, an isoxazole derivative, is a relatively new drug that has shown promise as an immunosuppressive agent in the treatment of rheumatic disease and transplantation (Xiao et al., 1994). Experimentally, this agent can block the generation of allo-specific antibodies, decrease the mononuclear infiltrate in grafts undergoing rejection, and reverse acute graft rejections. It has been found to be equal to or better than CsA in its ability to inhibit B cell–mediated autoimmune disease. Early mechanistic studies indicate that leflunomide can directly inhibit B-cell proliferation (IC$_{50}$ £20 mM), and this may account for the drug's ability to inhibit both T-cell–dependent and T-cell–independent specific antibody production. Leflunomide also can inhibit T-cell proliferation (IC$_{50}$ = 50 to 75 mM) induced by mitogens or antibody directed against CD3 or IL-2. IL-2 production is also attenuated, but expression of the IL-2 receptor (CD25) is not altered. Biochemical analyses indicate that this drug can inhibit IL-2–dependent protein tyrosine kinase activity and suggest that the mechanism of T-cell inhibition may be at the level of T-cell responsiveness to IL-2. Although similar in broad terms, this mechanism of action is distinctly different from the mechanism of action of RAP.

Aids Therapeutics Traditionally, antiviral therapies have not been extremely successful in their attempt to rid the host of viral infection. This may be due to the fact that these organisms target the DNA of the host. Thus, eradication of the infection means killing infected cells. Although numerous strategies have been developed to combat the AIDS virus (primarily targeting viral reverse transcriptase or viral protease and up-regulation of other immune responses), no one drug has produced any significant advance. This is possibly because the very nature of the infection has significant immunosuppressive consequences. Without doubt, more basic scientific knowledge about the physiology and biochemistry of the virus is required before rational drug design will yield an effective therapeutic agent.

Zidovudine (3'-azido-3'-deoxythymidine; AZT) is a pyrimidine analog that inhibits viral reverse transcriptase. It was the first drug shown to have any clinical efficacy in the treatment of HIV-1 infection. Unfortunately, its use is limited by myelotoxicity (macrocytic anemia and granulocytopenia). Animal studies have confirmed that the primary action of AZT is on innate immunity, although changes in both humoral and cell-mediated immunity have also been observed. Clinically, AZT increases the number of circulating CD4$^+$ cells and can transiently stimulate cell-mediated immune responses (lymphoproliferation, NK activity, and IFN-g production).

Stavudine (2',3'-didehydro-2',3'-dideoxythymidine; d4T) is another pyrimidine analog currently in clinical trials. Unlike its sister drug AZT, the limiting toxicity appears to be peripheral neuropathy rather than myelotoxicity. In addition, d4T also appears to increase the number of circulating CD4$^+$ cells. Animal studies suggest that d4T does not modulate generation of CTL, NK activity, PFC responses, mitogenicity of lymphocytes, or lymphocyte subsets.

Zalcitabine (2',3'-dideoxycytidine; ddC) is a third pyrimidine analog which has recently been approved for use. Clinically, there appears to be an increase in circulating CD4$^+$ cells and some restoration of CMI in HIV-infected persons. There also appears to be no significant myelotoxicity and, like d4T, the limiting toxic effect of ddC is peripheral neuropathy. Investigations in animals revealed no significant effect on immune status.

Videx (2',3'-dideoxyinosine; ddI) is the first purine analog approved for use in HIV infection. In clinical trials, the dose-limiting toxicities were shown to be peripheral neuropathy and pancreatitis. There appears to also be an increase in circulating CD4$^+$ cells, some restoration of CMI, and a reversal of HIV-induced myelotoxicity. Although ddI is converted into ddA-TP, the use of ddA as an antiviral agent was ruled out due to severe nephrotoxic effects. In animal models, both ddI and ddA produce suppression of humoral immunity.

Recombinant DNA–Derived Proteins The development of therapeutic proteins for clinical use is an ever expanding arena for both large and small pharmaceutical and biotechnology companies (reviewed in Warner and Haggerty, 1997). In general, biologics (e.g., blood or vaccine products) and recombinant DNA–derived proteins are derived in some manner from living organisms. Because of the very nature of many of the recombinant DNA–derived proteins, the immune system is often the target not only of therapy but also of toxicity. Manifestations of toxicity include exaggerated pharmacology, effects due to receptor-biochemical cross-talk, and disruptions in immune regulation by cytokine networks. Monoclonal antibodies can bind normal as well as targeted tissues, and any foreign protein may elicit the production of neutralizing antibodies against the therapeutic protein (i.e., the therapeutic protein may be immunogenic). The effects of neutralizing antibodies may also lead to hypersensitivity reactions via either IgE production or immune complex disease, resulting from the activation of the complement cascade and the subsequent release of vasoactive amines that produce anaphylaxis. The majority of recombinant DNA–derived proteins have been used as immunostimulants; these include IFN-a, IFN-g, GM-CSF, and erythropoietin (EPO). Their immunopharmacology (and toxicity) has been reviewed extensively elsewhere (Talmadge and Dean, 1994). An excellent review of the toxicity associated with CTLA4Ig, anti-CD3, and anti-CD4 (for immunosuppression, transplantation, autoimmunity), and IL-12 (as a cancer therapeutic and an immuno-stimulant), along with other immune related issues in the development of therapeutic proteins is provided in Warner and Haggerty (1997).

Drugs of Abuse Drug abuse is a social issue with far-reaching effects on the abuser as well as on friends and family. While drug paraphernalia has been directly associated with the spread of the AIDS virus, in recent years the actual abuse of some drugs has been linked to the progression, and possibly the onset, of AIDS. Although definitive scientific proof of the hypothesis is lacking, drugs which are often abused have been shown to alter immunocompetence.

Cannabinoids Much attention has been focused on the immunomodulatory effects of the cannabinoids (D^9-tetrahydrocannabinol; THC) owing to the therapeutic potential of this drug in the treatment of glaucoma and as an antiemetic in patients undergoing cancer chemotherapy. Early studies showed that exposure to THC decreases host resistance to bacterial and viral pathogens (reviewed by Kaminski, 1994). In addition, cannabinoids alter both humoral and cell-mediated immune responses. Suppression of NK and CTL activity by THC appears to be related to an effect occurring subsequent to target-cell binding. THC exposure also alters macrophage morphology and some nonspecific functions, but the effects on accessory cell activities (e.g., antigen processing and presentation) are only beginning to be elucidated. Recently, it has been shown that THC increases aspartyl cathepsin D proteolytic activity and impairs lysosomal processing in the macrophage (Matveyeva et al., 2000). What is clear, however, is that the suppression of humoral immunity is exquisitely dependent upon the temporal association between exposure and antigen sensitization. Oral exposure to THC during the sensitization process (in vivo antigen administration) suppresses the PFC response to sRBC. In contrast, exposure to THC prior to sensitization (but not during the sensitization time) resulted in no observable effects on the PFC response. This may be one of the most critical factors influencing the reported effects of THC on immune responsiveness.

As in the in vivo situation, for in vitro THC exposure (Mishell-Dutton cultures), the drug must be added within 2 h of the addition of antigen in order to suppress the PFC response (Schatz et al., 1992). Also, humoral responses to T-cell–dependent antigens but not T-cell–independent antigens are suppressed by THC exposure. Together with the fact that T-cell proliferative responses are suppressed after THC exposure in vivo, this suggests that THC affects primarily T cells and may alter early T-cell activation events (e.g., biochemical signaling). Most recently, cannabinoid receptor transcripts have been identified in human spleen, tonsils, peripheral blood lymphocytes, and macrophages (Bouaboula et al., 1993; Munro et al., 1993). Additionally, murine splenocytes exhibit a high degree of saturable, specific binding of THC with a K_d approximating 1 nM and a B_{max} of about 1000 receptors per cell (Kaminski et al., 1992). An understanding of a potential role of this receptor in immune responses awaits identification of the endogenous ligand.

Cocaine Cocaine is a potent local anesthetic and central nervous system (CNS) stimulant. This drug and its derivatives have been shown to alter several measures of immunocompetence, including humoral and cell-mediated immune responses and host resistance (Watson et al., 1983; Ou et al., 1989; Starec et al., 1991). Functions of PMNs—including superoxide production and cell-surface receptor expression as well as inhibition of macrophage killing ability by decreasing the production of reactive oxygen intermediates—have been reported (Haines et al., 1990; Lefkowitz et al., 1993). Cocaine also induces the secretion of TGF-b, which has been linked

to the observation that cocaine exposure enhances replication of the HIV-1 virus in human peripheral blood mononuclear cells (PBMC) (Chao et al., 1991; Peterson et al., 1991). Hols-apple et al. (1993) evaluated the effect of in vitro cocaine exposure on the generation of an antibody response against sRBCs and found effects only at concentrations that were not clinically relevant (100 mM; lethal blood concentrations are estimated to be around 6 mM). These investigators postulated that the immunosuppressive effects of cocaine in vivo were mediated by P450-generated reactive intermediates; they subsequently demonstrated sex and strain differences in cocaine immunosuppressive activity, which correlated with well-characterized differences in metabolic capability in mice. Male B6C3F1 mice are more sensitive than females and DBA/2 females are more sensitive than B6C3F1 females.

Opioids: Heroin and Morphine Chronic morphine exposure has been associated with increased susceptibility to both bacterial and viral antigens (Arora et al., 1990; Chao et al., 1990), and it is clear that exposure to opioids can suppress immune responses. What is not clear, however, is whether this action is a direct effect of the drug on immune cells or an indirect effect resulting from drug-induced increases in circulating corticosteroids. Evaluation of the immunocompetence of heroin addicts revealed a decrease in total T cells and E-rosette capability (McDonough et al., 1980). In that study, treatment with naloxone reversed these effects, suggesting a role for an opioid receptor in mediating immune suppression. LeVier and coworkers (1994) reported that chronic morphine exposure decreased serum C3, NK activity, total leukocyte counts, the PFC response to sRBC, and RES clearance. However, because many of these effects were not dose-related (i.e., the dose–response curve was flat), the investigators concluded that these effects were not receptor-mediated but were the result of increased circulating corticosteroids (which were significantly elevated in those animals). This conclusion is supported by the findings of other investigators as well (Pruett et al., 1992b). Morphine-induced suppression of macrophage phagocytosis and cytokine production has also been reported (Eisenstein et al., 1993; Tubaro et al., 1987; LeVier et al., 1993). In the study by LeVier and colleagues (1993), the glucocorticoid antagonist RU-486 was utilized to demonstrate that while suppression of hepatic macrophage function may be due in part to a receptor-mediated event, inhibition of splenic macrophage activity was wholly receptor-independent. A review by Giorgio and colleagues (1996) eloquently describes a likely hypothesis (involving neuroendocrine immunologic mechanisms) for the dual effects observed with opioids as well as a few other compounds with similar effects.

Ethanol Until recently (reviewed by Jerrells and Pruett, 1994), data concerning the immunomodulatory effects of ethanol (EtOH) exposure have largely been based on clinical observations of alcoholic patients. A prime reason for this is that rodents (the animal model of choice for extensive immunologic evaluation) do not voluntarily consume intoxicating quantities of EtOH. Thus, the criteria for the development of animal models for EtOH exposure need to be refined to assure that clinically relevant blood levels are attained and long-term exposure can be assessed. In addition, the effect of acute exposure (binge drinking) needs to be further assessed.

In humans, alcoholism is associated with an increased incidence of pulmonary infection and mortality from it. There is also an increased incidence of bacterial infection and spontaneous bacteremia in alcoholics with cirrhosis of the liver. A consistent finding in abusers of EtOH is the significant change in the mononuclear cells of the peripheral blood. In animal models, this is observed as depletion of T and B cells in the spleen and the T cells in the thymus, particularly $CD4^+/CD8^+$ cells. The latter effect may be related in part to increased levels of corticosteroids.

There are also numerous indications that acute EtOH exposure can have profound immunodepressive consequences: decreased PMN chemotaxis, decreased host resistance, and inhibition of the PFC response. EtOH administration also inhibits mitogen-driven T-cell proliferation and T-cell responsiveness to IL-2. The actions of EtOH exposure on B-cell antibody production and NK-cell activity are still controversial.

Electromagnetic Fields Several epidemiologic studies have suggested an association (albeit very small) between low-frequency (LF) (<300 Hz) electromagnetic fields (EMF) and cancer. Other epidemiologic studies have found no association. In response to growing concern over the effects of LF EMF (<300 Hz) on human health, many studies have been conducted to assess their ability to alter immunocompetence. While some studies, using in vitro exposures of animal or human immune cells, have shown mixed results, a comprehensive evaluation of immunocompetence in mice (using the NTP tier approach) has demonstrated that exposure to LF EMF (60 Hz) for 28 or 90 days does not alter immunocompetence (House et al., 1996).

Ultraviolet Radiation The immunomodulatory effects of ultraviolet radiation (UVR) have been reviewed (IPCS, 1996). UVR has been demonstrated to suppress delayed hypersensitivity responses in both animals and humans and to result in decreased host resistance to infection. The dose of UVR required to suppress the immune response depends on the strain of mouse and the antigen being used. Interestingly, however, it appears that the dose of UVR is not as important to the observed immunosuppression as is the interval between irradiation and antigen exposure (Noonan and De Fabo, 1990). The mechanism of immunosuppression by UVR is not completely clear. Induction of suppressor T cells or alterations in homing patterns have been suggested as possibilities. One plausible explanation is that UVR induces a switch from a predominantly Th1 response (favoring delayed hypersensitivity responses) to a Th2 response (favoring antibody responses). This hypothesis is supported by findings of altered cytokine secretion patterns indicative of a Th1 to Th2 switch (Araneo et al., 1989; Simon et al., 1990). This switch may explain decreased resistance to some infectious pathogens. It may also be related to effects of UVR on Langerhans cells in the skin.

Food Additives Thirty-five food flavoring ingredients (generally recognized as safe) have been screened for potential immunotoxicity. Compounds were administered to mice by oral gavage for 5 consecutive days at multiple dose levels (Gaworski et al., 1994). In addition to body weights, lymphoid organ weights, and cellularity, humoral immunity (sRBC PFC response) and host resistance to *L. monocytogenes* were evaluated. Only two materials gave results suggestive of enhanced susceptibility to infection (peppermint oil and citral dimethyl acetal). Only one material exhibited suppression of humoral immunity (hexanoic acid), and suppression was observed only in the presence of overt toxicity.

Silicon-Based Materials Silicon-based materials have known uses in consumer products such as cosmetics, toiletries, food stuffs, household products, and paints as well as in the medical field (e.g., as lubricants in tubing and syringes and as components in numerous implantable devices). In recent years, significant interest has focused on the biocompatibility of certain silicon-based materials (silicones) and the potential for these products to produce immunotoxic effects. Despite the fact that there has been persistent, unsubstantiated speculation that breast implants made with silicone materials may provoke connective tissue disease, no link between exposure to silicones and human disease has been established. Recently, a committee formed by the Institute of Medicine has concluded that "a review of the toxicology studies of silicones and other substances known to be in breast implant does not provide a basis for health concerns." An extensive report by the IOM Committee, including additional conclusions and recommendations for research, is publicly available (IOM, 2000).

Numerous studies have been conducted that both support and refute the specific actions of various silicon-based materials on the immune system. Two studies have been reported that extensively evaluated immune status following exposure to dimethylpolysiloxanes used in medical practice (Bradley et al., 1944a,1944b). In the first study, mice were implanted for 10 days with dimethylpolysiloxane fluid, gel, and elastomer as well as polyurethane as a control. There were no observable alterations in innate or acquired immune function. In fact, the materials tested afforded modest protection to an approximate LD_{50} challenge with *L. monocytogenes*. Implantation of the same materials for 180 days resulted in a modest suppression of NK-cell activity that did not correlate with altered susceptibility to challenge with B16F10 melanoma. No alterations in host resistance have been observed.

Studies have also been conducted on two-low molecular- weight cyclic siloxanes: octamethylcyclotetrasiloxane and decamethylcyclotetrasiloxane. One-month inhalation exposures of rats to high concentrations of octamethylcyclotetrasiloxane (up to 540 ppm) and decamethylcyclotetrasiloxane (up to a maximum 160 ppm) did not result in alterations in humoral immunity (Burns-Naas et al., 1998; Klykken et al., 1999). Inhalation exposure of human volunteers to octamethylcyclotetrasiloxane at 10 ppm for 1 h revealed no effects on several immune parameters (Looney et al., 1998). Repeated oral exposure of rodents to octamethylcyclotetrasiloxane at high concentrations has been observed to produce immunomodulatory activity in both humoral and innate immunity; however, as with other chemicals, there are concentrations below which no immunomodulation is observed (LeVier et al., 1995; Wilson et al., 1995; Le and Munson, 1997; Munson et al., 1997; Munson, 1998).

Finally, under highly specific experimental conditions that do *not* mimic human exposure, a few silicon-based materials have been observed to act as immunologic adjuvants (reviewed in Potter and Rose, 1996, and IOM, 2000; Woolhiser et al., 1995). Under typical exposure conditions, neither octamethylcyclotetrasiloxane, a combination of octamethylcyclotetrasiloxane and decamethylcyclotetrasiloxane, nor dimethylpolysiloxane acts as an immunologic adjuvant (Bradley et al., 1994a,1994b; Klykken and White, 1996; Klykken et al., 1999; Vohr and Bomhard, 2000).

Immune-Mediated Disease

As stated earlier, the purpose of the immune system is to protect the individual from disease states, whether infectious, parasitic, or cancerous—through both cellular and humoral mechanisms. In so doing, the ability to distinguish "self" from "nonself" plays a predominant role. However, situations arise in which the individual's immune system responds in a manner producing tissue damage, resulting in a self-induced disease. These disease states fall into two categories (1) hypersensitivity, or allergy, and (2) autoimmunity. Figure 12-16 is a schematic delineating the possible cascade of effects that can occur when a chemical produces an immune-mediated disease. Hypersensitivity reactions result from the immune system responding in an exaggerated or inappropriate manner. These reactions have

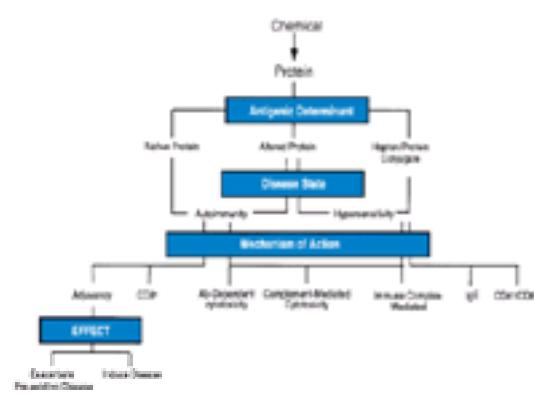
been subdivided by Coombs and Gell (1975) into four types, which represent four different mechanisms leading to tissue damage. In the case of autoimmunity, mechanisms of self-recognition break down and immunoglobulins and T-cell receptors react with self-antigens, resulting in tissue damage and disease.


Figure 12-16. Schematic diagram of chemical interaction leading to hypersensitivity reactions or autoimmunity.

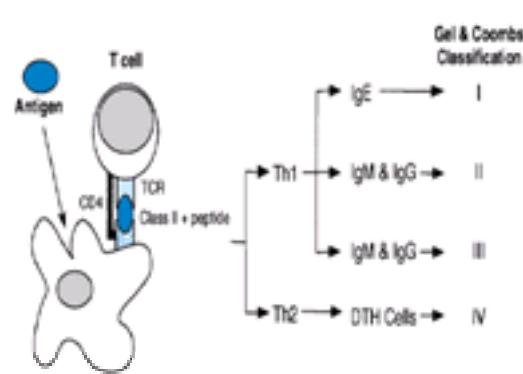
Hypersensitivity *Classification of Hypersensitivity Reactions* One characteristic common to all four types of hypersensitivity reactions is the necessity of prior exposure leading to sensitization in order to elicit a reaction upon subsequent challenge. In the case of types I, II and III, prior exposure to antigen leads to the production of specific antibody, IgE, IgM, or IgG, and, in the case of type IV, to the generation of memory T cells. Figure 12-17 illustrates the mechanisms of hypersensitivity reactions as classified by Coombs and Gell. Although not completely understood, regulation of immunoglobulin production is dependent in part on the characteristics of the antigen, the genetics of the individual, and environmental factors. The mechanisms of antibody production in hypersensitivity reactions are identical to those described earlier in the chapter (Fig. 12-7). A brief description of the four types of hypersensitivity reactions is presented below.


Figure 12-17. Schematic of classification of hypersensitivity reactions.

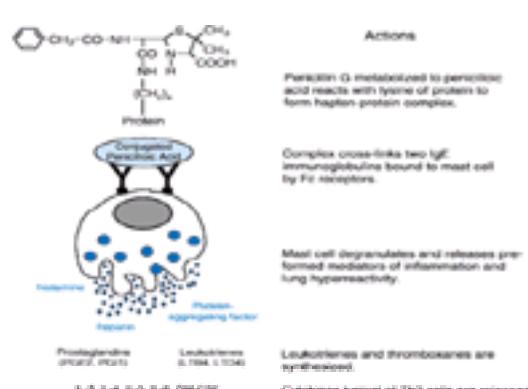
Type I (Immediate Hypersensitivity) Using penicillin as an example, Fig. 12-18 depicts the major events involved in a type I hypersensitivity reaction. Sensitization occurs as the result of exposure to appropriate antigens through the respiratory tract, dermally, or by exposure through the gastrointestinal tract. IgE production is highest in lymphatic tissues that drain sites of exposure (i.e., tonsils, bronchial lymph nodes, and intestinal lymphatic tissues, including Peyer's patches). It is low in the spleen. Serum concentration of IgE is low compared to other immunoglobulins, and serum half-life is short (Table 12-4). Once produced, IgE binds to local tissue mast cells before entering the circulation, where it binds to circulating mast cells, basophils, and tissue mast cells at distant sites. Once an individual is sensitized, reexposure to the antigen results in degranulation of the mast cells with the release of preformed mediators and cytokines typical of Th2 cells. Synthesis of leukotrienes and thromboxanes is also induced. These mediators promote vasodilation, bronchial constriction, and inflammation. Clinical manifestations can vary from urticarial skin reactions (wheals and flares) to signs of hay fever, including rhinitis and conjuctivitis, to more serious diseases, such as asthma and potentially life-threatening anaphylaxis. These responses may begin with-in minutes of reexposure to the offending antigen; therefore, type I hypersensitivity is often referred to as *immediate hypersensitivity*.


Figure 12-18. Schematic of type I hypersensitivity reaction.

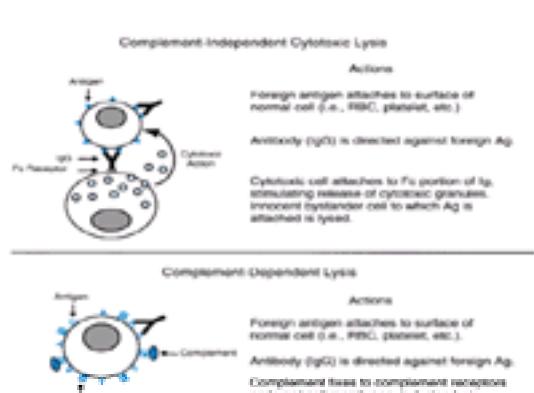
Type II (Antibody-Dependent Cytotoxic Hypersensitivity) Type II hypersensitivity is IgG-mediated. Figure 12-19 shows the mechanisms of action of a complement-independent cytotoxic reaction and complement-dependent lysis. Tissue damage may result from the direct action of cytotoxic cells—such as macrophages, neutrophils, or eosinophils—linked to immunoglobulin-coated target cells through the Fc receptor on the antibody or by antibody activation of the classic complement pathway. Complement activation may result in C3b or C3d binding to the target cell surface. This acts as a recognition site for effector cells. Alternatively, the C5b-9 membrane attack complex may be bound to the target cell surface, resulting in cell lysis (Fig. 12-3).


Figure 12-19. Schematic of type II hypersensitivity reactions.

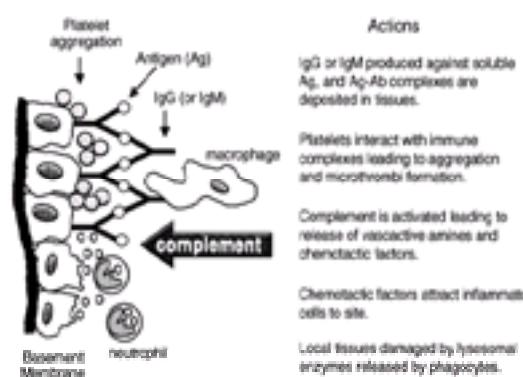
Type III (Immune Complex–Mediated Hypersensitivity) Type III hypersensitivity reactions also involve IgG immunoglobulins. The distinguishing feature of type III is that, unlike type II, in which immunoglobulin production is against specific tissue-associated antigen, immunoglobulin production is against soluble antigen in the serum (Fig. 12-20). This allows for the formation of circulating immune complexes composed of a lattice of antigen and immunoglobulin, which may result in widely distributed tissue damage in areas where immune complexes are deposited. The most common location is the vascular endothelium in the lung, joints, and kidneys. The skin and circulatory systems may also be involved. Pathology results from the inflammatory response initiated by the activation of complement. Macrophages, neutrophils, and platelets attracted to the deposition site contribute to the tissue damage.


Figure 12-20. Schematic of type III hypersensitivity reaction.

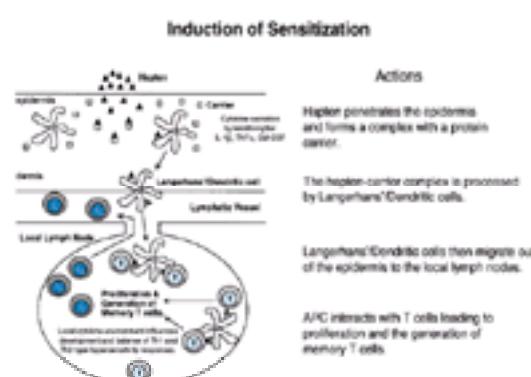
Type IV (Cell-Mediated Hypersensitivity) Type IV, or delayed-type hypersensitivity (DTH) responses, can be divided into two classes: contact hypersensitivity and tuberculin-type hypersensitivity. Contact hypersensitivity is initiated by topical exposure, and the associated pathology is primarily epidermal. It is characterized clinically by an eczematous reaction at the site of allergen contact and, like type I through III responses, consists of two phases: sensitization and elicitation. However, in this case sensitization is the result of the development of activated and memory T cells as opposed to antibody production (Fig. 12-21 and Fig. 12-22). Sensitization occurs when the hapten penetrates the epidermis and forms a complex with a protein carrier. The hapten–carrier complex is processed by Langerhans-dendritic cells that migrate out of the epidermis to the local lymph nodes. There, the APC presents the processed antigen to CD4 [+] T cells, leading to clonal expansion and the generation of memory T cells.


Figure 12-21. Schematic of sensitization phase of type IV hypersensitivity reaction.
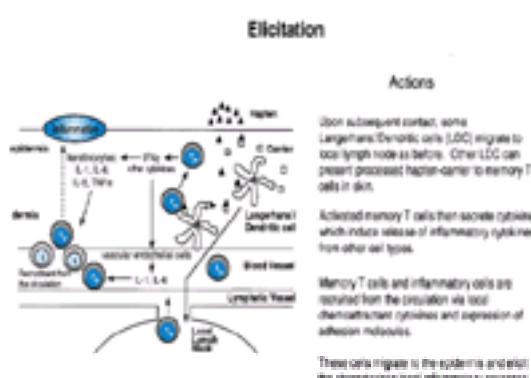

Figure 12-22. Schematic of elicitation phase of type IV hypersensitivity reaction.

Upon second contact, Langerhans-dendritic cells present the processed hapten–carrier complex to memory T cells in either the skin or the lymph nodes. These activated T cells then secrete cytokines that bring about further proliferation of T cells and induce the expression of adhesion molecules on the surface of keratinocytes and endothelial cells in the dermis. Both the expression of adhesion molecules and the secretion of proinflammatory cytokines by T cells and keratinocytes facilitate the movement of inflammatory cells into the skin, resulting in erythema and the formation of papules and vesicles. CD8 [+] cells may play a role in tissue damage. In cases where chemicals are lipid-soluble and can therefore readily cross the cell membrane, they can modify intracellular proteins. These cells then present modified peptides on their cell surface in conjunction with MCH class I molecules. CD8 [+] cells recognize these foreign peptides and cause tissue damage by either direct cytotoxic action or the secretion of cytokines that further promote the inflammatory response. The description given above has been the accepted dogma for the mechanism of delayed hypersensitivity for years. This is currently an area of intense research; a developing hypothesis for the elicitation phase of contact hypersensitivity involves a greater role for a non-specific inflammatory signal, CD8 [+] cells, and APCs other than Langerhans cells (Grabbe and Schwarz, 1998).

Tuberculin-type hypersensitivity is primarily a dermal reaction and begins following the intradermal injection of a specific antigen to which the individual has been previously exposed (such as a microbial antigen). Within hours, a cellular infiltrate (primarily CD4 [+] T cells) begins to appear. This infiltration continues as macrophages and Langerhans-dendritic cells begin to migrate into the area of injection. Circulation of immune cells to and from the local lymph nodes is thought to be like that in contact hypersensitivity. Also, like the contact hypersensitivity response, CD4 [+] T cells then secrete lymphokines that cause the expression of MHC class II on the surfaces of macrophages and keratinocytes. The result is activation of these cells, the release of proinflammatory mediators, and the generation of an area of firm red swelling in the dermal tissue.

Separation of hypersensitivity responses into the types I to IV as in the classification of Coombs and Gell is helpful in understanding mechanisms involved. It is important, however, to realize that this is a simplification and that often pathology is the result of a combination of these mechanisms. In addition, associated inflammation may be a non-immune acute response and/or the result of an immune-mediated event. For example, if one looks at the pathophysiology of respiratory

disease induced by the acid anhydrides, a mixture of immune and nonimmune events is found to be important. Direct toxic effects of the chemicals may lead to bronchial epithelial damage, causing cells to release cytokines that induce a nonimmune inflammatory response. Damage to epithelial cells may also expose underlying lamina propia, allowing the chemical to exert direct effects on inflammatory cells and to stimulate sensory vagal afferents, leading to reflex bronchoconstriction and hyperresponsiveness. Along with these non-immune mechanisms, all four classes of immune-mediated hypersensitivity responses to acid anhydrides have been shown to occur (Bernstein and Bernstein, 1994).

Assessment of Hypersensitivity Responses One of the most important and challenging problems in the field of immunotoxicology is determining the potential for chemicals to induce immunomodulation and, in the current context, to promote hypersensitivity reactions. Thus, it becomes essential to have validated predictive animal models and to understand the underlying mechanisms of action. The following is a review of the currently used methods of predicting types I and IV, the most frequently occurring hypersensitivity reactions to chemicals.

Assessment of Respiratory Hypersensitivity in Experimental Animals Methods for detecting pulmonary hypersensitivity have been reviewed by Sarlo and Karol (1994) and can be divided into two types: (1) those for detecting immunologic sensitization and (2) those for detecting pulmonary sensitization. In some cases the methodologies may overlap. In the case of types I to III, immunologic sensitization occurs when antigen-specific immunoglobulin is produced in response to exposure to an antigen or, in the case of type IV, when a population of sensitized T lymphocytes is produced. Pulmonary sensitization is determined by a change in respiratory function subsequent to the challenge of a sensitized animal or patient. In certain cases, immunologic sensitization may be confirmed by the detection of antigen-specific antibody; however, subsequent challenge does not produce clinical signs of respiratory distress. It is also possible to detect pulmonary sensitization in animal models where there is no detectable antigen-specific antibody production. In these cases, cell-mediated or other mechanisms may be involved or there may be a difficulty in antibody detection.

Guinea pig models have been most frequently used for detection of pulmonary reactions to chemicals. In the guinea pig, as in the human, the lung is the major shock organ for anaphylactic response. Like humans, the guinea pig also demonstrates immediate- and late-onset allergic reactions as well as bronchial hyperreactivity. The major difference in the mechanism of pulmonary responses between humans and guinea pigs is that the antibody involved in type I reactions in the former is IgE and in the latter is predominantly IgG1. Murine models are becoming more frequently utilized in the evaluation of respiratory hypersensitivity. As in the human, IgE is a major anaphylactogenic antibody in the mouse, and more murine immunologic reagents are available, allowing for more detailed mechanistic studies.

Methods utilized for respiratory exposure to chemicals are inhalation or either intranasal or intratracheal administration. There are advantages and disadvantages to each. Inhalation more closely represents environmental exposure by allowing for chemical contact with the upper as well as the lower respiratory tract. However, the equipment required is expensive and difficult to maintain. Exposure via the intranasal route is easily accomplished and allows for distribution of antigen to the upper and lower respiratory tract; however, studies have shown that a large proportion of the material can be recovered from the stomach (Robinson et al., 1996). In contrast, intratracheal instillation results in exposure to the lower respiratory tract only, and this procedure requires the use of anesthesia.

Immunologic sensitization may be determined by obtaining sequential blood samples throughout the induction period and measuring antibody titer. Pulmonary sensitization is evaluated by detecting the presence of pulmonary reactivity following challenge. This may be accomplished by visual inspection of the animals' respiratory pattern or more quantitatively by plethysmography. With plethysmography, changes in the respiratory rate, tidal volume, and plethysmographic pressure can be measured.

Inhalation models are generally used for low-molecular-weight compounds, whereas intratracheal and intranasal models are frequently used with high-molecular-weight compounds. One of the drawbacks of low-molecular-weight models is that often these compounds must conjugate with body proteins to become antigenic. Often, a challenge with the conjugated chemical is necessary to induce a pulmonary response. Adding this variable can make the analysis of test results more difficult. False negative results may occur due to variability in test article conjugation. Chemical conjugates are also necessary to measure immunologic response.

Assessment of IgE-Mediated Hypersensitivity Responses in Humans Described below are methods of human type I hypersensitivity testing. These test results, in conjunction with a relevant history and physical exam, can be diagnostic of IgE-mediated pulmonary disease. Two skin tests are available for immediate hypersensitivity testing. In both, the measured endpoint is a "wheal and flare" reaction—is the result of edema and erythema subsequent to the release of preformed mediators. The prick-puncture test introduces very small amounts of antigen under the skin and, owing to the reduced chance of systemic reaction, is recommended as a screening test. For test compounds not eliciting a reaction in the less sensitive test, the intradermal test using dilute concentrations of antigen may be used, but there is a higher risk of systemic reactions. For a more detailed description of testing methods see Demoly et al. 1998.

In vitro serologic tests, enzyme-linked immunosorbent assays (ELISAs), and radioallergosorbent tests (RASTs) may also be used to detect the presence of antigen-specific antibody in the patient's serum. These tests do not pose a risk of adverse reactions and may be used in situations where standardized reagents for skin testing are not available. Serologic testing is often used in population-based epidemiologic studies.

Bronchial provocation tests may be performed by having the patient inhale an antigen into the bronchial tree and evaluating his or her pulmonary response. In some cases this may be the only way to demonstrate that a test article is capable of producing an asthmatic response. Care must be taken in these test situations in that it is possible to produce severe asthmatic reactions or anaphylaxis in sensitized individuals.

Assessment of Contact Hypersensitivity in Experimental Animals Classically, the potential for a chemical to produce contact hypersensitivity has been assessed by the use of guinea pig models. These tests vary in their method of application of the test article, in the dosing schedule, and in the utilization of adjuvants. For a description of methods employed in representative tests, see Klecak (1987). The two most commonly utilized guinea pig models, the Büehler test (Büehler, 1965) and the guinea pig maximization test (Magnusson and Kligman, 1969), are described briefly below. In the Büehler test, the test article is applied to the shaven flank and covered with an occlusive bandage for 6 h. This procedure is repeated on days 7 and 14. On day 28, a challenge dose of the test article is applied to a shaven area on the opposite flank and covered with an occlusive dressing for 24 h. At 24 and 48 h after the patch is removed, test animals are compared with vehicle-treated controls for signs of edema and erythema. The guinea pig maximization test differs in that the test article is administered by intradermal injection, an adjuvant is employed, and irritating concentrations are used. Animals are given pairs of intradermal injections at a shaven area on the shoulders. One pair of injections contains adjuvant alone, one pair contains test article alone, and one pair contains the test article mixed with adjuvant. Seven days following injection, after the area is reshaven, the test article is applied topically and an occluded patch is applied for 48 h. In cases where the test article at the given concentration is non-irritating, the area is pretreated with 10% sodium lauryl sulfate 24 h before the patch is applied to produce a mild inflammatory response. Two weeks following topical application, the animals are challenged on the shaven flank with a non-irritating concentration of the test article, which remains under an occluded patch for 24 h. Then, after 24 and 48 h, the test site is examined for signs of erythema and edema. The endpoints for evaluation in the guinea pig assays are subjective and it is difficult to assess irritating or colored compounds using these models.

Over the past 15 years, efforts have been made to develop and validate more quantitative and immunologically based assay methods in other species, focusing mainly on the mouse and in vitro systems. Gad and coworkers (1986) developed the mouse ear-swelling test, which uses a quantitative measurement of ear thickness as an endpoint. Animals are sensitized by topical application of the test article for 4 consecutive days to abdominal skin that has been prepared by intradermal injection of adjuvant and tape stripping. On day 10, the animals are challenged by topical application of the test article to one ear and vehicle to the contralateral ear. Measurements are made of ear thickness 24 and 48 h later. A positive response is considered anything above a 20 percent increase in thickness of the treated ear over the control ear. Thorne and colleagues (1991) showed that dietary supplementation with vitamin A enhanced the mouse ear-swelling assay in the absence of adjuvants, injections, or occlusive patches.

The assays described above evaluate the elicitation phase of the response in previously sensitized animals. The mouse local lymph node assay has recently undergone peer review coordinated by the Interagency Coordinating Committee on the Validation of Alternative Methods and has been accepted by government agencies as a stand-alone alternative to the guinea pig assays for use in hazard identification of chemical sensitizers. In this assay, the induction phase of contact sensitization is measured by the incorporation of ^{3}H-thymidine into proliferating lymphocytes in lymph nodes draining the site where the test article has been applied. Animals are dosed by topical application of the test article to the ears for 3 consecutive days. The animals are rested for 2 days and then injected intravenously with 20 μCi of ^{3}H-thymidine. Five hours later, animals are sacrificed, the draining lymph nodes are dissected out, and single-cell suspensions are made and radioassayed. With consideration of dose response and statistical significance, a threefold increase in ^{3}H-thymidine counts in chemically exposed animals over vehicle control animals is considered to be a positive response. This assay offers several advantages over the guinea pig assays in that (1) has the potential to reduce the number of animals required and reduces animal distress; (2) it provides quantitative data that allow for statistical analysis; (3) and it provides dose–response data. Additionally, the assay evaluates the induction phase of the immune response, making it more applicable to mechanistic studies (NIH publication no. 99-44940). As an example, some compounds capable of producing contact sensitization also induce IgE production and subsequent respiratory hypersensitivity. Using three known allergenic

diisocyanates—diphenylmethane-4,4',-diisocyanate (MDI); dicyclohexylmethane-4,4'-diisocyanate (HMDI); and isophorone diisocyanate (IPDI)— Dearman and coworkers (1992) showed that all three known contact sensitizers induced lymphocyte proliferation in the draining lymph node but that only MDI, a known respiratory sensitizer, induced elevated levels of serum IgE and IgG2b. Attempts have been made to correlate cytokine levels produced by draining lymph node cells with contact and respiratory sensitizing potential.

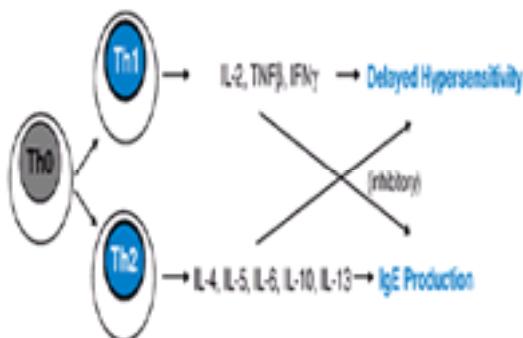
Antigens, once processed, are presented on the surface of the APC in conjunction with the MHC II antigen. Activation of either Th1 or Th2 cells stimulates the production of cytokines, which are instrumental in driving the system toward immunoglobulin production or the activation and proliferation of sensitized T cells (delayed-type hypersensitivity). The specific cytokines involved are shown in Fig. 12-23. IL-2, TNF-b, and IFN-g are produced by Th1 cells and lead to the development of delayed-type hypersensitivity, whereas IL-4, IL-5, IL-6, IL-10, and IL-13 are produced by Th2 cells and lead to the production of IgE (Mosmann et al., 1991). IFN-g not only promotes the induction of delayed hypersensitivity but also appears to have an inhibitory effect on IgE production (Mosmann and Coffman, 1989). Likewise, IL-10, which promotes IgE production, inhibits the delayed-type hypersensitivity response (Enk et al., 1993; Schwarz et al., 1994). Dearman and Kimber (1999) have demonstrated an elevation in INF-g but little IL-4 or IL-10 production in draining lymph nodes of animals exposed to contact allergens and, conversely, elevated production of IL-4 or IL-10 and little INF-g following exposure to chemical respiratory allergens. Measurement of cytokine levels may prove to be an important predictive tool for assessing the potential of chemicals to elicit hypersensitivity reactions.


Figure 12-23. Schematic of cytokines involved in hypersensitivity reactions.

Assessment of Contact Hypersensitivity in Humans Human testing for contact hypersensitivity reactions is by skin patch testing. Patch testing allows for the diagnostic production of acute lesions of contact hypersensitivity by the application of a suspected allergen to the skin. Patches containing specified concentrations of the allergen in the appropriate vehicle are applied under an occlusive patch for 48 h in most test protocols. Once the patch is removed and enough time elapses for the signs of mechanical irritation to resolve—approximately 30 min—the area is read for signs of erythema, papules, vesicles, and edema. Generally, the test is read again at 72 h and in some cases signs may not appear for up to 1 week or more. For more detailed information on patch testing, the reader is referred to Mydlarski et al. (1998).

Human repeat insult patch tests (HRIPT) are available as predictive tests in humans. Like predictive testing in animal models, there are many variations in attempts to increase the sensitivity of these procedures. These include preparation of the induction site by either stripping, the application of an irritating concentration of sodium lauryl sulfate, or use of high concentrations of the test article for induction of sensitization. In general, the application of multiple occlusive patches, up to ten for 48 h each at the same site, is followed by a rest period and then challenge under an occlusive patch at a different site. Positive reactions are scored in the same manner as for diagnostic patch tests.

Hypersensitivity Reactions to Xenobiotics *Polyisocyanates* Polyisocyanates have a widespread use in industry and are responsible for more cases of occupationally related lung disease than any other class of low-molecular-weight (LMW) compounds. These chemicals are used in the production of adhesives, paint hardeners, elastomers, and coatings. Occupational exposure is by inhalation and skin contact. Members of the group are known to induce the full spectrum of hypersensitivity responses, types I to IV, as well as nonimmune inflammatory and neuroreflex reactions in the lung (Bernstein and Bernstein, 1994; Grammer, 1985). Sensitized individuals have shown cross-reactivity between compounds in this group.

Toluene diisocyanate (TDI) is among the most widely used and most studied members of this group. Pulmonary sensitization to this compound can occur through either topical or inhalation exposure. It is a highly reactive compound that readily conjugates with endogenous protein. Laminin, a 70,000-kDa protein, has been identified as the protein that TDI conjugates in the airways. Studies with guinea pigs have confirmed the need for a threshold level of exposure to be reached in order to obtain pulmonary sensitization. This finding supports the human data in which pulmonary sensitization is frequently the result of exposure to a spill, whereas workers exposed to low levels of vapors for long periods of time fail to develop pulmonary sensitization. Unlike the case in many hypersensitivity reactions, where removal of the antigen allevi-ates the symptoms of disease, symptoms may persist for as long as years after cessation of exposure in many TDI-induced asthma patients.

Acid Anhydrides The acid anhydrides make up another group of compounds for which nonimmune and IgE, cytotoxic, immune complex, and cell-mediated reactions have been reported (Bernstein and Bernstein, 1994; Grammer, 1985). These reactive organic compounds are used in the manufacturing of paints, varnishes, coating materials, adhesives, and casting and sealing materials. Trimellitic acid anhydride (TMA) is one of the most widely used compounds in this group. Inhaled TMA fumes may conjugate with serum albumin or erythrocytes leading, to type I (TMA-asthma), type II (pulmonary disease–anemia), or type III (hypersensitivity pneumonitis) hypersensitivity reactions upon subsequent exposure. Topical exposure to TMA may lead to type IV hypersensitivity reactions, resulting in contact dermatitis. Also, re-exposure by inhalation may lead to a cell-mediated immune response in the lung, which plays a role in the pathology seen in conjunction with type II and III pulmonary disease. Human and animal testing has supported the clinical findings in TMA-exposed workers. Levels of serum IgE can be measured in exposed workers and are predictive of the occurrence of type I pulmonary reactions. Serum titers of IgA, IgG, and IgM have been detected in patients with high levels of exposure to TMA. Similar findings have been reported in studies with rhesus monkeys, in which exposed animals showed IgA, IgG, and IgM titers to TMA-haptenized erythrocytes. Inhalation studies with rats have produced a model corresponding to human TMA-induced pulmonary pneumonitis. Other anhydrides known to induce immune-mediated pulmonary disease include phthalic anhydride, himic anhydride, and hexahydrophthalic anhydride.

Metals Metals and metallic substances, including metallic salts, are responsible for producing contact and pulmonary hypersensitivity reactions. Metallic salts have been implicated in numerous immunologic and nonimmunologic pulmonary diseases. Exposure to these compounds may occur via inhalation or due to their solubility in aqueous media (they can be dissociated and transported into the lungs, where damage due to sensitization or nonimmunologic events takes place). Platinum, nickel, chromium, and cobalt are the most commonly implicated salts. For details the reader is referred to the reviews by Bernstein and Bernstein (1994), Menné (1987), and Marzulli and Maibach (1987).

PLATINUM Chlorplatinate salts are highly allergenic in comparison to other metalic salts. Exposure may occur in the mining and metallurgic industries, in chemical industries where platinum is used as a catalyst, and in the production of catalytic converters. Exposed workers are at risk of developing allergic rhinitis and asthma secondary to IgE production. Sensitized workers show positive skin tests and antigen-specific IgE by RAST testing.

COBALT Five percent of workers exposed to cobalt develop occupational asthma. These patients exhibit antigen-specific IgE, and their lymphocytes proliferate in response to free cobalt or cobalt conjugated to human serum albumin.

NICKEL Although nickel is a common contact sensitizer, pulmonary hypersensitivity reactions to nickel salts are rare. Occupational exposure to nickel is most common in the mining, milling, smelting, and refinishing industries. When they occur, pulmonary reactions are most frequently due to a direct toxic effect on the CNS and lung tissues. In addition to industrial contact, exposure occurs in the form of jewelry, coins, and fasteners on clothing, making nickel one of the most frequently contacted sensitizers for the general population. Studies have shown nickel sulfate to be the most frequent sensitizer when standard tray sensitizers are used, with positive results being between 6.7 and 11 percent. Nickel appears to require a long sensitization period, and studies have shown that patients may lose their hypersensitivity to nickel after long periods of avoidance.

CHROMIUM Chromium is another metal often associated with dermatoses and less frequently with respiratory disease. Occupational exposure to chromium is most frequent in industries involved in electroplating processes, leather tanning, and paint, cement, and paper pulp production. Chromium eczema (type IV hypersensitivity) is among the most common occupationally associated skin diseases. Predictive tests on normal human subjects have shown sensitization rates to chromium sulfate as high as 48 percent. Occupational asthma from chromium exposure is less well documented, and skin-prick tests have been negative. Evidence of IgE-mediated disease has been supported by immediate bronchial hyperreactivity after challenge and the identification of antigen-specific IgE antibodies. Cell-mediated (type IV) reactions have been postulated to play a role, since late asthmatic reactions following bronchial challenge have been seen.

BERYLLIUM Beryllium is a metal capable of producing both contact and tuberculin type IV hypersensitivity reactions. The role of CMI in beryllium-induced disease has been reviewed by Newman (1994). Beryllium exposure occurs most frequently in the aerospace industry, in high-technology ceramics and dental alloy manufacturing, and in the electronics, nuclear weapons, and nuclear reactors industries. A major source of exposure was in the production of fluorescent light bulbs until the discontinuance of its use for this purpose. Skin contact has been found to produce lesions of contact hypersensitivity, whereas lesions produced by penetration of splinters of beryllium under the skin are granulomatous in nature. Inhalation of beryllium can result in disease ranging from acute pneumonitis, tracheobronchitis, and chronic beryllium disease to an increase in the risk of lung cancer. Environmentally induced berylliosis was evidenced by the incidence of disease in non-factory workers in communities around beryllium extraction plants. Exposure resulted from emissions from plants and contact with beryllium-contaminated family members' clothing.

In cases of chronic beryllium disease, there is often a latent period of up to 10 years following first exposure. Lung pathology consists of multiple granulomas with mononuclear cell infiltrates—primarily macrophages, lymphocytes, and plasma cells—and fibrosis. Although lesions are usually localized in the lungs and associated lymph nodes, granulomatous involvement of other organs has been seen. As pulmonary disease progresses, effects on pulmonary circulation may lead to right-sided heart failure. Death due to berylliosis may then be due to respiratory or cardiac failure.

Unlike most hypersensitivity reactions in which removal from exposure to the offending agent usually abates the disease, removal from beryllium exposure does little to alter the course of the disease. Although the majority of beryllium is eliminated from the lung soon after inhalation, small amounts of retained beryllium are sufficient to induce and sustain the ongoing cellular immune response. Years after the last exposure, mass absorption data have shown beryllium to be present in lung granulomas.

Owing to the similarities in clinical symptoms and pathology between berylliosis and other granulomatous lung diseases, immunologic testing is important in definitive diagnosis. Patients with beryllium disease tested positive to patch testing with beryllium salt and often showed granulomatous lesions at the patch-test site within 3 weeks. However, these test procedures proved to be unsafe. Patch tests were found to induce sensitization in some patients and often caused exacerbation of lung disease. The beryllium-specific lymphocyte proliferation test (BeLT) has been utilized to detect beryllium sensitization. This test has proven to be a more sensitive indicator of early disease than patient history, physical exam, chest radiographs, or lung function test. Although this disease is not curable, progression of the disease process can be slowed by corticosteriod therapy. BeLT allows for earlier detection of sensitization. This results in improved patient monitoring and permits earlier institution of treatment. In industry, BeLT provides a means of detecting jobs with a high risk of exposure.

Drugs Hypersensitivity responses to drugs are among the major types of unpredictable drug reactions, accounting for up to 10 percent of all adverse effects. Drugs are designed to be reactive in the body and multiple treatments are common. This type of exposure is conducive to producing an immunologic reaction. Immunologic mechanisms of hypersensitivity reactions to drugs include types I through IV. For a detailed review of drug allergy see DeSwarte (1985). Penicillin is the most common agent involved in drug allergy and is discussed here as an example. Exposure to penicillin is responsible for 75 percent of the deaths due to anaphylaxis in the United States. The route of administration, dosage, and length of treatment all appear to play a role in the type and severity of hypersensitivity reaction elicited. Severe reactions are less likely following oral administration as compared to parenteral, and prolonged treatment with high doses increases the risk of acute interstitial nephritis and immune hemolytic anemia. The high incidence of allergic reaction to penicillin is in part due to widespread exposure to the compound. Not only has there been indiscriminant use of the drug, but exposure occurs through food products including milk from treated animals and the use of penicillin as an antimicrobial in the production of vaccines. Efforts have been made to reduce unnecessary exposure.

Reactions to penicillin are varied and may include any of the four types of hypersensitivity reactions. The most commonly seen clinical manifestation of type I reactions is urticaria; however, anaphylactic reactions occur in about 10 to 40 of every 100,000 patients receiving injections. Clinical signs of rhinitis and asthma are much less frequently observed. Blood dyscrasias can occur due to the production of IgG against penicillin metabolites bound to the surface of red blood cells (type II reaction). Penicillin has also been implicated in type III reactions leading to serum-sickness-like symptoms. Owing to the high frequency of type IV reactions when penicillin is applied topically, especially to inflamed or abraded skin, products are no longer available for topical application. Type IV reactions generally result in an eczematous skin reaction, but—infrequently—a life-threatening form of dermal necrosis may result. In these cases there is severe erythema and a separation of the epidermis at the basal layer. This reaction, which gives the clinical appearance of severe scalding, is thought to be a severe delayed reaction.

Pesticides Pesticides have been implicated as causal agents in both contact and immediate hypersensitivity reactions. Definitive diagnosis is often difficult or lacking in reported cases and animal and human predictive data often do not correlate well. Pesticide hypersensitivity responses have been reviewed by Thomas and coworkers (1990) and are described briefly below.

One of the difficulties in obtaining good epidemiologic data to document reactions to pesticides is the nature of exposure. Agricultural workers are among those most commonly exposed, and the fact that workers are exposed to multiple chemicals as well as harsh environmental factors makes diagnosis difficult. Furthermore, diagnostic follow-up among this group is infrequent.

In the case of barban, a carbamate insecticide, the reported incidence of contact sensitivity due to exposure is rare; however, predictive testing with the guinea pig maximization test (GPMT) and the diagnostic human patch test indicates that this pesticide is a potent sensitizer. Likewise, malathion, captan, benomyl, maneb, and naled have been identified as strong to extreme sensitizers using the GPMT. Human predictive data, diagnostic patch testing, and the reported incidence in the literature of toxicity with the use of these compounds are often not in agreement with the animal data.

Pesticides have been implicated in cases of immediate hypersensitivity, including rhinitis, conjunctivitis, asthma, and anaphylaxis. However, there has been no definitive proof of the association. It is possible that observed reactions are of an irritant nature rather than being an immunologic response. It has been shown that the asthmatic response to organophosphate insecticides is not due to the acetylcholinesterase activity, since the administration of atropine, a cholinergic antagonist, failed to block the response. Animal studies show some evidence to support the role of immediate hypersensitivity responses to pesticides. Mice injected intraperitoneally with malathion or 2,4-dichlorophenoxyacetic acid conjugates developed IgE antibody. However, antibody was not detected to these chemicals when they were applied topically. More epidemiologic and mechanistic studies are needed in the area of pesticide hypersensitivity to further define these relationships.

Others NATURAL RUBBER LATEX PRODUCTS Allergic reactions to natural rubber latex products have become an important occupational health concern over the past decade. Natural rubber latex is derived from the rubber tree *Hevea brasiliensis* and is used in the manufacture of over 40,000 products including examination and surgical gloves, among other medical products. Dermatologic reactions to latex include irritant dermatitis due to chemical additives or mechanical abrasion and the occlusive conditions caused by wearing gloves; contact dermatitis (which represents approximately 80 percent of the allergic responses) due to the chemical additives used in the glove manufacturing (e.g., thiurams, carbamates, mercapto compounds, and phenylenediamines), and potentially more serious IgE-mediated responses due to residual latex proteins that remained in the finished products. The IgE responses may manifest as urticaria, asthma, or life-threatening anaphylaxis. For a review of latex allergy, see Germolec (1999).

COSMETICS AND PERSONAL HYGIENE PRODUCTS Contact dermatitis and dermatoconjuctivitis may result from exposure to many cosmetic and personal hygiene products, including makeup, deodorants, hair sprays, hair dyes and permanent-waving solutions, nail polish, soaps, face creams, and shampoos (Liberman et al., 1985). These agents contain coloring agents, lanolin, paraffin, petrolatum, vehicles, perfumes, and antimicrobials such as paraben esters, sorbic acid, phenolics, organic mercurials, quaternary ammonium compounds, EDTA, and formaldehyde. The devices used to apply these products may also induce allergic reactions. Diagnosis may be accomplished by patch testing; however, in patch testing, it is often necessary to employ products used by the patient in addition to those on a standard test tray. In cases of dermatoconjunctivitis, false-negative testing may occur. The skin of the eyelids may be more sensitive to agents than that of the forearm or back, making patch testing unreliable. Elimination-provocation procedures may be helpful in the diagnosis of difficult cases. All suspect offending agents must be removed from the patient's environment. Once clinical signs have resolved, agents may be reintroduced one at a time while the patient is observed for the recurrence of signs.

ENZYMES Enzymes are another group capable of eliciting type I hypersensitivity responses (Gutman, 1985). Subtilin, a proteolytic enzyme derived from *Bacillus subtilis,* is used in laundry detergents to enhance their cleaning ability. Both individuals working in the environment where the product is made and those using the product may become sensitized. Subsequent exposure may produce signs of rhinitis, conjunctivitis, and asthma. An alveolar hypersensitivity reaction associated with precipitation antibodies and an Arthus-type reaction from skin testing has also been seen. Papain is another enzyme known to induce IgE-mediated disease. It is a high-molecular-weight sulfhydryl protease obtained from the fruit of the papaya tree and most commonly used as a meat tenderizer and a clearing agent in the production of beer. However, it is also used in the production of tooth powders, laxatives, and contact-lens cleaning solutions.

FORMALDEHYDE Formaldehyde was discussed above as one of the components of cosmetics capable of causing a contact hypersensitivity reaction. Formaldehyde exposure also occurs in the textile industry, where it is used to improve wrinkle resistance, and in the furniture, auto upholstery, and resins industries. The general public may be exposed to low levels of formaldehyde in products as ubiquitous as newspaper dyes and photographic films and paper. This low-molecular-weight compound is extremely soluble in water and haptenates human proteins easily (Maibach, 1983). Human predictive testing with 1 to 10% formalin (formalin is 37% formaldehyde) for induction and 1% formalin for challenge showed sensitization rates of 4.5 to 7.8 percent (Marzulli and Maibach, 1974). Occupational exposure to formaldehyde has been associated with the occurrence of asthma, although it has been difficult to demonstrate antibodies to formaldehyde in the affected individuals (Hendrick et al., 1982).

For further information and a listing of chemicals known to cause hypersensitivity reactions affecting the respiratory system and skin, see Chap. 15 and Chap. 19.

Autoimmunity In the section on hypersensitivity presented above, we discussed two mechanisms, types II and III, by which host tissues are damaged by the host's own immune system, creating autoimmune-like disease. In these situations, unaltered self antigens are not the target of the immune mechanisms but damage occurs to cells bearing hapten on membranes or to innocent bystander cells in close proximity to antigen-antibody complexes. For example, damage produced in autoimmune Goodpasture's disease is similar to that seen in type III hypersensitivity reactions in the lung due to TMA. Although the resulting pathology may be the same for autoimmune reactions and hypersensitivity, mechanisms of true autoimmune disease are distinguished from hypersensitivity. In cases of autoimmunity, self antigens are the target, and in the case of chemical-induced autoimmunity, is the disease state is induced by a modification of host tissues or immune cells by the chemical and not the chemical acting as an antigen/hapten.

Mechanisms of Autoimmunity The immunopathogenesis of autoimmune disease has been reviewed by Rose (1994) and is described briefly below as background information for understanding how chemicals may induce autoimmunity. Three types of molecules are involved in the process of self-recognition: immunoglobulins (Igs), T-cell receptors (TCRs), and the products of major histocompatibility complex (MHC). Igs and TCRs are expressed clonally on B and T cells, respectively, whereas MHC molecules are present on all nucleated cells. The ability of lymphocytes to distinguish one molecule from another stems from the antigen binding a specific lymphocyte receptor. In B-cell lines, through rearrangement of heavy and light Ig chains, tremendous diversity (10^6 to 10^7 specificities), occurs among Ig recognition structures. Likewise, a similar number of specific TCRs are produced as the result of gene rearrangement in T cells induced by peptide hormones produced by thymic epithelial cells. Two major types of B and T cells are produced. B cells expressing CD5 predominate in embryonic life and are later found mostly in the intestinal mucosa. These cells produce high levels of IgM, and much of it is autoantibody. Although most B cells do not express CD5 prior to class switching, they do express high levels of IgM. Influenced by cytokines produced by interacting T cells following antigen stimulation, these cells produce primarily IgG, IgA, or IgE. Similarly, T cells develop from one of two lineages—those with abTCRs and those with gdTCRs. Although most mature T cells express abTCRs, gdTCRs are predominant on mucosal surfaces. As described earlier in the chapter, abTCRs continue differentiation into CD4$^+$ or CD8$^+$ T cells. CD4$^+$ cells have primarily helper and inducer functions and recognize antigens in the context of MHC class II molecules. CD8$^+$ T lymphocytes are mainly cytotoxic cells and recognize antigenic determinants in conjunction with MHC class I molecules.

The process of negative selection against autoreactive T cells in the thymus is important in the prevention of autoimmune disease. T cells expressing abTCRs that fit self MHC molecules with high affinity undergo apoptosis (programmed cell death) at an accelerated rate, whereas those with a low affinity for self antigen and a high affinity for foreign antigen undergo positive selection and proliferate in the thymus, eventually migrating to the peripheral lymphatics. Although negative selection greatly reduces the numbers of self-reactive T cells, some of these cells do leave the thymus and remain in circulation in a state of anergy. These cells are able to bind their designated antigen but do not undergo proliferation owing to a lack of necessary second signal. This second signal is generally provided by an APC in the form of a cytokine, IL-2, or a cell surface receptor that interacts with the T cell.

Reactive CD4$^+$ T cells recognize only processed antigen presented by APCs—generally macrophages, B cells, or dendritic cells—in conjunction with MHC class II molecules. These APCs take up exogenous antigens, cleave them with proteolytic enzymes, and express them on their cell surfaces. In contrast, intracellular antigens are processed and presented on cell surfaces in conjunction with MHC class I molecules. These antigens may be the products of malignant or normal cells or may result from infection with bacterial, viral, or other intracellular pathogens. The processed antigen–MHC class I complex is recognized by a specific TCR on a CD8$^+$ lymphocyte.

Several mechanisms are available that may break down self-tolerance, leading to autoimmunity. The first is exposure to antigens not available in the thymus during embryonic development. Therefore, the antigen-specific T cell–reactive lymphocytes not subjected to negative selection could induce an autoimmune reaction. Examples include myelin and organ-specific antigens such as thyroglobulin. Breakdown of self-tolerance to these antigens may be induced by exposure to adjuvants or to another antigenically related protein. The second is the overcoming of T-cell anergy by chronic lymphocyte stimulation. Finally, there is interference with normal immunoregulation by CD8$^+$ T cell suppressor cells, which may create an environment conducive to the development of autoimmune disease.

Effector mechanisms involved in autoimmune disease can be the same as those described earlier for types II and III hypersensitivity or, in the case of pathology associated with solid tissues, including organs, they may involve CD8$^+$ cytotoxic T cells. Tissue damage associated with CD8$^+$ cells may be the result of direct cell-membrane damage and lysis induced by binding or the results of cytokines produced and released by the T cell. TN-b has the ability to kill susceptible cells and IFN-g may increase the expression of MHC class I on cell surfaces, making them more susceptible to CD8$^+$ cells. Cytokines may also be chemotactic for macrophages, which can cause tissue damage directly or indirectly through the release of proinflammatory cytokines. As is the case with hypersensitivity reactions, autoimmune disease is often the result of more than one mechanism working simultaneously. Therefore, pathology may be the result of antibody-dependent cytotoxicity, complement-dependent antibody-mediated lysis, or direct or indirect effects of cytotoxic T cells.

Genetic and environmental factors appear to affect the susceptibility of individuals to autoimmune disease. Familial predisposition to autoimmune disease has been found, as well as a similarity in MHC genetic traits among individuals involved. Certain chemicals and drugs are known to induce autoimmune disease in genetically predisposed individuals, and examples of these are discussed below. The role of environmental pollutants is uncertain; more study is needed in this area. One point of interest is that in all known cases of drug-induced autoimmunity, the disease has abated once the offending chemical was removed.

Assessment of Autoimmune Responses Few models are available for accessing the potential of a chemical to induce autoimmune disease, and these have major limitations. The most commonly used models include graft-versus-host disease (GVHD), the popliteal lymph node (PLN) model in mice, and human lymphocyte transformation assays. Although these models may have some predictive value, at this point immunohistopathology is the only definitive diagnostic tool.

There are numerous reports of chemicals that have been associated with autoimmunity. These relationships may be causative through direct mechanisms or they may be indirect, acting as an adjuvant. They may also serve to exacerbate a preexisting autoimmune state (reviewed by Kilburn and Warshaw, 1994; Coleman and Sim, 1994). In the area of autoimmunity, exact mechanisms of action are not always known. Table 12-11 lists chemicals known to be associated with autoimmunity, showing the proposed self-antigenic determinant or stating adjuvancy as the mechanism of action. A brief discussion of selected drug and nondrug chemicals is provided.

Table 12-11 Chemical Agents Known to be Associated with Autoimmunity

PROPOSED MECHANISM/CHEMICAL	CLINICAL MANIFESTATION	DETERMINANT	REFERENCE
Drugs			
Methyldopa	Hemolytic anemia	Rbc antigens	Murphy and Kelton (1991)
Hydralazine	SLE-like syndrome	Myeloperoxidase	Cambridge et al. (1994)
Isoniazid	SLE-like syndrome	Myeloperoxidase	Jiang et al. (1994)
Procainamide	SLE-like syndrome	DNA	Totoritis et al. (1988)
Halothane	Autoimmune hepatitis	Liver microsomal proteins	Kenna et al. (1987)
Nondrug chemicals			
Vinyl Chloride	Scleroderma-like syndrome	Abnormal protein synthesized in liver	Ward et al. (1976)
Mercury	Glomerular neropathy	Glomerular basement membrane protein	Pelletier et al. (1994)
Silica	Scleroderma	Most likely acts as an adjuvant	Pernis and Paronetto (1962)

Autoimmune Reactions to Xenobiotics *Methyldopa* Methyldopa is a centrally acting sympatholytic drug that has been widely used for the treatment of essential hypertension. With the advent of newer antihypertensive drugs, the use of methyldopa has declined. Platelets and erythrocytes are targeted by the immune system in individuals treated with this drug. In the case of thrombocytopenia, antibodies are detected against platelets, which is indicative of immune recognition of a self- or altered self-antigen. Hemolytic anemia occurs in at least 1 percent of individuals treated with methyldopa, and up to 30 percent of these individuals develop antibodies to erythrocytes as manifest in a positive Coombs test. The antibodies are not directed against the chemical or a chemical membrane conjugate.

Hydralazine, Isoniazid, and Procainamide Hydralazine, isoniazid, and procainamide produce autoimmunity, which is manifest as a sytemic lupus erythematosus (SLE)-like syndrome. Antibodies to DNA have been detected in individuals showing this syndrome. Hydralazine is a direct-acting vasodilator drug used in the treatment of hypertension. Isoniazid is an antimicrobial drug used in the treatment of tuberculosis. Procainamide is a drug that selectively blocks Na $^+$ channels in myocardial membranes, making it useful in the treatment of cardiac arrhythmias. Studies with hydralazine and isoniazid indicate that the antigenic determinant is myeloperoxidase. Immunoglobulins are produced against myeloperoxidase in individuals treated with these drugs. DNA is the apparent antigenic determinant for procainamide. For these three drugs, there is no evidence indicating that the immune system is recognizing the chemical or a chemical conjugate. In addition, these drugs have also been shown to produce hypersensitivity responses not associated with the SLE syndrome.

Halothane Halothane, one of the most widely studied of the drugs inducing autoimmunity, is an inhalation anesthetic that can induce autoimmune hepatitis. The incidence of this iatrogenic disease in humans is about 1 in 20,000. The pathogenesis of the hepatitis results from the chemical altering self (a specific liver protein) to such a degree that the immune system recognizes the altered self and antibodies are produced. Studies using rat microsomes show that halothane has to be oxidized by cytochrome P450 enzymes to trifluoroacetylhalide before it binds to the protein. Investigations indicate that in affected individuals antibodies to specific microsomal proteins are produced.

Vinyl Chloride Vinyl chloride, which is used in the plastics industry as a refrigerant and in the synthesis of organic chemicals, is a known carcinogen and is also associated with a scleroderma-like syndrome. The disease affects multisystemic collagenous tissues, manifesting itself as pulmonary fibrosis, skin sclerosis, and/or fibrosis of the liver and spleen. Ward and coworkers (1976) reported on 320 exposed workers, showing that 58 (18 percent) had a scleroderma-like syndrome. The individuals who showed the disease were in a group genetically similar (i.e., HLA-DR5) to patients with classic idiopathic scleroderma patients. Although the exact mechanism whereby this chemical produces autoimmunity is unclear, it is presumed that vinyl chloride acts as an amino acid and is incorporated into protein. Because this would produce a structurally abnormal protein, which would be antigenic, an immune response would be directed against tissues with the modified protein present.

Mercury This widely used metal is now known to have several target systems, including CNS and renal system. Mercury also has two different actions with respect to the immune system. The first action is direct injury, described previously. Mercury also produces an autoimmune disease demonstrated as glomerular nephropathy. Antibodies produced to laminin are believed to be responsible for damage to the basement membrane of the kidney. Mice and rats exposed to mercury also show antinuclear antibodies. The role of these antibodies in the autoimmune disease is not clear. However, they represent a known biomarker of autoimmunity. Studies in the brown Norway rat point to a mercury-induced autoreactive CD4$^+$ cell as being responsible for the polyclonal antibody response. Mercury chloride induces an increase in the expression of MHC class II molecules on B lymphocytes as well as shifting the T helper cell population along the Th2 line. It is the Th2 cell that promotes antibody production. The imbalance between Th1 and Th2 cells is believed to be caused by the depletion of cysteine and the reduced form of gluthathione in Th1 cells. These chemical groups are known to be important in the synthesis of and responsiveness to IL-2 in T cells. Thus, Th1 cells that synthesize and respond to IL-2 would be at a greater risk than Th2 cells.

Mercury-induced autoimmunity has a strong genetic component. This has been extensively studied in the rat. Some strains of rats, such as the Lewis rat, are completely resistant, while others, such as the brown Norway, are exquisitely sensitive. Susceptibility appears to be linked to three or four genes, one of which is the major histocompatibility complex. An excellent review of mercury and autoimmunity is provided by Pelletier and coworkers. (1994).

Silica Crystalline silica (silicon dioxide) is a primary source of elemental silicon and is used commercially in large quantities as a constituent of building materials, ceramics, concretes, and glasses. Experimental animals as well as humans exposed to silica may have perturbations in the immune system. Depending on the length of exposure, dose, and route of administration of silica, it may kill macrophages or may act as an immunostimulant. Silica has been shown to be associated with an increase in scleroderma in silica-exposed workers (reviewed by Kilburn and Warshaw, 1994). This effect is believed to be mediated via an adjuvant mechanism. Adjuvancy as a mechanism of causing autoimmunity has been implicated with a number of other chemicals, including paraffin and silicones. Inherent in adjuvancy as a mechanism of producing autoimmunity is that the population affected by these chemicals must already be at risk for the autoimmune disease. This is supported by the data indicating a genetic component to many autoimmune diseases.

Table 12-12 shows chemicals that have been implicated in autoimmune reactions, but in these cases the mechanism of autoimmunity has not been as clearly defined or confirmed. The list includes both drug and nondrug chemicals. The heterogeneity of these structures and biological activities illustrate the breadth of potential for the induction of chemically mediated autoimmune disease.

Table 12-12 Chemicals Implicated in Autoimmunity

MANIFESTATION	IMPLICATED CHEMICAL	REFERENCE
Scleroderma	Solvents (toluene, xylene)	Walder (1965)
	Tryptophan	Silver et al. (1990)
	Silicones	Feck et al. (1984)
Systemic lupus erythematosus	Phenothiazines	Canoso et al. (1990)
	Penicillamine	Harpey et al. (1971)
	Propylthiouracil	DeSwarte (1985)
	Quinidine	Jiang et al. (1994)
	l-dopa	DeSwarte (1985)
	Lithium carbonate	Ananth et al. (1989)
	Trichloroethylene	Kilburn and Warshaw (1992)
	Silicones	Feck et al. (1984)

Multiple Chemical Sensitivity Syndrome Multiple chemical sensitivity syndrome (MCS) has been associated with hypersensitivity responses to chemicals. The disease associated with MCS is characterized by multiple subjective symptoms related to more than one system. The more common symptoms are nasal congestion, headaches, lack of concentration, fatigue, and memory loss. Many mechanisms have been suggested to explain how chemicals cause these symptoms; however, there remains considerable controversy as to a cause–effect relationship. Clinical ecologists, the major proponents of MCS, have focused on immunologic

mechanisms to explain the etiology. They hypothesize that MCS occurs when chemical exposure sensitizes certain individuals, and, upon subsequent exposure to exceedingly small amounts of these or unrelated chemicals, the individual exhibits an adverse response. Controlled studies on the immunologic status of individuals with MCS have shown no alterations in their immune system or any indication that MCS results from impairment of the immunity, including inappropriate immune response to chemicals. The search for a theoretical basis for MCS is now being focused on the nervous system. Two untested hypotheses have emerged. The first involves a nonspecific inflammatory response to low-level irritants known as "neurogenic inflammation." The second involves induction of lasting changes in limbic and neuronal activity (via kindling) that alter a broad spectrum of behavioral and physiologic functions. The reader is referred to a review by Sikorski and colleagues (1995) for details and references concerning MCS.

NEW FRONTIERS AND CHALLENGES

Immunotoxicology has grown significantly since its beginnings as a recognized subdiscipline of toxicology in the late 1970s. Early work focused on the development of methods that were sensitive and predictive and on an understanding of xenobiotic-induced immunomodulation—in particular, immunosuppression. With unprecedented growth in the understanding of immune regulation (brought about in the 1980s as a result of the emergence of AIDS) came investigations into mechanisms of action (including cellular interactions, modulation of transcription factors, and alterations in gene regulation) and in the use of in vitro methods to study these mechanisms and to attempt to predict effects in the whole animal. While these types of investigations continued to grow, the 1990s saw a surge in investigations into the understanding of immune-mediated disease: hypersensitivity and autoimmunity. As understanding of the human genome grows, pharmaceutical companies move faster and deeper into biotechnology, public concern and scientific debate over genetically modified foods increases, concern for the effects of chemicals on children's health grows, concern and debate over the potential impact of chemically induced endocrine disruption continues, the push to use kinetic and mechanistic data in human health risk assessments continues, and increased pressure to reduce the use of animals in testing increases, there is no doubt that immunotoxicology will continue to grow and expand in many ways. The following are a few of the new frontiers and challenges facing the immunotoxicologist of today and tomorrow.

Molecular Biology Methods: Proteomics and Genomics

The use of molecular biology methods in immunotoxicology in the past has been primarily in the understanding of the mechanism of action of identified immunotoxicants. Much research is currently focused on investigating induction of certain mRNAs (e.g., cytokines, transcription factors) in elucidating mechanism or as possible biomarkers of exposure. Proteomics (the study of all expressed proteins in a particular cell, and thus the functional expression of the genome) and genomics (the study of all genes encoded by an organism's DNA), combined with bioinformatics, are making it possible to evaluate chemically induced alterations in entire pathways and signaling networks. The utility of molecular biology tools such as proteomics and genomics in elucidating mechanism of action is obvious. However, can these powerful tools be used to identify new or suspected immunotoxicants? Is it possible that common profiles of gene expression will emerge for classes of structurally related or structurally dissimilar known or suspected immunotoxicants? How is the profile or gene expression related to administered dose, tissue dose, and time course of action of a chemical? Is human gene expression in response to chemical exposure the same as that in the animal or cell culture? If it is determined that these methods are useful tools in the identification of possible immunotoxicants, how should they be validated?

Animal Models: Transgenics and SCID

The developments in molecular biology have not only permitted the evaluation of specific genes or arrays of genes but have also allowed for the manipulation of the embryonic genome, creating transgenic and knockout mice (reviewed in IPCS, 1996). As a consequence of transgenic technology, complex immune responses can be dissected into their components. In this way, the mechanisms by which immunotoxicants act can be better understood. Mice lacking certain receptors, transcription factors, cytokines, etc., can be used for similar mechanistic studies. Severe combined immuno-deficient mice (SCID) can easily be engrafted with human or rat immune cells (SCID/hu and SCID/ra) and have been used to study immune regulation, hematopoiesis, hypersensitivity, and autoimmunity. Uses of reconstituted SCID mice have been considered elsewhere (IPCS, 1996), and their use in mechanistic studies is obvious. As with the use of molecular biological techniques, however, there are several questions regarding the broader utility of transgenics and SCID animals in immunotoxicology. Because of their altered biological status, how do they compare with standard animal models with respect to time course of action, dose response, pharmacokinetics, and other factors of chemical toxicity? Are the homing patterns of engrafted cells identical to those in the standard animal (i.e., to the extent possible, how identical are the immune systems of these mice compared to standard mice)? Can these animal models be used to identify new or suspected immunotoxicants, and if so, are they as or more sensitive, predictive, and/or cost-effective as traditional animal models?

Developmental Immunotoxicology

The development (ontogeny) of the mammalian immune system occurs primarily in utero, though some postnatal development or maturation does occur. Developmental immunotoxicology involves investigation into the effects that xenobiotics have on the ontogeny of the immune system and includes prenatal (in utero), perinatal (<36 h of age), and neonatal periods of exposure (reviewed in Barnett, 1996). Recent studies suggest that immune development in humans and other species may be altered after perinatal exposure to immunotoxic chemicals, including chemotherapeutics, corticosteroids, polycyclic hydrocarbons, and polyhalogenated hydrocarbons (reviewed in Barnett, 1996, and in Holladay, 1999). It has also been suggested that these effects may be more dramatic or persistent than those following exposure during adult life. With the passage of the Food Quality Protection Act (FQPA), more attention has focused on children's health and thus on this emerging area of immunotoxicology. Specifically, an understanding of the development and functioning of the juvenile immune system and subsequent validated methods (similar to those currently validated in adult animal models) are needed.

Systemic Hypersensitivity

An adverse immune response, in the form of systemic hypersensitivity, is among the most frequent causes for withdrawal of drugs that have made it to the market; such a response can account for approximately 15 percent of adverse reactions to xenobiotics (de Weck, 1983; Guzzie, 1995). These findings are generally unexpected in that they were not predicted in preclinical toxicology and immunotoxicology studies. A primary reason for this is the lack of good preclinical models for predicting systemic hypersensitivity responses, particularly to orally administered chemicals. This concern applies not only to the pharmaceutical industry but also to the food industry (proteins and genetically modified foods). It has been noted that a positive guinea pig hypersensitivity test (any test) has less than a 25 percent chance of predicting human clinical responses with respect to systemic hypersensitivity of drugs (Weaver et al., 1999). Assays are needed that are more predictive of drug antigenicity or hypersensitivity in humans. In the area of food allergy, again there are no validated animal models available, although the brown Norway rat and the Balb/c mouse have been shown to have some promise (Kimber et al., 1999, 2000; Knippels et al., 1999, 2000).

Computational Toxicology

The possibility of ascertaining certain molecular properties of a molecule even before it is synthesized is a highly beneficial use of computational chemistry. In fact, computational chemistry has been a rapidly growing and valued field, particularly in the fast-paced and highly competitive pharmaceutical industry. As a result of the usefulness of this tool, interest has grown in the use of computational toxicology methods to predict the potential biological/toxicologic activity of chemicals. The premise is that the structure of a chemical determines the physiochemical properties and reactivities that underlie its biological and toxicologic properties [quantitative structure-activity relationships (QSAR)]. Being able to predict potential adverse effects cannot only aid in the designed development of new chemicals but also has the potential to reduce the need for animal testing. It may ultimately or potentially lead to better health and environmental protection through the strategic application of limited testing resources and existing information assets to help sort out or identify the most hazardous chemicals. Computational toxicology can also help in screening large numbers of chemicals more efficiently for a variety of toxicologic endpoints. Computational methods will not assure 95 to 100 percent accuracy in the prediction of toxicity, and they will not eliminate the need for testing, but these methods will help reduce and prioritize the testing that is required. The use of computational toxicology cannot replace the need for toxicologists. These individuals will still be needed for their understanding of the relationship between the predicted endpoints and product or component ADME profiles (absorption, distribution, metabolism, and elimination) and the true potential for human exposure as determined by the process, method of application, and end use of the product. Immunotoxicologists studying hypersensitivity have begun to investigate whether computational methods can be used to screen for potential chemical sensitizers (Karol, et al., 1996, 1999; Graham et al., 1997; Gerberick, 1999). Thus, computational toxicology is a tool that may offer promise in the identification/prediction of chemical sensitization. The use of computational methods to predict other aspects of immunotoxicology has not been explored.

Biomarkers

True biomarkers indicate exposure to a specific chemical as well as susceptibility to adverse effect; and/or are predictive of disease associated with chemical

exposure. They must be sensitive, specific, relevant, reproducible, and measurable in the population. The most sensitive (and desirable) biomarkers would be those that indicate *exposure* in the absence of immediate adverse effect. Biomarkers of *effect* would indicate subclinical effects of chemical exposure. Various avenues are currently being explored as potential biomarkers, including cytokine gene expression patterns, flow cytometry, and immunomodulation in alternative species such as fish, just to name a few. The International Programme on Chemical Safety (IPCS, 1996) has concluded that, as with other systems in toxicology, few biomarkers are available for immunotoxicity, particularly for assessing immunotoxicity of individual susceptibility. More epidemiologic studies are needed to obtain a better view of the utility of biomarkers for detecting immunotoxic events and, ultimately, possible health risks that may be associated with exposure to chemicals that modulate the immune system.

Risk Assessment

With the demonstration that (1) chemicals can perturb the immune system of animals, (2) perturbation of immune function is correlated with an increased risk of infectious disease, and (3) perturbations in immune function can occur in the absence of any clinically observable effect, attention has focused on the risk to the human population following exposure to chemicals that can alter immune function in animals. However, these initial assessments of the use of immunotoxicology data in animals as predictors of risk for human clinical effects have limitations (reviewed in Luster et al., 1994, and IPCS, 1996). These include the fact that though many were good indicators, no single immune test has been observed to be highly predictive of altered host resistance. Also, to demonstrate chemical-related clinical immune effects in the human population, a significant number of individuals may be required. Variability in the virulence of infectious agents in the human population, the complexity of the immune system, and the redundancy ("immune reserve"; multiple components capable of responding to a foreign challenge) in the immune system may all contribute to the difficulty in quantifying relationships between chemical-induced alterations in immune status and alterations in host resistance in humans. Finally, there is the question of whether the relationship between functional immune changes and susceptibility to disease follows a linear (i.e., any change in immune function may increase the susceptibility to disease) or threshold-like model (i.e., small changes in immune function may be without appreciable changes in host resistance). Although there are suggestions in the literature that this relationship may follow a linear model, the answer to this question in the context of a broad array of chemicals is not clear. Further investigation in this area is warranted.

CONCLUDING COMMENT AND FUTURE DIRECTIONS

Our understanding of the immune system as a target for toxicity, whether it be via xenobiotic-induced immune injury or immune-mediated disease, continues to progress in concert with our knowledge of the biochemistry and physiology of the immune system. The balance between immune recognition and destruction of foreign invaders and the proliferation of these microbes and/or cancer cells can be a precarious one. Xenobiotics that alter the immune system can upset this balance, giving the edge to the invader. Furthermore, new xenobiotics continuously being introduced represent the potential for increased hypersensitivity and/or autoimmune responses. Validated methods are in place to detect xenobiotics that produce adverse effects related to the immune system. Once these are identified, fundamental principles of toxicology can be applied leading to risk assessment and determination of "no- effect" levels. These methods must continually be improved using the latest knowledge and technologies in order to provide a safe environment.

TOXIC RESPONSES OF THE LIVER

Mary Treinen-Moslen

INTRODUCTION

Numerous industrial compounds and therapeutic agents have been found to injure the liver. Consequently, the use of such chemicals has been eliminated or restricted. For example, carbon tetrachloride was commonly used in unventilated garages for degreasing automobile engines. Plastic industry workers without any protective equipment once crawled down into giant vats coated with residue containing vinyl chloride (Kramer, 1974). Now exposures to the potent hepatotoxins carbon tetrachloride and vinyl chloride are tightly regulated. However, each year new chemicals are found to damage the liver, such as the drugs Rezulin (troglitazone), prescribed for type 2 diabetes, and Rimadyl (carprofen), prescribed for dogs with arthritis. Usage of Rezulin in clinical medicine and Rimadyl in veterinary medicine was recently withdrawn or restricted based on reports of hepatic damage in more than 100 humans and over 8000 dogs, respectively (Kohlroser et al., 2000; Adams, 2000). During the 3-year period before the serious and sometimes fatal hepatotoxicity associated with their use was generally recognized, these two drugs were widely prescribed to over 800,000 humans and more than 4 million dogs. Initially promising drugs have been withdrawn during clinical trials when their hepatotoxicity became manifest after weeks or months of exposure. The 1993 clinical trial of fialuridine as a therapy for chronic viral hepatitis was suddenly terminated when some of the participating patients died of liver failure (McKenzie et al., 1995). Humans and animals continue to ingest hepatotoxins in foods, teas, and contaminated water. The serious problem of chemically induced liver damage has inspired excellent monographs (Zimmerman, 1978; Farrell, 1994; McCuskey and Earnest, 1997).

Observations on hepatotoxicants have advanced the understanding of hepatic functions and cell injury. Factors are known that determine why the liver, as opposed to other organs, is the dominant target site of specific toxins. Scientists have identified mechanisms by which chemicals injure specific populations of liver cells. New techniques in molecular biology, immunochemical probes, and the availability of transgenic animals provide new insights into basic physiologic and pathologic processes. Yet many questions remain. Why does end-stage liver disease occur in only 10 to 15 percent of those who chronically consume excess alcohol? How do genetic and acquired factors enhance vulnerability to alcohol and other toxicants?

Toxicologists regard the phrase "produces liver injury" as vague, since liver cells respond in many different ways to acute and chronic insults by chemicals. A basic understanding of chemical hepatotoxicity requires some appreciation of the physiology and anatomy of the liver. Key aspects for such appreciation are (1) major functions of the liver, (2) structural organization of the liver, and (3) processes involved in the excretory function of the liver, namely bile formation. These aspects contribute to the vulnerability of hepatic cells to chemical insults.

PHYSIOLOGY AND PATHOPHYSIOLOGY

Hepatic Functions

The liver's strategic location between intestinal tract and the rest of the body facilitates the performance of its enormous task of maintaining metabolic homeostasis of the body (Table 13-1). Venous blood from the stomach and intestines flows into the portal vein and then through the liver before entering the systemic circulation. Thus the liver is the first organ to encounter ingested nutrients, vitamins, metals, drugs, and environmental toxicants as well as waste products of bacteria that enter portal blood. Efficient scavenging or uptake processes extract these absorbed materials from the blood for catabolism, storage, and/or excretion into bile.

Table 13-1 Major Functions of Liver and Consequences of Impaired Hepatic Functions

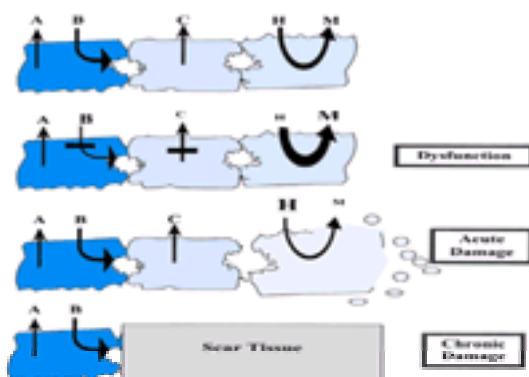
All of the major functions of the liver can be detrimentally altered by acute or chronic exposure to toxicants (Table 13-1). When toxicants inhibit or otherwise impede hepatic transport and synthetic processes, dysfunction can occur without appreciable cell damage (Fig. 13-1). Loss of function also occurs when toxicants kill an appreciable number of cells and when chronic insult leads to replacement of cell mass by nonfunctional scar tissue. Alcohol abuse is the major cause of liver disease in most western countries (Crawford, 1999); thus ethanol provides a highly relevant example of a toxin with multiple functional consequences (Lieber, 1994). Early stages of ethanol abuse are characterized by lipid accumulation (fatty liver) due to diminished use of lipids as fuels and impaired ability to synthesize the lipoproteins that transport lipids out of the liver. As alcohol-induced liver disease progresses, appreciable cell death occurs, the functioning mass of the liver is replaced by scar tissue, and hepatic capacity for biotransformation of certain drugs progressively declines. People with hepatic cirrhosis due to chronic alcohol abuse frequently become deficient at detoxifying both the ammonia formed by catabolism of amino acids and the bilirubin derived from breakdown of hemoglobin. Uncontrollable hemorrhage due to inadequate synthesis of clotting factors is a common fatal complication of alcoholic cirrhosis. A consequence of liver injury that merits emphasis is that loss of liver functions can lead to aberrations in other organ systems and to death.


Figure 13-1. Cartoon depicting toxicant-mediated events that lead to loss of representative functions of hepatocytes, such as A ,albumin secretion; B, bilirubin uptake and export into bile; C, clotting factor secretion; H and M, hormone uptake and bioactivation to metabolites.

Dysfunction without cell damage can occur when toxicants inhibit uptake and secretion or excessively stimulate bioactivation. The dysfunction can be selective when a toxicant impedes secretion of only some compounds. Acute damage and chronic damage produce a loss of function in the cell population that dies or is replaced by scar tissue.

Structural Organization

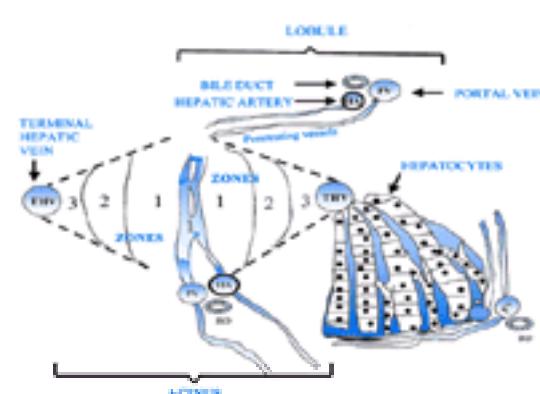
Two concepts exist for organization of the liver into operational units, namely the lobule and the acinus. Classically, the liver was divided into hexagonal lobules oriented around terminal hepatic venules (also known as central veins). At the corners of the lobule are the portal triads (or portal tracts), containing a branch of the portal vein, a hepatic arteriole, and a bile duct (Fig. 13-2). Blood entering the portal tract via the portal vein and hepatic artery is mixed in the penetrating vessels, enters the sinusoids, and percolates along the cords of parenchymal cells (hepatocytes), eventually flows into terminal hepatic venules, and exits the liver via the hepatic vein. The lobule is divided into three regions known as centrolobular, midzonal, and periportal. Preferred as a concept of a functional hepatic unit is the acinus. The base of the acinus is formed by the terminal branches of the portal vein and hepatic artery, which extend out from the portal tracts. The acinus has three zones: zone 1 is closest to the entry of blood, zone 3 abuts the terminal hepatic vein, and zone 2 is intermediate. Despite the utility of the acinar concept, lobular terminology is still used to describe regions of pathologic lesions of hepatic parenchyma. Fortunately, the three zones of the acinus roughly coincide with the three regions of the lobule (Fig. 13-2).


Figure 13-2. Schematic of liver operational units, the classic lobule and the acinus.

The lobule is centered around the terminal hepatic vein (central vein), where the blood drains out of the lobule. The acinus has as its base the penetrating vessels, where blood supplied by the portal vein and hepatic artery flows down the acinus past the cords of hepatocytes. Zones 1, 2, and 3 of the acinus represent metabolic regions that are increasingly distant from the blood supply.

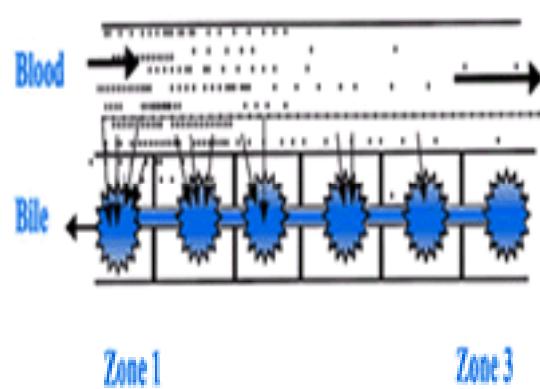
Acinar zonation is of considerable functional consequence regarding gradients of components both in blood and in hepatocytes (Jungermann and Kietzmann, 2000). Blood entering the acinus consists of oxygen-depleted blood from the portal vein (60 to 70 percent of hepatic blood flow) plus oxygenated blood from the hepatic artery (30 to 40 percent). Enroute to the terminal hepatic venule, oxygen rapidly leaves the blood to meet the high metabolic demands of the parenchymal cells. Approximate oxygen concentrations in zone 1 are 9 to 13 percent, compared with only 4 to 5 percent in zone 3. Therefore hepatocytes in zone 3 are exposed to substantially lower concentrations of oxygen than hepatocytes in zone 1. In comparison to other tissues, zone 3 is hypoxic. Another well-documented acinar gradient is that of bile salts (Groothuis et al., 1982). Physiologic concentrations of bile salts are efficiently extracted by zone 1 hepatocytes with little bile salt left in the blood that flows past zone 3 hepatocytes (Fig. 13-3).


Figure 13-3. Schematic of the acinar gradient of bile salts.

Efficient uptake of bile salts by zone 1 hepatocytes results in very low levels of bile salts in the blood that flows past zone 3 hepatocytes. A less steep gradient exists for the uptake of bilirubin and other organic anions.

Heterogeneities in protein levels of hepatocytes along the acinus generate gradients of metabolic functions. Hepatocytes in the mitochondria-rich zone 1 are predominant in fatty acid oxidation, gluconeogenesis, and ammonia detoxification to urea. Gradients of enzymes involved in the bioactivation and detoxification of xenobiotics have been observed along the acinus by immunohistochemistry (Jungermann and Katz, 1989). Notable gradients for hepatotoxins are the higher levels of glutathione in zone 1 and the greater amounts of cytochrome P450 proteins in zone 3, particularly the CYP2E1 isozyme inducible by ethanol (Tsutsumi, 1989).

Hepatic sinusoids are the channels between cords of hepatocytes where blood percolates on its way to the terminal hepatic vein. Sinusoids are larger and more irregular than normal capillaries. The three major types of cells in the sinusoids are endothelial cells, Kupffer cells, and Ito cells (Fig. 13-4). In addition, there are rare pit cells, a lymphocyte-type cell with anti-tumor activity. Sinusoids are lined by thin, discontinuous endothelial cells with numerous fenestrae (or pores) that allow molecules smaller than 250 kDa to cross the interstitial space (known as the space of Disse) between the endothelium and hepatocytes. Very little if any basement

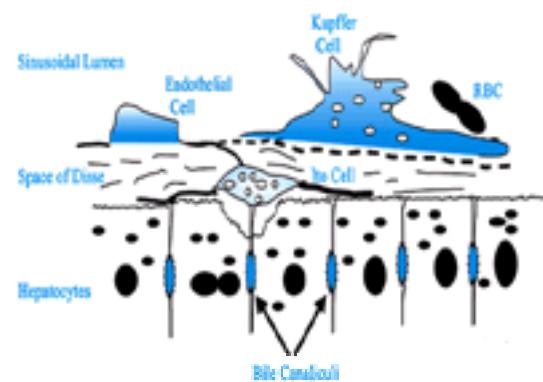
membrane separates the endothelial cells from the hepatocytes. The numerous fenestrae and the lack of basement membrane facilitate exchanges of fluids and molecules, such as albumin, between the sinusoid and hepatocytes but hinder movement of particles larger than chylomicron remnants. Endothelial cells are important in the scavenging of lipoproteins and denatured proteins. Hepatic endothelial cells also secrete cytokines.


Figure 13-4. Schematic of liver sinusoidal cells.

Note that the Kupffer cell resides within the sinusoidal lumen. The Ito cell is located in the space of Disse between the thin, fenestrated endothelial cells and the cord of hepatocytes.

Kupffer cells are the resident macrophages of the liver and constitute approximately 80 percent of the fixed macrophages in the body. Kupffer cells are situated within the lumen of the sinusoid. The primary function of Kupffer cells is to ingest and degrade particulate matter. Also, Kupffer cells are a source of cytokines and can act as antigen-presenting cells (Laskin, 1990). Ito cells (also known by the more descriptive terms of *fat-storing cells* and *stellate cells*) are located between endothelial cells and hepatocytes. Ito cells synthesize collagen and are the major site for vitamin A storage in the body.

Bile Formation

Bile is a yellow fluid containing bile salts, glutathione, phospholipids, cholesterol, bilirubin and other organic anions, proteins, metals, ions, and xenobiotics (Klaassen and Watkins, 1984). Formation of this fluid is a specialized function of the liver. Adequate bile formation is essential for uptake of lipid nutrients from the small intestine (Table 13-1), for protection of the small intestine from oxidative insults (Aw, 1994), and for excretion of endogenous and xenobiotic compounds. Hepatocytes begin the process by transporting bile salts, glutathione, and other solutes into the canalicular lumen, which is a space formed by specialized regions of the plasma membrane between adjacent hepatocytes (Fig. 13-4). Tight junctions seal the canalicular lumen from materials in the sinusoid. The structure of the biliary tract is analogous to the roots and trunk of a tree, where the tips of the roots equate to the canalicular lumens. Canaliculi form channels between hepatocytes that connect to a series of larger and larger channels or ducts within the liver. The large extrahepatic bile ducts merge into the common bile duct. Bile can be stored and concentrated in the gallbladder before its release into the duodenum. However, the gallbladder is not essential to life and is absent in several species, including the horse, whale, and rat.

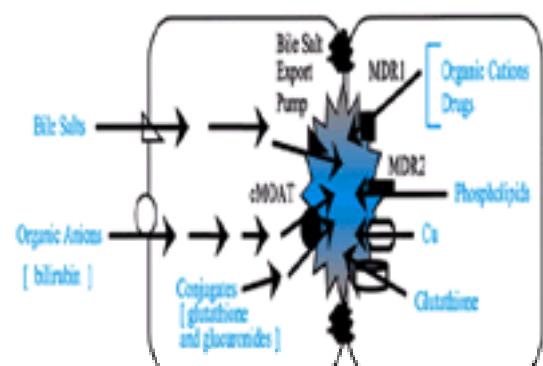
Our understanding of bile formation has evolved from a descriptive orientation toward identification of specific cellular and subcellular processes (Trauner et al., 1998). The major driving force is the active transport of bile salts and other osmolytes into the canalicular lumen. Transporters on the sinusoidal and canalicular membranes of hepatocytes are responsible for the uptake of bile salts and bilirubin from blood and then the secretion of these solutes into the canalicular lumen (Fig. 13-5). Similarly, biliary secretion of drugs, hormones, and xenobiotics involves an extraction from the blood, transcytosis across hepatocytes, and then transport across the canalicular membrane by ATP-dependent exporters. Lipophilic cationic drugs, estrogens, and lipids are exported by the canalicular MDR (multiple-drug resistance) p-glycoproteins, one of which is exclusive for phospholipids (Gosland et al., 1993; Kusuhara et al., 1998). Conjugates of glutathione, glucuronide, and sulfate are exported by the canalicular multiple organic anion transporter (cMOAT), which is also somewhat confusingly known as MRP2, based on similarities of cMOAT with the product of the multidrug-resistance gene.


Figure 13-5. Processes involved in hepatocyte uptake and biliary secretion of endogenous solutes and toxicants.

Transporters localized to the sinusoidal membrane extract solutes from the blood. Exporters localized to canalicular membrane move solutes into the lumen of the canaliculus. Exporters of particular relevance to canalicular secretion of toxic chemicals and their metabolites are the canalicular multiple organic anion transporter (MOAT) system and the family of multiple-drug resistant (MDR) P-glycoproteins.

Metals are excreted into bile by a series of partially understood processes that include (1) uptake across the sinusoidal membrane by facilitated diffusion or receptor-mediated endocytosis; (2) storage in binding proteins or lysosomes; and (3) canalicular secretion via lysosomes, a glutathione-coupled event, or a specific canalicular membrane transporter (Ballatori, 1991). Biliary excretion is important in the homeostasis of multiple metals, notably copper, manganese, cadmium, selenium, gold, silver, and arsenic (Klaassen, 1976; Gregus and Klaassen, 1986). Species differences are known for biliary excretion of several toxic metals; for example, dogs excrete arsenic into bile much more slowly than rats. Inability to export Cu into bile is a central problem in Wilson's disease, a rare genetic disorder characterized by accumulation of Cu in the liver and then in other tissues. The exact nature of the defect in Cu export is uncertain, since the product of the Wilson's disease gene does not localize to the canalicular membrane (Nagano et al., 1998).

Canalicular lumen bile is propelled forward into larger channels by dynamic, ATP-dependent contractions of the pericanalicular cytoskeleton (Watanabe et al., 1991). Bile ducts, once regarded as passive conduits, modify bile by absorption and secretion of solutes (Lira et al., 1992). Biliary epithelial cells also express a variety of phase I and phase II enzymes, which may contribute to the biotransformation of chemical toxicants present in bile (Lakehal et al., 1999).

Secretion into biliary ducts is usually but not always a pre-lude to toxicant clearance by excretion in feces or urine. Exceptions occur when compounds such as arsenic are repeatedly delivered into the intestinal lumen via bile, efficiently absorbed from the intestinal lumen, and then redirected to the liver via portal blood, a processes known as *enterohepatic cycling*. A few compounds, such as methyl mercury, are absorbed from the biliary tract; the extensive reabsorption of methyl mercury from the gallbladder is thought to contribute to the long biological half-life and toxicity of this toxin (Dutczak et al., 1991). Alternatively, secretion into bile of toxicant metabolites can be a critical prelude to the development of injury in extrahepatic tissues. A clinically relevant example of bile as an important delivery route for a proximate toxicant is that of diclofenac, a widely prescribed nonsteroidal anti-inflammatory drug (NSAID) that causes small intestinal ulceration. Convincing experiments with mutant rats lacking a functional canalicular MOAT exporter (Fig. 13-5) have shown that these mutants secrete little of the presumptive proximate

toxicant metabolite into bile and are resistant to the intestinal toxicity of diclofenac (Seitz and Boelsterli, 1998).

Toxicant-related impairments of bile formation are more likely to have detrimental consequences in populations with other conditions where biliary secretion is marginal. For example, neonates exhibit delayed development of multiple aspects of bile formation, including synthesis of bile salts and the expression of sinusoidal and canalicular transporters (Arrese et al., 1998). Neonates are more prone to develop jaundice when treated with drugs that compete with bilirubin for biliary clearance. Populations with sepsis are also of concern based on animal studies indicating that sepsis is associated with down-regulation of multiple canalicular exporters (Trauner et al., 1998).

Types of Injury and Toxic Chemicals

Hepatic response to insults by chemicals depends upon the intensity of the insult, the population of cells affected, and whether the exposure is acute or chronic (Fig. 13-1). Acute poisoning with carbon tetrachloride causes rapid lipid accumulation, before necrosis becomes evident. Some chemicals produce a very specific type of damage; others, notably ethanol, produce sequential types of damage or combinations of damage (Table 13-2). Note that the representative hepatotoxins listed in Table 13-2 include pharmaceuticals (valproic acid, cyclosporin A, diclofenac), recreational drugs (ethanol, ecstasy), a vitamin (vitamin A), metals (Fe, Cu, Mn), hormones (estrogens, androgens), industrial chemicals (dimethylformamide, methylene dianiline), compounds found in teas (germander) or foods (phalloidin, pyrrolidine alkaloids), and toxins produced by fungi (sporidesmin) and algae (microcystin). See Fig. 13-6 for the structures of representative hepatotoxic chemicals.

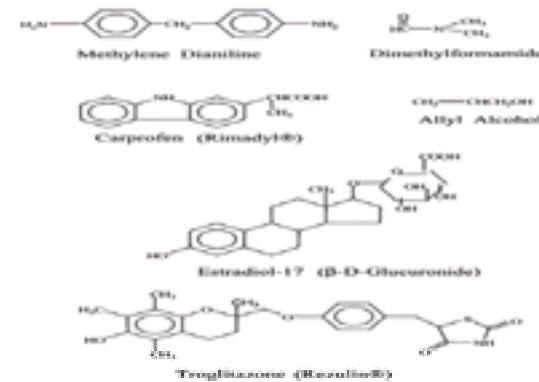
Table 13-2 Types of Hepatobiliary Injury


Figure 13-6. Structures of representative hepatotoxic chemicals.

Fatty Liver This change, also known as steatosis, is defined biochemically as an appreciable increase in the hepatic lipid content, which is <5 percent by weight in normal human liver. Histologically, in standard paraffin-embedded and solvent-extracted sections, hepatocytes containing excess fat appear to have multiple round, empty vacuoles that displace the nucleus to the periphery of the cell. Use of frozen sections and special stains is needed to document the contents of the vesicles as fat. Fatty liver can stem from one or more of the following events: oversupply of free fatty acids to the liver, interference with the triglyceride cycle, increases in synthesis or esterification of fatty acids, decreased fatty acid oxidation, decreased apoprotein synthesis, and decreased synthesis or secretion of very low density lipoproteins.

Steatosis is a common response to acute exposure to many but not all hepatotoxins (Farrell, 1994). An exception is acetaminophen. Compounds that produce prominent steatosis associated with lethality include the antiepileptic drug valproic acid (Hall, 1994) and the antiviral agent fialuridine (Honkoop et al., 1997). Often, toxin-induced steatosis is reversible and does not lead to death of hepatocytes. The metabolic inhibitors ethionine, puromycin, and cycloheximide cause fat accumulation without causing death of cells. Many other conditions besides toxin exposure, such as obesity, are associated with marked fat accumulation in the liver. Therefore assumptions about cause-effect relationships in regard to toxins and steatosis need to be made judiciously.

Cell Death Liver cells can die by two different modes, necrosis and apoptosis. Necrosis is characterized by cell swelling, leakage, nuclear disintegration, and an influx of inflammatory cells. Apoptosis is characterized by cell shrinkage, nuclear fragmentation, formation of apoptotic bodies, and a lack of inflammation. Apoptosis is more difficult to detect histologically because of the rapid removal of affected cells (Corcoran et al., 1994). Lysed debris of necrotic cells can persist for days when large numbers of cells die. When necrosis occurs in hepatocytes, the associated plasma membrane leakage can be detected biochemically by assaying plasma (or serum) for liver cytosol-derived enzymes. Particularly informative are the activity levels of alanine aminotransferase (ALT), a predominantly hepatocyte enzyme, unlike lactate dehydrogenase (LDH), which is found in many tissues. Biochemical assays provide a relatively simple way to screen populations for potential hepatocyte necrosis due to occupational or environmental toxins. A careful occupational health study by Redlich et al. (1988; 1990) in a New Haven, Connecticut, plant with primitive systems for worker protection found that exposure to dimethylformamide was associated with liver damage. Serum ALT levels were appreciably elevated in most of the exposed workers; however, liver biopsies indicated that a substantial cause of the liver damage in one of the workers was an infectious agent. Thus a limitation of biochemical indices of hepatocyte necrosis is the inability to distinguish between chemically induced effects and other causes such as hepatitis virus.

Hepatocyte death can occur in a focal, zonal, or panacinar (panlobular) pattern. Focal cell death is characterized by the randomly distributed death of single hepatocytes or small clusters of hepatocytes. Zonal necrosis is death to hepatocytes predominantly in zone 1 (periportal) or zone 3 (centrolobular). Many toxins cause zone 3 necrosis, while fewer agents are known to specifically damage cells in zone 1 or zone 2. Information about the zonal location of injury by a given chemical helps identify a sensitive, noninvasive index of functional change. For example, serum levels of bile salts are more likely to be elevated after damage to zone 1 than to zone 3 due to the direction of the gradient for bile salt uptake from blood (Fig. 13-3).

Some reasons why chemical toxins preferentially damage hepatocytes in specific zones are discussed further on, under "Factors in Liver Injury." Zone 3 necrosis can affect just a narrow rim of cells around the central vein, or it may extend into zone 2. Panacinar necrosis is massive death of hepatocytes with only a few or no remaining survivors. An intermediate form of substantial necrosis is called *bridging necrosis* because the extensive zones of cell lysis become confluent with each other. Mechanisms of toxin-induced injury to liver cells include lipid peroxidation, binding to cell macromolecules, mitochondrial damage, disruption of the cytoskeleton, and massive calcium influx. Progression from injury to death may involve activation of sinusoidal cells and, with repeated toxicant exposure, may lead to an antibody-mediated immune attack.

Canalicular Cholestasis This form of liver injury is defined physiologically as a decrease in the volume of bile formed or an impaired secretion of specific solutes into bile. Cholestasis is characterized biochemically by elevated serum levels of compounds normally concentrated in bile, particularly bile salts and bilirubin. When biliary excretion of the yellowish bilirubin pigment is impaired, this pigment accumulates in the skin and eyes, producing jaundice, and spills into urine, which becomes bright yellow or dark brown. Dyes that are excreted in bile, such as bromsulphalein (BSP), have been used to assess biliary function. The histologic features of cholestasis

can be very subtle and difficult to detect without ultrastructural studies. Structural changes include dilation of the bile canaliculus and the presence of bile plugs in bile ducts and canaliculi. Toxin-induced cholestasis can be transient or chronic; when substantial, it is associated with cell swelling, cell death, and inflammation. Many different types of chemicals—including metals, hormones and drugs—cause cholestasis (Table 13-2).

Bile Duct Damage Another name for damage to the intrahepatic bile ducts is *cholangiodestructive cholestasis* (Cullen and Ruebner, 1991). A useful biochemical index of bile duct damage is a sharp elevation in serum activities of enzymes localized to bile ducts, particularly alkaline phosphatase. In addition, serum levels of bile salts and bilirubin are elevated, as observed with canalicular cholestasis. Initial lesions following a single dose of cholangiodestructive agents include swollen biliary epithelium, debris of damaged cells within ductal lumens, and inflammatory cell infiltration of portal tracts. Chronic administration of toxins that cause bile duct destruction can lead to biliary proliferation and fibrosis resembling biliary cirrhosis. Another response is the loss of bile ducts, a condition known as *vanishing bile duct syndrome*. This persisting problem has been reported in patients receiving antibiotics (Davies et al., 1994).

Methylene dianiline, a compound used to make epoxy resins, is a noteworthy cause of bile duct damage. Small doses of methylene dianiline produce selective bile duct injury and thus provide an experimental model to study mechanisms of chemically induced bile duct damage (Kanz et al., 1992). The potent toxicity of methylene dianiline was first recognized in 1966, when an epidemiologic study established this compound as the causal agent of "Epping jaundice"—an outbreak of jaundice and severe hepatobiliary disease in more than 80 residents of the English village of Epping. The affected villagers had eaten bread made from flour contaminated with this compound (Kopelman et al., 1966). A more recent episode of methylene dianiline poisoning occurred at a "technoparty" where six young people ingested this agent due to confusion between its MDA abbreviation and the MDMA abbreviation for the synthetic amphetamine popularly known as Ecstasy (Tillman et al., 1997). All six individuals developed the jaundice, dark urine, abdominal pain, and nausea consistent with bile duct damage. If these young people had ingested the intended drug Ecstasy, they might also have developed liver problems. Although Ecstasy does not target bile ducts, numerous cases of severe liver damage have been reported after single and repeated exposure to this recreational drug (Andreu et al., 1998).

Sinusoidal Damage The sinusoid is, in effect, a specialized capillary with numerous fenestrae for high permeability. The functional integrity of the sinusoid can be compromised by dilation or blockade of its lumen or by progressive destruction of its endothelial cell wall. Dilation of the sinusoid will occur whenever efflux of hepatic blood is impeded. The rare condition of primary dilation, known as *peliosis hepatis,* has been associated with exposure to anabolic steroids and the drug danazol. Blockade will occur when the fenestrae enlarge to such an extent that red blood cells become caught in them or pass through with entrapment in the interstitial space of Disse. Such changes have been illustrated by scanning electron microscopy after large doses of the drug acetaminophen (Walker et al., 1983). A consequence of extensive sinusoidal blockade is that the liver becomes engorged with blood cells while the rest of the body goes into shock. Microcystin produces this effect within hours in rodents (Hooser et al., 1989). Microcystin dramatically deforms hepatocytes by altering cytoskeleton actin filaments, but it does not affect sinusoidal cells (Hooser et al., 1991). Thus the deformities that microcystin produces on the cytoskeleton of hepatocytes likely produce a secondary change in the structural integrity of the sinusoid owing to the close proximity of hepatocytes and sinusoidal endothelial cells (Fig. 13-4).

Progressive destruction of the endothelial wall of the sinusoid will lead to gaps and then ruptures of its barrier integrity, with entrapment of red blood cells. These disruptions of the sinusoid are considered the early structural features of the vascular disorder known as veno-occlusive disease (DeLeve et al., 1999). Well established as a cause of veno-occulsive disease are the pyrrolizidine alkaloids (e.g., monocrotaline, retrorsine, and seneciphylline) found in some plants used for herbal teas and in some seeds that contaminate food grains. Numerous episodes of human and animal poisoning by pyrrolizidine alkaloids have been reported around the world, including massive problems affecting thousands of people in Afghanistan in 1976 and 1993 (Huxtable, 1997). Veno-occlusive disease is also a serious complication in about 15 percent of the patients given high doses of chemotherapy (e.g., cyclophosphamide) as part of bone-marrow transplantation regimens (DeLeve et al., 1999). Experimental studies indicate that toxicant-induced killing of sinusoidal endothelial cells can occur without bioactivation by hepatocytes (DeLeve and Huybrechts, 1996). Depletion of glutathione within sinusoidal endothelial cells precedes the preferential injury to this type of hepatic cell (Wang et al., 2000).

Cirrhosis This form of injury is the end, often fatal, stage of chronic progressive liver injury. Cirrhosis is characterized by the accumulation of extensive amounts of fibrous tissue, specifically collagen fibers, in response to direct injury or to inflammation. Fibrosis can develop around central veins and portal tracts or within the space of Disse, which limits diffusion of material from the sinusoid. With repeated chemical insults, destroyed hepatic cells are replaced by fibrotic scars. With continuing collagen deposition, the architecture of the liver is disrupted by interconnecting fibrous scars. When the fibrous scars subdivide the remaining liver mass into nodules of regenerating hepatocytes, fibrosis has progressed to cirrhosis and the liver has meager residual capacity to perform its essential functions.

Cirrhosis is not reversible, has a poor prognosis for survival, and is usually the result of repeated exposure to chemical toxins. For example, cirrhosis associated with vitamin A has been reported in patients with dermatologic problems on high-dose therapy (^{3}100,000 IU) for an average of 7 years (Geubel et al., 1991). The risk for cirrhosis in alcoholics increases dramatically in males who consume ^{3}80 g/day and in females who consume ^{3}20 g day for 10 years. Note that the amount of ethanol in 8 beers, 8 glasses of wine, or 7 oz of 80-proof liquor is approximately equivalent to 80 g. The greater vulnerability of females to alcohol can be explained only partially by their smaller body size and lower capacity for ethanol metabolism in the stomach.

Tumors Chemically induced neoplasia can involve tumors that are derived from hepatocytes, bile duct cells, or the rare, highly malignant angiosarcomas derived from sinusoidal lining cells. Hepatocellular cancer has been linked to abuse of androgens and a high prevalence of aflatoxin-contaminated diets. The synergistic effect of co-exposure to aflatoxin and hepatitis virus B was clearly documented by a recent prospective study where the risk for hepatocellular carcinoma was found to be increased threefold in aflatoxin-exposed men with chronic hepatitis B infection (Sun et al., 1999). The investigators monitored urine specimens from the subjects for a metabolite of aflatoxin in order to verify dietary aflatoxin exposure. Angiosarcomas have been tightly associated with occupational exposure to vinyl chloride and arsenic (Farrell, 1994).

Exposure to Thorotrast has been linked to tumors derived from hepatocytes, sinusoidal cells, and bile duct cells (cholangiocarcinoma). The history of Thorotrast (radioactive thorium dioxide) is a sad tale of a useful agent with an unanticipated toxicity due to prolonged retention within the body. Between 1920 and 1950, an estimated 2.5 million people were injected with suspensions of Thorotrast as a contrast medium for radiologic procedures. The compound accumulates in Kupffer cells, the resident macrophage of the sinusoid, and emits radioactivity throughout its very extended half-life. Thus, it is not surprising that multiple types of liver tumors are linked to thorium dioxide exposure. One study of Danish patients exposed to Thorotrast found that the risk for bile duct and gallbladder cancers was increased 14-fold and that for liver cancers more than 100-fold (Andersson and Storm, 1992).

FACTORS IN LIVER INJURY

Why is the liver the target site for so many chemicals of diverse structure? Why do many hepatotoxicants preferentially damage one type of liver cell? Our understanding of these fundamental questions is incomplete. Influences of several factors are of obvious importance (Table 13-3). Location and specialized processes for uptake and biliary secretion produce higher exposure levels in the liver than in other tissues of the body and strikingly high levels within certain types of liver cells. Then the abundant capacity for bioactivation reactions influences the rate of exposure to proximate toxicants. Subsequent events in the pathogenesis appear to be critically influenced by responses of sinusoidal cells and the immune system. Discussion of the evidence for the contributions of these factors to the hepatotoxicity of representative compounds requires commentary about mechanistic events; therefore this section of the chapter is closely related to the next one, entitled "Mechanisms of Liver Injury."

Table 13-3 Factors in the Site-Specific Injury of Representative Hepatotoxicants

Table 13-4 lists experimental systems useful for defining factors and mechanisms of liver injury. In vitro systems using the isolated perfused liver, isolated liver cells, and cell fraction allow observations at various levels of complexity without the confounding influences of other systems. Models using co-cultures or agents that inactivate a given cell type can document the contributions and interactions between cell types. Whole-animal models are essential for assessment of the progression of injury and responses to chronic insult. Use of agents that induce, inhibit, deplete, or inactivate can define roles of specific processes, although potential influences of nonspecific actions can confound interpretations. Application of molecular biology techniques for gene transfection or repression attenuates some of these interpretive problems. Knockout rodents provided extremely useful models for complex aspects of hepatotoxicity. The reason for the persuasiveness of observations from experiments with knockout rodents is that the gene product of interest is not present and therefore not just inhibited by a nonspecific agent with potential confounding effects on other processes.

In vitro systems
    Cell fractions
    Primary cell cultures
    Primary cell co-cultures
    Transfected cell systems
    Isolated perfused livers

In vivo systems
    Multiple species and strains
    Transgenic and knockout rodents

Table 13-4 Experimental Systems

Uptake and Concentration

Hepatic "first pass" uptake of ingested toxic chemicals is facilitated by the location of the liver downstream of the portal blood flow from the gastrointestinal tract. Lipophilic compounds, particularly drugs and environmental pollutants, readily diffuse into hepatocytes because the fenestrated epithelium of the sinusoid enables close contact between circulating molecules and hepatocytes. Thus, the membrane-rich liver concentrates lipophilic compounds. Other toxins are rapidly extracted from blood because they are substrates for sinusoidal transporters present exclusively or predominantly in the liver.

Phalloidin and microcystin are illustrative examples of hepatotoxins that target the liver as a consequence of extensive uptake into hepatocytes by sinusoidal transporters (Frimmer, 1982; Runnegar et al., 1995a,b). Ingestion of the mushroom *Amanita phalloides* is a common cause of severe, acute hepatotoxicity in continental Europe and North America. Microcystin has produced numerous outbreaks of hepatotoxicity in sheep and cattle who drank pond water containing the blue-green alga *Microcystis aeruginosa* (Farrell, 1994). An episode of microcystin contamination of the water source used by a hemodialysis center in Brazil led to acute liver injury in 81 percent of the 124 exposed patients and the subsequent death of 50 of these (Jochimsen et al., 1998). Microcystin contamination was verified by analysis of samples from the water-holding tank at the dialysis center and from the livers of patients who died. This episode indicates the vulnerability of the liver to toxicants regardless of the route of administration. Because of its dual blood supply from both the portal vein and the hepatic artery, the liver is presented with appreciable amounts of all toxicants in the systemic circulation.

An early clue to preferential uptake as a factor in phalloidin's target-organ specificity was the observation that bile duct ligation, which elevates systemic bile salt levels, protects rats against phalloidin-induced hepatotoxicity in association with an 85 percent decrease in hepatic uptake of phalloidin (Walli et al., 1981). Subsequent studies found that co-treatment with substrates (e.g., cyclosporin A, rifampicin) known to prevent the in vivo hepatotoxicity of phalloidin or microcystin would also inhibit their uptake into hepatocytes by sinusoidal transporters for bile acids or organic anions (Ziegler and Frimmer 1984; Runnegar et al., 1995a).

Accumulation within liver cells, by processes that facilitate uptake and storage, is a determining factor in the hepatotoxicity of vitamin A and several metals. Vitamin A hepatotoxicity initially affects the sinusoidal Ito cells, which actively extract and store this vitamin. Early responses to high-dose vitamin A therapy are Ito cell engorgement, activation, increase in number, and protrusion into the sinusoid (Geubel et al., 1991). Cadmium hepatotoxicity becomes manifest when the cells exceed their capacity to sequester cadmium as a complex with the metal-binding protein metallo-thionein. This protective role for metallothionein was definitively documented by observations with transgenic mice. Specifically, high expression of this metal-binding protein in the transgenic mice rendered them more resistant than wild-type mice to the hepatotoxicity and lethality of cadmium poisoning (Liu et al., 1995).

Iron poisoning will produce severe liver damage. Hepatocytes contribute to the homeostasis of Fe by extracting this essential metal from the sinusoid by a receptor-mediated process and maintaining a reserve of Fe within the storage protein ferritin. Acute Fe toxicity is most commonly observed in young children who accidentally ingest iron tablets. The cytotoxicity of free Fe is attributed to its function as an electron donor for the formation of reactive oxygen species, which initiate destructive oxidative stress reactions. Accumulation of excess Fe beyond the capacity for its safe storage in ferritin is initially evident in the zone 1 hepatocytes, which are closest to the blood entering the sinusoid. Thus the zone 1 pattern of hepatocyte damage after iron poisoning is attributable to location for (1) the preferential uptake of Fe and (2) the higher oxygen concentrations that facilitate the injurious process of lipid peroxidation (Table 13-3). Chronic hepatic accumulation of excess iron in cases of hemochromatosis is associated with a spectrum of hepatic disease including a greater than 200-fold increased risk for liver cancer.

Bioactivation and Detoxification

Hepatocytes have very high constitutive activities of the phase I enzymes that often convert xenobiotics to reactive electrophilic metabolites. Also, hepatocytes have a rich collection of phase II enzymes that add a polar group to a molecule and thereby enhance its removal from the body. Phase II reactions usually yield stable, nonreactive metabolites. In general, the balance between phase I and phase II reactions determines whether a reactive metabolite will initiate liver cell injury or be safely detoxified. The balance can be shifted towards liver injury by acquired or genetic conditions that enhance bioactivation processes or impair detoxification processes. Notable acquired conditions for such a shift in balance are drug or pollutant induction of phase I enzymes and/or depletion of antioxidants.

Ethanol Genetic conditions of high clinical relevance to the bioactivation/detoxification balance are the polymorphisms in the enzymes that control the two-step metabolism of ethanol. Specifically, ethanol is bioactivated by alcohol dehydrogenase to acetaldehyde, a reactive aldehyde, which is subsequently detoxified to acetate by aldehyde dehydrogenase. Both enzymes exhibit genetic polymorphisms that result in higher concentrations of acetaldehyde—a "fast" activity isozyme of alcohol dehydrogenase [ALD2*2] and a physiologically very "slow" mitochondrial isozyme of aldehyde dehydrogenase [ALDH2*2]. Approximately 50 percent of Asian populations but virtually no Caucasians have the slow aldehyde dehydrogenase; alcohol consumption by people with this slow polymorphism leads to uncomfortable symptoms of flushing and nausea due to high systemic levels of acetaldehyde. Thus this slow detoxification polymorphism serves as a strong deterrent for alcoholism. The alcohol dehydrogenase fast polymorphism, which occurs in about 20 percent of Asian and less than 5 percent of Caucasian populations, has also been linked to a lower rate of alcoholism. An extremely low risk for alcoholism has been found in Asians with both polymorphisms that lead to higher levels of acetaldehyde (Chen et al., 1999a).

Allyl alcohol toxicity is also influenced by a balance between the formation and detoxification of its reactive aldehyde metabolite, acrolein, by sequential actions of alcohol dehydrogenase and aldehyde dehydrogenase enzymes. Age and gender differences in allyl alcohol hepatotoxicity can be explained by variations in the balance between these two enzymes (Rikans and Moore, 1987). Allyl alcohol is used in the production of resins, plastics, and fire retardants. The preferential occurrence of allyl alcohol injury in zone 1 hepatocytes (Table 13-3) is due to oxygen-dependent bioactivation. This aspect of its mechanism of hepatotoxicity was demonstrated by creative experiments where the typical decline in the oxygen gradient from zone 1 to zone 3 was reversed by a retrograde (backward) perfusion of isolated perfused livers (Badr et al., 1986).

Cytochrome P450 The importance of cytochrome P450-dependent bioactivation as a mechanism of hepatotoxicity must be emphasized. This common theme can be

a factor even for assumedly *safe* compounds since some P450 isozymes generate reactive oxygen species during biotransformation reactions (Albano et al., 1996). Concern about CYP2E1 generation of reactive oxygen species and other free radicals has come largely from efforts to determine why only a fraction of chronic heavy drinkers develop serious, end-stage liver damage. Dietary manipulations that lead to more severe alcohol-associated liver damage in the animal model show a linkage between dietary induction of CYP2E1 and hepatotoxicity (French et al., 1995; Korourian et al., 1999). These manipulation have involved the amount of dietary lipid, the type of fatty acid in the lipid component of the diet, diets deficient in carbohydrates, and co-exposure to inhibitors of CYP2E1. The issue is complex because ethanol is an inducer of P450; heavy drinkers exhibit approximately threefold higher activities of CYP2E1 than nondrinkers. However, the observed modulation of liver injury by dietary manipulations does indicate a role for nutrients in the hepatotoxicity of alcohol.

CYP2E1 is not the only cytochrome P450 isozyme with an impact on hepatotoxicity. An appropriately germane example is the folk medicine plant germander (*Teucrium chamaedrys L.*), which was considered a safe component of herbal teas until widespread consumption of capsules containing large amounts of germander for weight control in France was linked to multiple cases of hepatic damage (Larrey et al., 1992; Loeper et al., 1994). Systematic experimental studies have identified the specific toxic constituent in germander plants, demonstrated a predominant role for the CYP3A isozyme in germander bioactivation to reactive electrophiles, and determined that toxicity can be attenuated by maintenance of glutathione levels (Loeper et al., 1994; Lekehal et al., 1996). This kind of information has practical applications for identifying populations at enhanced risk for germander toxicity due to acquired conditions—such as obesity, sudden weight loss, or concurrent ingestion of other folk medications or pharmaceuticals—that might shift the balance between CYP3A bioactivation and glutathione-dependent detoxification.

Carbon Tetrachloride Cytochrome P450-dependent conversion of CCl_4 to $\cdot CCl_3$ and then to $CCl_3OO\cdot$ is the classic example of xenobiotic bioactivation to a free radical that initiates lipid peroxidation by abstracting a hydrogen atom from the polyunsaturated fatty acid of a phospholipid (Rechnagel, 1967). Experimental studies have identified numerous treatments and conditions that modulate the extent of liver damage produced by CCl_4. Protective situations include baby animals with little cytochrome P450; treatments with compounds that inhibit cytochrome P450; and pretreatment with a small dose of the same toxin that diminishes cytochrome P450 levels (Reynolds and Moslen, 1980). Augmenting situations include hypoxia, diabetes, diets low in vitamin E (since this antioxidant scavenges lipid peroxide radicals), and pretreatment with other chemicals, notably ethanol and acetone, which induce CYP2E1, the isozyme most effective in the activation of CCl_4. Anecdotal reports of human exposures to this toxicant suggest a greater vulnerability in individuals who should have high levels of hepatic CYP2E1 due to a history of alcohol abuse (Manno et al., 1996). Uncertainties about the importance of other P450 isozymes have been squelched by documentation of virtual resistance to the hepatotoxicity of CCl_4 in CYP2E1 knockout mice (Wong et al., 1998). Investigations about events in the pathogenesis of carbon tetrachloride hepatotoxicity paved the way for identification of factors important in the toxicity of other insults that also cause lipid peroxidation.

Acetaminophen The hepatotoxicity of this extensively used analgesic is a clinically important problem and an exemplary instance of how acquired factors (e.g., diet, drugs, diabetes, obesity) can enhance hepatotoxicity. Typical therapeutic doses of acetaminophen are not hepatotoxic, since the dominant pathways of biotransformation are conjugation with glucuronide or sulfate with little drug bioactivation. Injury after large doses of acetaminophen is enhanced by fasting and other conditions that deplete glutathione and is minimized by treatments that enhance hepatocyte synthesis of glutathione, particularly cysteine, the rate-limiting amino acid in glutathione synthesis. Introduction of interventive therapy with *N*-acetylcysteine, a well- tolerated source of intracellular cysteine, has saved the lives of many who took overdoses of acetaminophen, usually in suicide attempts (Smilkstein et al., 1988).

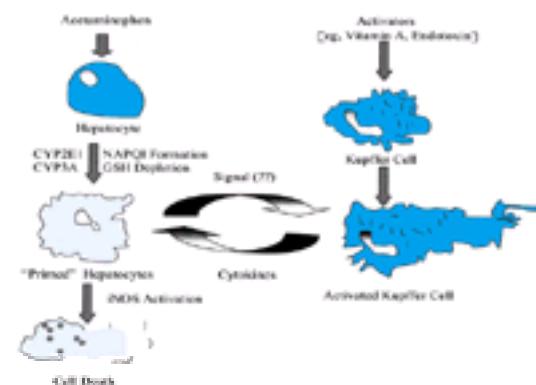
Alcoholics are vulnerable to the hepatotoxic effects of acetaminophen at dosages within the high therapeutic range (Lieber, 1994). This acquired enhancement has widely been attributed to accelerated bioactivation of acetaminophen to the electrophilic *N*-acetyl-*p*-benzoquinone imine (NAPQI) intermediate by ethanol induction of CYP2E1 (Fig. 13-7). However, alcoholic beverages also contain higher-chain alcohols, such as isopentanol, in appreciable amounts up to 0.5% (w/v), and alcohol consumption has many effects on the liver besides induction of CYP2E1 (Lieber, 1994). The assumed exclusive role for CYP2E1 bioactivation is controversial, in part because agents used to inhibit this isozyme also inhibit other isozymes of cytochrome P450. Evidence for roles of other alcohols besides ethanol and for other isozymes of P450 is available in the literature. For example, CYP2E1 knockout mice are *not* devoid of a toxic response to acetaminophen (Lee et al., 1996). Particularly convincing evidence is provided by a new report showing (1) synergistic enhancement of acetaminophen hepatotoxicity in rats pretreated with liquid diets containing ethanol plus isopentanol and (2) attenuation of acetaminophen hepatotoxicity when the alcohol-pretreated animals were given a specific inhibitor of CYP3A (Sinclair et al., 2000). This report should heighten suspicion about the potential influences of other CYP3A inducers on acetaminophen toxicity, since hepatic activities of this isozyme are increased by many drugs and by dietary chemicals such as caffeine.


Figure 13-7. Schematic of key events in the bioactivation and hepatotoxicity of acetaminophen.

Bioactivation of acetaminophen by cytochrome P450 isozymes leads to the formation of the reactive intermediate *N*-acetyl-*p*-benzoquinone (NAPQI), which can deplete glutathione or form covalent adducts with hepatic proteins. Experimental observations suggest that such effects "prime" hepatocytes for cytokines released by activated Kupffer cells. Progression to cell death is thought to involve activation of iNOS and other processes that produce reactive nitrogen species and oxidative stress. Agents that activate Kupffer cells exacerbate the toxicity. Exchange of signals between toxicant-primed and activated Kupffer cells is likely a factor in the acute hepatotoxicity produced by many compounds that damage hepatocytes.

Covalent binding, or adduction, of the reactive NAPQI intermediate of acetaminophen to hepatic proteins is a widely accepted mechanism for the hepatotoxicity of this drug. Adduction of a macromolecule could alter its functional integrity and thus constitute a detrimental molecular change. Early acceptance of the adduction mechanism for acetaminophen stemmed from close parallels found between the magnitude of injury and the extent of covalent binding in livers of animals given labeled acetaminophen (Mitchell et al., 1973). A key variable in these seminal experiments was the availability of glutathione for detoxification. Development of antibodies that recognize adducts of acetaminophen to macromolecules allowed demonstration of adduct formation before cell damage, predominantly in zone 3, where histologic injury occurs (Roberts et al., 1991). Thus adduct formation as a mechanism of injury is plausible temporally and locationally. One difficulty that researchers encountered in looking for a dose-dependent relationship between acetaminophen adducts and liver damage was an appropriate time to measure adduct formation, since damaged cells leak adducted proteins as well as enzymes indicative of tissue-specific injury (e.g., ALT).

A persisting concern about the adduction theory for acetaminophen toxicity is whether adduct formation is the *critical* event in acetaminophen toxicity or a *biomarker* of exposure to electrophilic metabolites. Prompting this concern are questions about how adduction to hepatocyte proteins could explain the importance of macrophages to the toxicity of this drug. A series of studies (Laskin et al., 1990; Gardner et al., 1998) have demonstrated protection by inactivation of hepatic macrophages (Kupffer cells) and contributions of reactive nitrogen species. Pretreatments that inactivate macrophages and attenuate toxicity by acetaminophen did *not,* however, diminish the extent of acetaminophen adduct formation (Michael et al., 1999). Yet the pretreatments did diminish the extent of hepatocyte adduction by reactive nitrogen species, an intriguing observation that fits with the reported contributions of reactive nitrogens to acetaminophen toxicity. Michael et al. (1999) have proposed an attractive "two hit" type of revised theory for the hepatotoxicity of acetaminophen. Perhaps adduction by a reactive drug metabolite "primes" the hepatocytes for destructive insults by reactive nitrogen species (e.g., peroxynitrite) (Fig. 13-7).

Activation of Sinusoidal Cells

Four kinds of observations, collectively, indicate roles for sinusoidal cell activation as primary or secondary factors in toxin-induced injury to the liver:

1. Kupffer cells and Ito cells exhibit an activated morphology— enlarged and ruffled—after acute and chronic exposure to hepatotoxicants (Laskin et al., 1990).

2. Pretreatments that activate or inactivate Kupffer cells appropriately modulate the extent of damage produced by classic toxicants (e.g., acetaminophen, carbon tetrachloride, and alcohol). For example, a series of studies by Sipes and colleagues demonstrated that Kupffer cell activation by vitamin A profoundly enhances the acute toxicity of carbon tetrachloride; this enhancement did not occur when animals were also given an inactivator of Kupffer cells (ElSisi et al., 1993).
3. Activated Kupffer cells secrete appreciable amounts of soluble cytotoxins, including reactive oxygen and nitrogen species. Administration of agents that scavenge or inhibit these soluble cytotoxins attenuates the effects of sinusoidal cell enhancement (Gardener et al., 1998; Thurman et al., 1997).
4. Acute and chronic exposure to alcohol directly or indirectly affects sinusoidal cells (Thurman et al., 1997).

Kupffer cells are rapidly activated when the liver is perfused with solutions containing ethanol. Alcoholics have elevated systemic levels of endogenous Kupffer cell activators, notably tumor necrosis factor and the bacterial product endotoxin. The extent of liver injury in animal models of alcoholic hepatitis is consistently diminished by treating animals with antibiotics that lower endotoxin levels or with antibodies to tumor necrosis factor. This antibiotic protection disappears when the animals also receive endotoxin. New animal experiments with knockout mice provide strong evidence for an essential role of tumor necrosis factor in alcohol-induced liver injury (Yin et al., 1999). The knockout mice used in these experiments lacked a receptor for tumor necrosis factor. Observations during the latter phases of chronic alcohol-induced liver disease, when there is an abundance of collagen scarring, show activated, transformed Ito cells; transformed Ito cells are thought to be little factories for collagen synthesis.

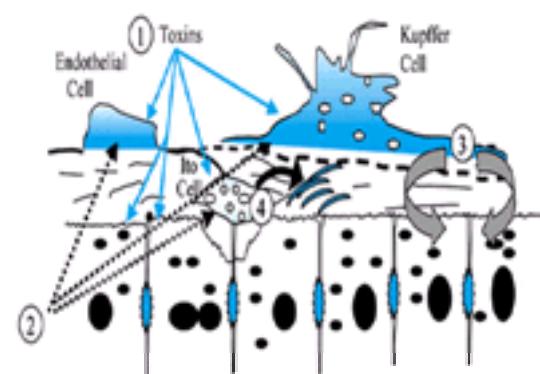
Figure 13-8 summarizes information presented in this and earlier sections of this chapter about the multiplicity of toxin-induced interactions with and between various liver cells. The effect on a given cell type can be direct or may result from a cascade of signals and responses between cell types.


Figure 13-8. Schematic depicting the complex cascade of toxin-evoked interactions between hepatocytes and sinusoidal cells.

Sinusoidal cell responses to toxins can lead to either injury or activation. A scenario could involve (1) toxin injury to hepatocytes, (2) signals from the injured hepatocyte to Kupffer and Ito cells, followed by (3) Kupffer cell release of cytotoxins and (4) Ito cell secretion of collagen. Activation of Kupffer cells is an important factor in the progression of injury evoked by many toxicants. Stimulation of collagen production by activated Ito cells is a proposed mechanism for toxicant-induced fibrosis. [Concept from Crawford JM: The liver and the biliary tract, in Cotran RS, Kumar V, Robbins SL (eds): *Robbins: Pathologic Basis of Disease,* 6th ed. Philadelphia: Saunders, 1999, pp 845–901, with permission.]

Inflammatory and Immune Responses

Migration of neutrophils, lymphocytes, and other inflammatory cells into regions of damaged liver is a well-recognized feature of the hepatotoxicity produced by many chemicals. In fact, the potentially confusing term *hepatitis* refers to hepatocyte damage by any insult where hepatocyte death is associated with an influx of inflammatory cells. The progressive phase of alcohol-induced liver disease (between simple fatty liver and cirrhosis) is called *alcoholic hepatitis.* The liver damage occasionally observed after multiple exposures to the anesthetic halothane is known as *halothane hepatitis.*

A relevant question for chemically induced acute damage to the liver is: Does the influx of inflammatory cells facilitate beneficial removal of debris from damaged liver cells or does the influx contribute in a detrimental way to the extent of liver damage after chemical injury? Detrimental effects are plausible, since activated neutrophils release cytotoxic proteases and reactive oxygen species. Pretreatments with prostaglandins and other compounds with anti-inflammatory activity reduce the acute hepatotoxicity of a-naphthyl-isothiocyanate (ANIT), an extensively studied compound that causes histologic damage to hepatocytes and bile ducts (Dahm et al., 1991); CCl₄; and other compounds (Farrell, 1994). More direct evidence for a detrimental role of neutrophils has come from experiments where depletion of neutrophils diminished the hepatotoxic and cholestatic effects of ANIT. Further insight into the roles of neutrophils in ANIT toxicity has been obtained by use of co-culture techniques for isolated primary hepatocytes, bile duct cells, and neutrophils (Hill et al., 1999). Placement of different types of cells on opposite sides of a permeable chamber indicated a chain reaction of events whereby ANIT-treated bile duct cells release a factor that attracts neutrophils and stimulates them to damage hepatocytes.

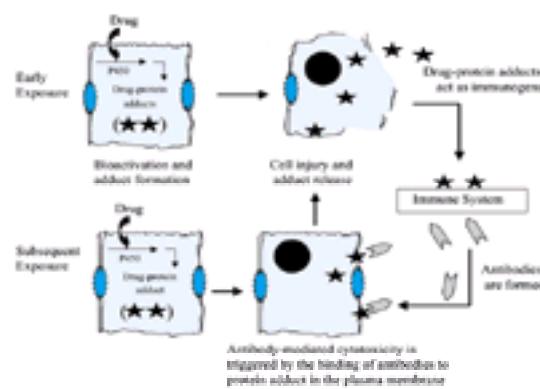
Immune responses are considered factors in the hepatotoxicity occasionally observed after repeated exposure to chemicals, usually drugs. Individuals who develop infrequent, unpredictable response are considered to be hypersensitive. An immune-mediated response is considered plausible when the problem subsides after therapy is halted and then recurs on drug challenge or restoration of therapy. Although the concept is generally accepted, compelling evidence for immune-mediated responses is available only for ethanol, halothane, and a few other hepatotoxicants (Pohl, 1990). Some kind of chemical-related molecular change is needed to stimulate an immunological attack, such as the formation of adducts between a reactive metabolite of the drug and hepatocyte proteins. Figure 13-9 depicts key features of the assumed scenario whereby hepatic protein adducts could become antigenic and stimulate the production of antibodies. If on reexposure, more drug-protein adducts are formed, cells with such adducts could be attacked by systemic antibodies. Bioactivation to reactive species capable of forming protein adducts is a commonality for many drugs thought to produce immune-mediated hepatic injury (Selim and Kaplowitz, 1999).


Figure 13-9. Proposed scenario of events leading to immune-mediated hepatotoxicity after repeated exposure to a toxicant that produces drug-protein adducts (★)

Reports about sporadic instances of apparent immune-mediated injury in individuals taking the widely prescribed NSAID diclofenac have spurred extensive research on this popular and effective anti-arthritic drug (Sallie et al., 1991; Farrell, 1994). Hepatic bioactivation of diclofenac leads to the formation of multiple adducts. Some of the diclofenac adducts localize to hepatocyte membrane proteins (Hargus et al., 1994), where recognition by antibodies is feasible. There is considerable evidence for immune-mediated responses as factors in ethanol-induced liver disease. Acetaldehyde, the reactive metabolite of ethanol, forms adducts with hepatic proteins. Circulating antibodies that recognize acetaldehyde-adducted proteins can be found in patients with liver disease related to alcohol, and in some studies the antibody titer is higher in those with more severe disease (Rolla et al., 2000). However, specific contributions of drug-protein adducts and their antibodies to the pathogenesis

of diclofenac and alcohol have yet to be defined.

MECHANISMS OF LIVER INJURY

Some aspects of the mechanistic basis for hepatotoxicity are generic, since liver cells are vulnerable to the same types of insults that injure other tissues. Preferential liver damage frequently ensues simply from the location of the liver and/or its high capacity for converting chemicals to reactive entities. Exceptions that merit explanation are the toxins that target the cytoskeleton due to their exclusive uptake by hepatocytes and the drugs that damage hepatic mitochondria due to the potentially fatal systemic consequences. This section emphasizes mechanisms that produce cholestasis, because biliary secretion is a unique and vital function of the liver.

Disruption of the Cytoskeleton

Phalloidin and microcystin disrupt the integrity of hepatocyte cytoskeleton by affecting proteins that are vital to its dynamic nature. The detrimental effects of these two potent hepatotoxicants are independent of their biotransformation and are exclusive for hepatocytes, since there is no appreciable uptake of either toxin into other types of cells. Tight binding of phalloidin to actin filaments prevents the disassembly phase of the normally dynamic rearrangement of the actin filament constituent of the cytoskeleton. Phalloidin uptake into hepatocytes leads to striking alterations in the actin-rich web of cytoskeleton adjacent to the canalicular membrane; the actin web becomes accentuated and the canalicular lumen dilates (Phillips et al., 1986). Experiments using time-lapse video microscopy have documented dose-dependent declines in the contraction of canalicular lumens between isolated hepatocyte couplets after incubation with a range of phalloidin concentrations (Watanabe and Phillips, 1986).

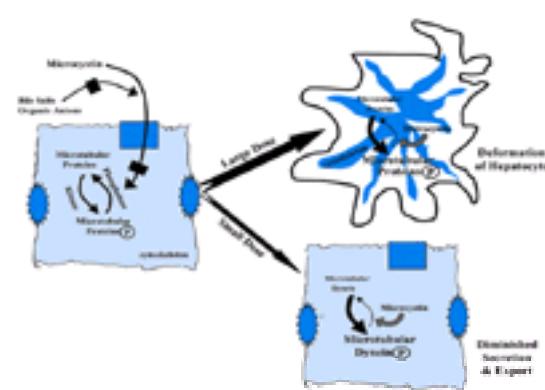
Microcystin uptake into hepatocytes leads to hyperphosphorylation of cytoskeletal proteins secondary to this toxicant's covalent binding to the catalytic subunit of serine/threonine protein phosphatases (Runnegar et al., 1995c). Reversible phosphorylations of cytoskeletal structural and motor proteins are critical to the dynamic integrity of the cytoskeleton. As depicted in Fig. 13-10, extensive hyperphosphorylation produced by large amounts of microcystin leads to marked deformation of hepatocytes due to a unique collapse of the microtubular actin scaffold into a spiny central aggregate (Hooser et al., 1991). Lower doses of microcystin, insufficient to produce the gross structural deformations, diminish uptake and secretory functions of hepatocytes in association with preferential hyperphosphorylation of the cytoplasmic motor protein dynein (Runnegar et al., 1999). Dynein is a mechanicochemical protein that drives vesicles along microtubules using energy from ATP hydrolysis; central to the hydrolysis of the dynein-bound ATP is a cycle of kinase phosphorylation and phosphatase dephosphorylation. Thus, hyperphosphorylation of dynein freezes this motor pump. New experiments that looked at effects of chronic exposure to low levels of microcystin have raised new concerns about the health effects of this water contaminant. Specifically, low levels of microcystin promote liver tumors and kill hepatocytes in the zone 3 region, where microcystin accumulates (Solter et al., 1998).


Figure 13-10. Schematic of events in the mechanism by which microcystin damages the structural and functional integrity of hepatocytes.

Microcystin is taken up exclusively into hepatocytes by a sinusoidal transporter in a manner inhibitable by bile salts and organic anions. Then microcystin inhibition of protein phosphatases leads to hyperphosphorylation of cytoskeletal proteins whose dynamic functions are dependent upon reversible phosphorylations. Extensive hyperphosphorylation of microtubular proteins leads to a collapse of the microtubular actin filament scaffold into a spiky aggregate that produces a gross deformation of hepatocytes. More subtle changes in microtubule-mediated transport activities have been linked to hyperphosphorylation of dynein, a cytoskeletal motor protein. (Concept courtesy of Dr. Maria Runnegar, University of Southern California School of Medicine.)

Information about the binding of phalloidin and microcystin to specific target molecules is valuable for two reasons. First, the linkages of specific binding to loss of target protein functions provide compelling evidence that such binding constitutes a defined molecular mechanism of injury. Second, the demonstrations of high-affinity binding to a target molecule without confounding effects on other processes or tissues have *translated* into applications of these toxins as tools for cell biology research. For example, phalloidin complexed with a fluorochrome (e.g., rhodamine phalloidin or Texas Red phalloidin) is used to visualize the actin polymer component of the cytoskeleton in all types of permeabilized cells. The collapse of actin filaments into spiny aggregates after microcystin treatment was visualized by fluorescence microscopy of cells stained with rhodamine phalloidin (Hooser et al., 1991). Low levels of microcystin are being used to discriminate the roles of dynein from other cytoskeletal motor proteins (Runnegar et al., 1999).

Cholestasis

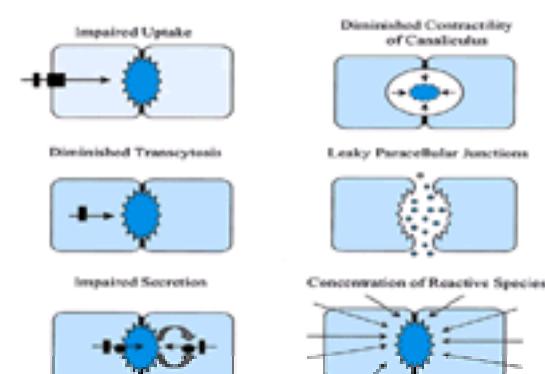
Bile formation is vulnerable to toxicant effects on the functional integrity of sinusoidal transporters, canalicular exporters, cytoskeleton-dependent processes for transcytosis, and the contractile closure of the canalicular lumen (Fig. 13-11). Changes that weaken the junctions that form the structural barrier between the blood and the canalicular lumen allow solutes to leak out of the canalicular lumen. These paracellular junctions provide a size and charge barrier to the diffusion of solutes between the blood and the canalicular lumen while water and small ions diffuse across these junctions. One hepatotoxin that causes tight-junction leakage is ANIT (Krell, 1987).


Figure 13-11. Schematic of six potential mechanisms for cholestasis involving inhibited uptake, diminished transcytosis, impaired secretion, diminished contractility of the canaliculus, leakiness of the junctions that seal the canalicular lumen from the blood, and detrimental consequences of high concentrations of toxic entities in the pericanalicular area.

Note that impaired secretion across the canalicular membrane can result from inhibition of a transporter or retraction of a transporter away from the canalicular membrane.

Cholestatic effects of pharmaceuticals present serious complications that often require restrictions in dose or termination of therapy. Such problems are encountered with cyclosporin A, an immunosuppressive drug frequently reported to cause elevated levels of serum bile salts and bilirubin as well as a reductions in bile flow (Farrell, 1994). Careful studies with hepatocyte membrane fractions demonstrated that cyclosporin A is a potent competitive inhibitor of the ATP-dependent bile salt exporter on the canalicular membrane (Bohme et al., 1994). Agents can also impede canalicular export activities by stimulating the retraction of canalicular exporters away from the canalicular membrane or by down-regulating their expression (Trauner et al., 1998; Kubitz et al., 1999).

Compounds that produce cholestasis do not necessarily act by a single mechanism or at just one site. Chlorpromazine impairs bile acid uptake and canalicular contractility (Farrell, 1994). Multiple alterations have been well documented for estrogens, a well-known cause of reversible canalicular cholestasis (Vore, 1991; Bossard et al., 1993). Problems occur with both synthetic estrogens and metabolites of endogenous estrogens, particularly D-ring glucuronides. Estrogens decrease bile salt uptake by effects at the sinusoidal membrane including a decrease in the Na^+, K^+-ATPase necessary for Na-dependent transport of bile salts across the plasma membrane and changes in lipid component of this membrane. At the canalicular membrane, estrogens diminish the transport of glutathione conjugates and reduce the number of bile salt transporters.

An additional mechanism for canalicular cholestasis is concentration of reactive forms of chemicals in the pericanalicular area (Fig. 13-11). Most chemicals that cause canalicular cholestasis are excreted in bile. Therefore the proteins and lipids in the canalicular region must encounter a high concentration of these chemicals. Observations consistent with this concentration mechanism have been reported for Mn and 1,1-dicloroethylene. Manganese is a known cholestatic agent in humans and experimental animals (Lustig et al., 1982). Treatments that modify the extent of Mn-induced cholestasis produce consonant changes in the amount of Mn recovered in the canalicular membrane fraction (Ayotte and Plaa, 1985). A postulated mechanism for the canaliculus as the target site of low doses of 1,1-dichloroethylene is the congregation of its reactive thioether glutathione conjugates (Liebler et al., 1988) in the pericanalicular region (Moslen and Kanz, 1993). One striking effect of 1,1-dichloroethylene is a rapid decrease in biliary secretion phospholipids, a function of the MDR2 exporter (Woodard and Moslen, 1998). Concentration within a confined region is also a plausible factor in the target site selectivity of chemicals that damage bile ducts, since all recognized bile duct toxins are excreted in bile. Sporidesmin, a fungus-derived bile duct toxin, is concentrated in bile up to 100-fold (Farrell, 1994).

Mitochondrial Damage

Preferential injury to mitochondrial DNA, as opposed to nuclear DNA, is a plausible mechanistic basis for the structural and functional alterations to hepatic mitochondria associated with nucleoside analog therapy for hepatitis B and AIDS infections and with alcohol abuse. Of particular concern is the lactic acidosis that results when the liver, due to a massive deficit in hepatic mitochondrial function, can no longer maintain systemic lactate homeostasis or even supply its own ATP needs without anaerobic glycolysis.

Mitochondrial DNA codes for several proteins in the mitochondrial electron transport chain. Nucleoside analog drugs cause mitochondrial DNA damage directly when incorporation of the analog base leads to miscoding or early termination of polypeptides. The severe hepatic mitochondrial injury produced by the nucleoside analog fialuridine is attributed to its higher affinity for the polymerase responsible for mitochondrial DNA synthesis than for the polymerases responsible for nuclear DNA synthesis (Honkoop et al., 1997). Mitochondrial DNA is also more vulnerable to miscoding (mutation) due to its limited capacity for repair.

Alcohol abuse can lead to mitochondrial injury by mechanisms involving metabolic imbalance and/or oxidative stress. A shift in the bioactivation/detoxification balance for ethanol can lead to an accumulation of its reactive acetaldehyde metabolite within mitochondria, since mitochondrial aldehyde dehydrogenase is the major enzymatic process for detoxification of acetaldehyde. Bioactivation of large amounts of ethanol by alcohol dehydrogenase hampers the detoxification reaction, since the two enzymes require a common, depletable cofactor—namely, nicotinamide adenine di-nucleotide (NAD). Any type of ethanol-induced change that enhances the leakiness of the mitochondrial transport chain would lead to an increased release of reactive oxygen species capable of attacking nearby mitochondrial constituents. Animal experiments have shown that high doses of ethanol lead to adduction of mitochondrial cytochrome oxidase by reactive oxygen species and to declines in the activity of this electron transport chain protein (Chen et al., 1999b). Ethanol-induced damage to mitochondrial DNA by what appears to be oxidative stress pathway is attenuated by antioxidant pretreatment (Mansouri et al., 1999). Too little is known about antioxidant deficiencies as acquired risk factors for alcohol-induced liver damage.

FUTURE DIRECTIONS

Our understanding of mechanisms and critical factors in chemically mediated hepatotoxicity will continue to improve through the application of model systems that allow for the observation of events at the level of the cell, organelle, and molecule. Advances in the area of cholestasis are possible using highly purified canalicular membranes, hepatocyte couplets that secrete bile, and cultures of primary bile duct cells. Consequences of damage to specific parts of the liver will be clarified through experiments with chemicals that have defined target sites. Important interrelationships between sinusoidal cells and other types of liver cells can be identified using coculture systems or treatments that modify functions of each type of sinusoidal cell. Knockout rodents and other applications of molecular biology will provide insight into the roles of bioactivation and excretion processes in hepatotoxicity.

CHAPTER 14

TOXIC RESPONSES OF THE KIDNEY

Rick G. Schnellmann

The functional integrity of the mammalian kidney is vital to total body homeostasis, as the kidney plays a principal role in the excretion of metabolic wastes and in the regulation of extracellular fluid volume, electrolyte composition, and acid–base balance. In addition, the kidney synthesizes and releases hormones, such as renin and erythropoietin, and metabolizes vitamin D_3 to the active 1,25-dihydroxy vitamin D_3 form. A toxic insult to the kidney therefore could disrupt any or all of these functions and could have profound effects on total-body metabolism. Fortunately, the kidneys are equipped with a variety of detoxification mechanisms and have considerable functional reserve and regenerative capacities. Nonetheless, the nature and severity of the toxic insult may be such that these detoxification and compensatory mechanisms are overwhelmed, and renal failure ensues. The outcome of renal failure can be profound; permanent renal damage may result, requiring chronic dialysis treatment or kidney transplantation.

FUNCTIONAL ANATOMY

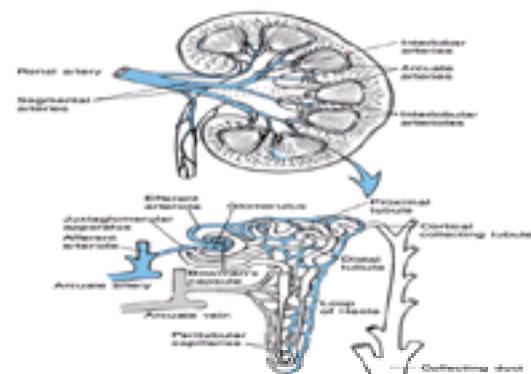
Gross examination of a sagittal section of the kidney reveals three clearly demarcated anatomic areas: the cortex, medulla, and papil-la (Fig. 14-1 and Fig. 14-2). The cortex constitutes the major portion of the kidney and receives a disproportionately higher percentage (90 percent) of blood flow compared to the medulla (~6 to 10 percent) or papilla (1 to 2 percent). Thus, when a blood-borne toxicant is delivered to the kidney, a high percentage of the material will be delivered to the cortex and will have a greater opportunity to influence cortical rather than medullary or papillary functions. However, medullary and papillary tissues are exposed to higher luminal concentrations of toxicants for prolonged periods of time, a consequence of the more concentrated tubular fluid and the more sluggish flow of blood and filtrate in these regions.


Figure 14-1. Schematic of the human kidney showing the major blood vessels and the microcirculation and tubular components of each nephron. [From Guyton AC, Hall JE (eds): Textbook of Medical Physiology. Philadelphia: Saunders, 1996, p 318, with permission.]
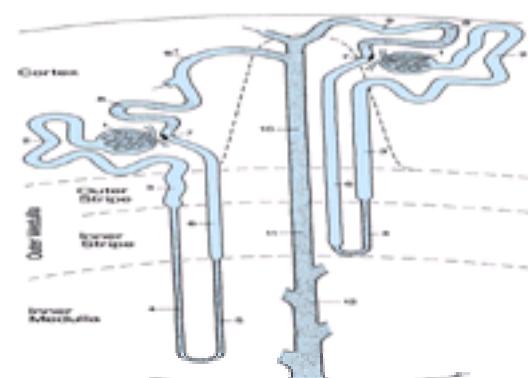

Figure 14-2. Schematic of short- and long-looped nephrons and the collecting system.

A medullary ray is delineated by a dashed line within the cortex. (1) Renal corpuscle including Bowman's capsule and the glomerulus; (2) proximal convoluted tubule; (3) proximal straight tubule; (4) descending thin limb; (5) thin ascending limb; (6) thick ascending limb; (7) macula densa, located within the final portion of the thick ascending limb; (8) distal convoluted tubule; (9) connecting tubule; (9*) connecting tubule of the juxtamedullary nephron, which forms an arcade; (10) cortical collecting duct; (11) outer medullary collecting duct; (12) inner medullary collecting duct. [From Kriz W: Standard nomenclature for structures of the kidney. *Am J Physiol* 254:F1–F8, 1988, with permission.]

The functional unit of the kidney, the nephron, may be considered in three portions: the vascular element, the glomerulus, and the tubular element.

Renal Vasculature and Glomerulus

The renal artery branches successively into interlobar, arcuate, and interlobular arteries (Fig. 14-1). The last of these give rise to the afferent arterioles, which supply the glomerulus; blood then leaves the glomerular capillaries via the efferent arteriole. Both the afferent and efferent arterioles, arranged in a series before and after the glomerular capillary tuft, respectively, are ideally situated to control glomerular capillary pressure and glomerular plasma flow rate. Indeed, these arterioles are innervated by the sympathetic nervous system and contract in response to nerve stimulation, angiotensin II, vasopressin, endothelin, prostanoids, and cytokines, affecting glomerular pressures and blood flow. The efferent arterioles draining the cortical glomeruli branch into a peritubular capillary network, whereas those draining the juxtamedullary glomeruli form a capillary loop, the vasa recta, supplying the medullary structures. These postglomerular capillary loops provide an efficient arrangement for delivery of nutrients to the postglomerular tubular structures, delivery of wastes to the tubule for excretion, and return of reabsorbed electrolytes, nutrients, and water to the systemic circulation.

The glomerulus is a complex, specialized capillary bed composed primarily of endothelial cells that are characterized by an attenuated and fenestrated cytoplasm, visceral epithelial cells characterized by a cell body (podocyte) from which many trabeculae and pedicles (foot processes) extend, and a glomerular basement membrane (GBM), which is a trilamellar structure sandwiched between the endothelial and epithelial cells (Fig. 14-3). A portion of the blood entering the glomerular capillary network is fractionated into a virtually protein-free and cell-free ultrafiltrate, which passes through Bowman's space and into the tubular portion of the

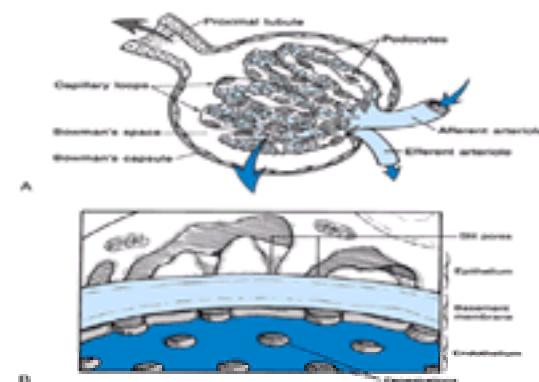
nephron. The formation of such an ultrafiltrate is the net result of the Starling forces that determine fluid movement across capillary beds—that is, the balance between transcapillary hydrostatic pressure and colloid oncotic pressure (Maddox and Brenner, 1991). Filtration is therefore favored when transcapillary hydrostatic pressure exceeds plasma oncotic pressure. An additional determinant of ultrafiltration is the effective hydraulic permeability of the glomerular capillary wall, in other words, the ultrafiltration coefficient (K_f), which is determined by the total surface area available for filtration and the hydraulic permeability of the capillary wall. Consequently, chemically induced decreases in glomerular filtration rate (GFR) may be related to decreases in transcapillary hydrostatic pressure and glomerular plasma flow due to increased afferent arteriolar resistance or to decreases in the surface area available for filtration, resulting from decreases in the size and/or number of endothelial fenestrae or detachment or effacement of foot processes.


Figure 14-3. Schematic of the ultrastructure of the glomerular capillaries. B. Cross section of the glomerular capillary membrane with the capillary endothelium, basement membrane, and epithelium podocytes. [From Guyton AC, Hall JE, 1996, p 32, with permission.]

Although the glomerular capillary wall permits a high rate of fluid filtration (approximately 20 percent of blood entering the glomerulus is filtered), it provides a significant barrier to the transglomerular passage of macromolecules. Experiments using a variety of charged and neutral tracers have established that this barrier function is based on the ability of the glomerulus to act as a size-selective and charge-selective filter (Brenner et al., 1977). In general, the filtration of macromolecules is inversely proportional to the molecular weight of a substance; thus, small molecules, such as inulin (MW 5500), are freely filtered, while large molecules, such as albumin (MW 56,000 to 70,000), are restricted. Filtration of anionic molecules tends to be restricted compared to that of neutral or cationic molecules of the same size. These permselective properties of the glomerulus appear to be directly related to the physicochemical properties of the different cell types within the glomerulus (Kanwar et al., 1991). In particular, charge-selective properties of the glomerulus appear to be related to the anionic groups of the GBM coupled with the anionic coating of the epithelial and endothelial cells (Fig. 14-3). These highly anionic components produce electrostatic repulsion and hinder the circulation of polyanionic macromolecules, thereby markedly retarding passage of these molecules across the filtration barrier. Toxicants that neutralize or reduce the number of fixed anionic charges on glomerular structural elements therefore will impair the charge- and/or size-selective properties of the glomerulus, resulting in urinary excretion of polyanionic and/or high-molecular-weight proteins.

Proximal Tubule

The proximal tubule consists of three discrete segments: the S_1 (pars convoluta), S_2 (transition between pars convoluta and pars recta), and S_3 (the pars recta) segments (Fig. 14-2). The S_1 segment is the initial portion of the proximal convoluted tubule and is characterized by a tall brush border and a well-developed vacuolar lysosomal system. The basolateral membrane is extensively interdigitated and many long mitochondria fill the basal portion of the cell, characteristic of Na^+-transporting epithelia. The S_2 segment comprises the end of the convoluted segment and the initial portion of the straight segment. These cells possess a shorter brush border, fewer apical vacuoles and mitochondria, and less basolateral interdigitation compared to the S_1 cells. The S_3 segment comprises the distal portion of proximal segments and extends to the junction of the outer and inner stripe of the outer medulla. The S_3 cells have a well-developed brush border but fewer and smaller lysosomes and mitochondria than S_1 and S_2 cells.

The formation of urine is a highly complex and integrated process in which the volume and composition of the glomerular filtrate is progressively altered as fluid passes through each of the different tubular segments. The proximal tubule is the workhorse of the nephron, as it reabsorbs approximately 60 to 80 percent of solute and water filtered at the glomerulus. Toxicant-induced injury to the proximal tubule therefore will have major consequences to water and solute balance. Water reabsorption is through a passive iso-osmotic process, driven primarily by Na^+ reabsorption, mediated by the Na^+,K^+-ATPase localized in the basolateral plasma membrane. In addition to active Na^+ reabsorption, the proximal tubule reabsorbs other electrolytes, such as K^+, HCO_3^-, Cl^-, PO_4^{3-}, Ca^{2+}, and Mg^{2+}. The proximal tubule contains numerous transport systems capable of driving concentrative transport of many metabolic substrates, including amino acids, glucose, and citric acid cycle intermediates. The proximal tubule also reabsorbs virtually all of the filtered low-molecular-weight proteins by specific endocytotic protein reabsorption processes. In addition, small linear peptides may be hydrolyzed by peptidases associated with the proximal tubular brush border. An important excretory function of the proximal tubule is secretion of weak organic anions and cations by specialized transporters that drive concentrative movement of these ions from postglomerular blood into proximal tubular cells, followed by secretion into tubular fluid. Toxicant-induced interruptions in the production of energy for any of these active transport mechanisms or the function of critical membrane-bound enzymes or transporters can profoundly affect proximal tubular and whole-kidney function.

The different segments of the proximal tubule exhibit marked biochemical and physiologic heterogeneity (Goldstein, 1993). For example, filtered HCO_3^-, low-molecular-weight proteins, amino acids, and glucose are primarily reabsorbed by the S_1 segment. Transport capacities for these substances in the S_2 and S_3 segments are appreciably less; for example, glucose reabsorption in the S_2 and S_3 segments is about 50 percent and 10 percent of that in the S_1 segment, respectively. In contrast, the principal site of organic anion and cation secretion is in the S_2 and S_1/S_2 segments, respectively. Oxygen consumption, Na^+,K^+-ATPase activity, and gluconeogenic capacity are greater in the S_1 and S_2 segments than in the S_3 segment. Catabolism and apical transport of glutathione (GSH) occurs to a much greater extent in the S_3 segment, where the brush-border enzyme g-glutamyltranspeptidase (GGT) is present in greater amounts. Chemically induced injury to distinct proximal tubular segments therefore may be related in part to their segmental differences in biochemical properties (see " Site-Selective Injury," below).

Loop of Henle

The thin descending and ascending limbs and the thick ascending limb of the loop of Henle are critical to the processes involved in urinary concentration (Fig. 14-2). Approximately 25 percent of the filtered Na^+ and K^+ and 20 percent of the filtered water are reabsorbed by the segments of the loop of Henle. The tubular fluid entering the thin descending limb is iso-osmotic to the renal interstitium; water is freely permeable and solutes, such as electrolytes and urea, may enter from the interstitium. In contrast, the thin ascending limb is relatively impermeable to water and urea, and Na^+ and Cl^- are reabsorbed by passive diffusion. The thick ascending limb is impermeable to water, and active transport of Na^+ and Cl^- is mediated by the Na^+/K^+-$2Cl^-$ cotransport mechanism, with the energy provided by the Na^+,K^+-ATPase. The relatively high rates of Na^+,K^+-ATPase activity and oxygen demand, coupled with the meager oxygen supply in the medullary thick ascending limb, are believed to contribute to the vulnerability of this segment of the nephron to hypoxic injury. The close interdependence between metabolic workload and tubular vulnerability has been demonstrated, revealing that selective damage to the thick ascending limb in the isolated perfused kidney can be blunted by reducing tubular work and oxygen consumption (via inhibition of the Na^+,K^+-ATPase with ouabain) or by increasing oxygen supply (via provision of an oxygen carrier, hemoglobin) (Brezis and Epstein, 1993). Conversely, increasing the tubular workload (via the ionophore amphotericin B) exacerbates hypoxic injury to this segment (Brezis et al., 1984).

Distal Tubule and Collecting Duct

The macula densa comprises specialized cells located between the end of the thick ascending limb and the early distal tubule, in close proximity to the afferent arteriole (Fig. 14-2). This anatomic arrangement is ideally suited for a feedback system whereby a stimulus received at the macula densa is transmitted to the arterioles of the same nephron. Under normal physiologic conditions, increased solute delivery or concentration at the macula densa triggers a signal resulting in afferent arteriolar constriction leading to decreases in GFR (and hence decreased solute delivery). Thus, increases in fluid/solute out of the proximal tubule, due to impaired tubular reabsorption, will activate this feedback system, referred to as *tubuloglomerular feedback* (TGF) and resulting in decreases in the filtration rate of the

same nephron. This regulatory mechanism is viewed as a powerful volume-conserving mechanism, designed to decrease GFR in order to prevent massive losses of fluid/electrolytes due to impaired tubular reabsorption. Humoral mediation of TGF by the renin-angiotensin system has been proposed, and evidence suggests that other substances may be involved. The distal tubular cells contain numerous mitochondria but lack a well-developed brush border and an endocytotic apparatus characteristic of the pars convoluta of the proximal tubule. The early distal tubule reabsorbs most of the remaining intraluminal Na$^+$, K$^+$, and Cl$^-$ but is relatively impermeable to water.

The late distal tubule, cortical collecting tubule, and medullary collecting duct perform the final regulation and fine tuning of urinary volume and composition. The remaining Na$^+$ is reabsorbed in conjunction with K$^+$ and H$^+$ secretion in the late distal tubule and cortical collecting tubule. The combination of medullary and papillary hypertonicity generated by countercurrent multiplication and the action of antidiuretic hormone (vasopressin, ADH) serve to enhance water permeability of the medullary collecting duct. Agents that interfere with ADH synthesis, secretion, or action therefore may impair concentrating ability. Additionally, because urinary concentrating ability is dependent upon medullary and papillary hypertonicity, agents that increase medullary blood flow may impair concentrating ability by dissipating the medullary osmotic gradient.

Table 14-1 illustrates the efficiency of the nephrons in the conservation of electrolytes, substrates, and water and excretion of nitrogenous wastes (urea).

	FILTERED, meq/24 h	REABSORBED, meq/24 h	EXCRETED, meq/24 h	REABSORBED, %
Glucose (g/day)	180	180	0	100
Bicarbonate (meq/day)	4,320	4,318	2	>99.9
Sodium (meq/day)	25,560	25,410	150	99.4
Chloride (meq/day)	19,440	19,260	180	99.1
Water (L/day)	169	167.5	1.5	99.1
Urea (g/day)	48	24	24	50
Creatinine (g/day)	1.8	0	1.8	0

Table 14-1 Filtration, Reabsorption, and Excretion Rates of Different Substances by the Kidneys*

PATHOPHYSIOLOGIC RESPONSES OF THE KIDNEY

Acute Renal Failure

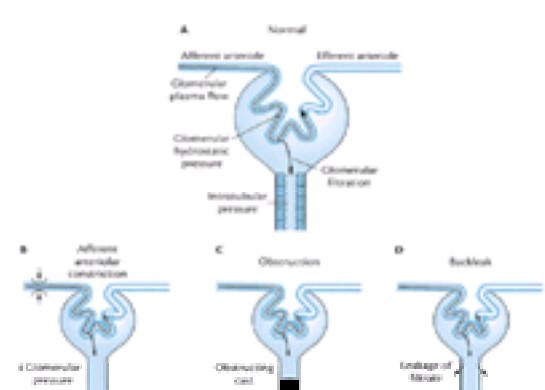
One of the most common manifestations of nephrotoxic damage is acute renal failure (ARF), characterized by an abrupt decline in GFR with resulting azotemia. Any decline in GFR is complex and may result from prerenal factors (afferent arteriolar constriction, hypovolemia, insufficient cardiac output, obstruction of renal arteries), postrenal factors (ureteral or bladder obstruction), and intrarenal factors (tubular epithelial cell death/loss, tubular obstruction) resulting in back-leak, glomerular nephritis, and tubulointerstitial nephritis (Fig. 14-4). Figure 14-5 illustrates the pathways that lead to diminished GFR following chemical exposure. As discussed above, pre- and postrenal factors can lead to decreased GFR. If a chemical causes tubular damage directly, then tubular casts can cause tubular obstruction, increased tubular pressure, and decreased GFR. The tubular damage may result in epithelial cell death/loss, leading to back-leak of glomerular filtrate and a decrease in GFR. If a chemical causes intrarenal hemodynamic alterations that lead to vasoconstriction, the resulting medullary hypoxia may cause tubular damage and/or decreases in perfusion pressure, glomerular hydrostatic pressure, and GFR. Finally, a chemical may disrupt glomerular function, resulting in decreased glomerular ultrafiltration and GFR. Table 14-2 provides a partial list of chemicals that produce ARF through these different mechanisms. Importantly, in most instances ARF is a consequence of tubular damage and/or increased renal vascular resistance.


Figure 14-4. Mechanisms of reduction of the glomerular filtration rate (GFR).

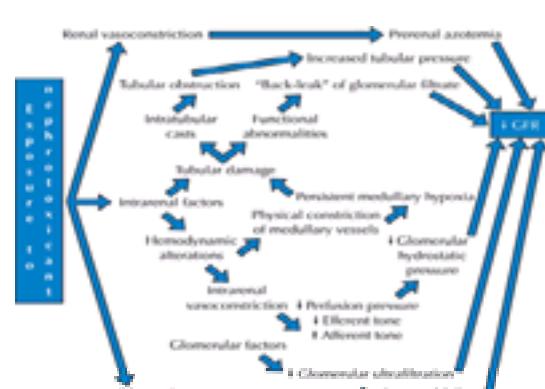
A. GFR depends on four factors: (1) adequate blood flow to the glomerulus; (2) adequate glomerular capillary pressure; (3) glomerular permeability; and (4) low intratubular pressure. B. Afferent arteriolar constriction decreases GFR by reducing blood flow, resulting in diminished capillary pressure. C. Obstruction of the tubular lumen by cast formation increases tubular pressure; when tubular pressure exceeds glomerular capillary pressure, filtration decreases or ceases. D. Back-leak occurs when the paracellular space between cells increases and the glomerular filtrate leaks into the extracellular space and bloodstream [From Molitoris BA, Bacallao R: Pathophysiology of ischemic acute renal failure: Cytoskeletal aspects, in Berl T, Bonventre JV (eds): *Atlas of Diseases of the Kidney.* Philadelphia: Current Medicine, 1999, p 13.5, with permission.]


Figure 14-5. Mechanisms that contribute to decreased GFR in acute renal failure.

After exposure to a nephrotoxicant, one or more mechanisms may contribute to a reduction in the GFR. These include renal vasoconstriction resulting in prerenal azotemia and obstruction due to precipitation of a drug or endogenous compound within the kidney. Intrarenal factors include direct tubular obstruction and dysfunction resulting in tubular back-leak and increased tubular pressure. Alterations in the levels of a variety of vasoactive mediators may result in decreased renal perfusion pressure or efferent arteriolar tone and increased afferent arteriolar tone, leading to in decreased glomerular hydrostatic pressure. [Schnellmann RG, Kelly KJ: Pathophysiology of nephrotoxic acute renal failure, in Berl T, Bonventre JV (eds): *Atlas of Diseases of the Kidney.* Philadelphia: Current Medicine, 1999, p 15.4, with permission.]

Table 14-2 Mechanisms of Chemically Induced Acute Renal Failure

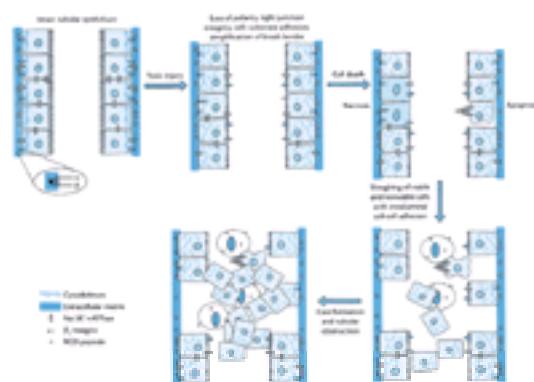
The maintenance of tubular integrity is dependent on cell-to-cell and cell-to-matrix adhesion; these interactions are mediated in part by integrins and cell adhesion molecules (Fig. 14-6). It has been hypothesized that after a chemical or hypoxic insult, adhesion of non–lethally damaged, apoptotic, and oncotic cells to the basement membrane is compromised, leading to their detachment from the basement membrane and appearance in the tubular lumen (Goligorksy et al., 1993). Morphologically, such an event would lead to gaps in the epithelial cell lining, potentially resulting in back-leak of filtrate and diminished GFR. These detached cells may aggregate in the tubular lumen (cell-to-cell adhesion) and/or adhere or reattach to adherent epithelial cells downstream, resulting in tubular obstruction. Further, the loss of expression of integrins on the basolateral membrane may be responsible for the exfoliation of tubular cells, and the redistribution of integrins from the basolateral to the apical membrane facilitates adhesion of detached cells to the in situ epithelium.


Figure 14-6. After injury, alterations can occur in the cytoskeleton and in the normal distribution of membrane proteins such as Na $^+$,K$^+$-ATPase and b$_1$ integrins in sublethally injured renal tubular cells.

These changes result in loss of cell polarity, tight junction integrity, and cell-substrate adhesion. Lethally injured cells undergo oncosis or apoptosis, and both dead and viable cells may be released into the tubular lumen. Adhesion of released cells to other released cells and to cells remaining adherent to the basement membrane may result in cast formation, tubular obstruction, and further compromise the GFR. [Schnellmann RG, Kelly KJ: Pathophysiology of nephrotoxic acute renal failure, in Berl T, Bonventre JV (eds): *Atlas of Diseases of the Kidney*. Philadelphia: Current Medicine, 1999, p 15.5, with permission.]

Other studies have indicated that leukocyte adhesion molecules play a critical role in ARF, possibly because of the ability of activated leukocytes to release cytokines and reactive oxygen species (ROS), resulting in capillary damage/leakage, which may lead to the vascular congestion often observed in ARF. Bonventre and colleagues have demonstrated that treatment of rats with either monoclonal antibodies against the integrins, CD11a and CD11b, or a monoclonal antibody against ICAM-1 (a ligand for CD11a) conferred significant protection against renal ischemic injury (Kelly et al., 1994; Rabb et al., 1994), suggesting a critical role for leukocyte–endothelial adhesion in the pathophysiology of ischemic ARF.

Whereas chemically induced ARF can be initiated by proximal tubular cell injury, nephrotoxicants also may inhibit cellular proliferation and migration, thereby delaying renal functional recovery. For example, Leonard et al. (1994) demonstrated that cisplatin impaired tubular regeneration resulting in prolonged renal dysfunction, effects that were in contrast to the regenerative response and renal functional recovery following tobramycin-induced nephrotoxicity. Using an in vitro model, Counts et al. (1995) reported that following mechanically induced injury to a proximal tubular monolayer, proliferation and migration were inhibited by the heavy metal HgCl$_2$, the mycotoxin fumonisin B$_1$, and dichlorovinyl-L-cysteine (DCVC), suggesting that nephrotoxicants may inhibit/delay the regenerative process.

Adaptation Following Toxic Insult

Fortunately, the kidney has a remarkable ability to compensate for a loss in renal functional mass. Micropuncture studies have revealed that following unilateral nephrectomy, GFR of the remnant kidney increases by approximately 40 to 60 percent, an effect associated with early compensatory increases in glomerular plasma flow rate and glomerular hydraulic pressure. Compensatory increases in single-nephron GFR are accompanied by proportionate increases in proximal tubular water and solute reabsorption; glomerulotubular balance is therefore maintained and overall renal function appears normal by standard clinical tests. Consequently, chemically induced changes in renal function may not be detected until these compensatory mechanisms are overwhelmed by significant nephron loss and/or damage.

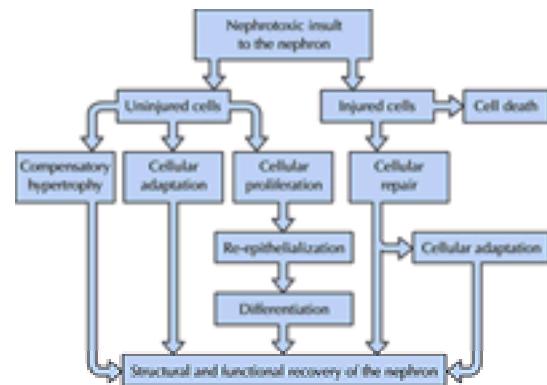
There are a number of cellular and molecular responses to a nephrotoxic insult. After a population of renal cells are exposed to a toxicant, a fraction of the cells will be severely injured and undergo cell death by apoptosis or oncosis (see below) (Fig. 14-7). Those cells that are nonlethally injured may undergo cell repair and/or adaptation, which contribute to the structural and functional recovery of the nephron (Fig. 14-8). In addition, there is a population of cells that are uninjured and may undergo compensatory hypertrophy, cellular adaptation, and cellular proliferation. At this time there is little evidence for a stem cell in the kidney; consequently, it is thought that renal cells undergo dedifferentiation, proliferation, migration, and differentiation. The cellular proliferation and compensatory hypertrophy contribute to the structural and functional recovery of the nephron. Growth factors delivered to renal epithelial cells from local and systemic sources may help orchestrate the proliferative response of the nephron. Several growth factors—such as epidermal growth factor (EGF), insulin-like growth factor-1 (IGF-1), hepatocyte growth factor (HGF), fibroblast growth factors, and transforming growth factors a and b have been implicated in proximal tubular regeneration (Hammerman and Miller, 1994). Interestingly, exogenous administration of EGF, HGF, or IGF-1 accelerates renal repair following ischemic-, gentamicin-, bromohydroquinone-, and/or HgCl$_2$-induced ARF. However, it is not clear which endogenous growth factors are required for tubular regeneration.


Figure 14-7. The response of the nephron to a nephrotoxic insult.

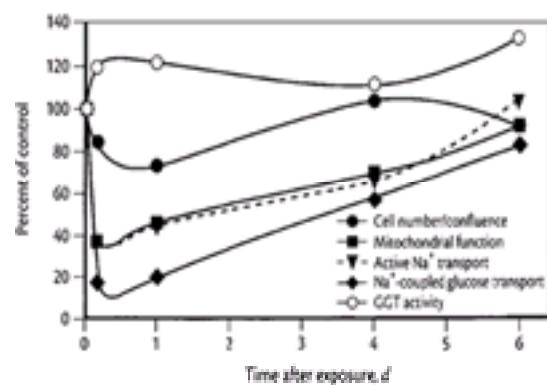
After a population of cells is exposed to a nephrotoxicant, the cells respond; ultimately the nephron recovers function or, if cell death and loss are extensive, nephron function ceases. Terminally injured cells undergo cell death through oncosis or apoptosis. Cells injured sublethally undergo repair and adaptation in response to the nephrotoxicant. Cells not injured and adjacent to the injured area may undergo dedifferentiation, proliferation, migration or spreading, and differentiation. Cells not injured may also undergo compensatory hypertrophy in response to the cell loss and injury. Finally the uninjured cells also may undergo adaptation in response to a nephrotoxicant exposure. [Schnellmann RG, Kelly KJ: Pathophysiology of nephrotoxic acute renal failure, in Berl T, Bonventre JV (eds): *Atlas of Diseases of the Kidney*. Philadelphia: Current Medicine, 1999, p 15.4, with permission.]


Figure 14-8. Inhibition and repair of renal proximal tubule cellular functions after exposure to the model oxidant t-butylhydroperoxide.

Approximately 25 percent cell loss and marked inhibition of mitochondrial function, active Na^+ transport, and Na^+-coupled glucose transport occurred 24 h after oxidant exposure. The activity of the brush-border membrane enzyme g-glutamyl transferase (GGT) was not affected by oxidant exposure. Cell proliferation and migration or spreading was complete by day 4, whereas active Na^+ transport and Na^+-coupled glucose transport did not return to control levels until day 6. These data suggest that selective physiologic functions are diminished after oxidant injury and that a hierarchy exists in the repair process. [Schnellmann RG, Kelly KJ: Pathophysiology of nephrotoxic acute renal failure, in Berl T, Bonventre JV (eds): *Atlas of Diseases of the Kidney*. Philadelphia: Current Medicine, 1999, p 15.6, with permission.]

Two of the most notable cellular adaptation responses are metallothionein induction (see "Cadmium," below) and stress protein induction. Heat-shock proteins (Hsps) and glucose-regulated proteins (Grps) are two examples of stress protein families that are induced in response to a number of pathophysiologic states such as heat shock, anoxia, oxidative stress, toxicants, heavy metal exposure, and tissue trauma. The distribution of individual stress proteins varies between different cell types in the kidney and within subcellular compartments (Goering et al., 2000). These proteins are believed to play an important housekeeping role in the maintenance of normal protein structure and/or the degradation of damaged proteins and thereby to provide a defense mechanism against toxicity and/or for the facilitation of recovery and repair. Hsp induction in renal tissue has been demonstrated following renal ischemia (Van Why et al., 1992; Enami et al., 1991) and treatment with nephrotoxicants such as gentamicin (Komatsuda et al., 1993), haloalkane cysteine conjugates (Chen et al., 1992), and $HgCl_2$ (Goering et al., 1992). Interestingly, proximal tubular Hsps have been identified as molecular targets of the reactive metabolites of the haloalkane cysteine conjugate tetrafluoroethyl- L-cysteine (TFEC) (Bruschi et al., 1993), an effect that could alter the normal housekeeping functions of the proximal tubule and thereby potentially contribute to and exacerbate TFEC nephrotoxicity. Grp78 is an endoplasmic reticulum stress protein, and recent evidence shows that Grp78 is induced following a cellular stress (Halleck et al., 1997). Prior induction of Grp78 in a renal cell line rendered cells tolerant to a subsequent TFEC exposure. These findings suggest that cellular adaptation is an importance response to renal cell injury and death.

Chronic Renal Failure

Progressive deterioration of renal function may occur with long-term exposure to a variety of chemicals (e.g., analgesics, lithium, cyclosporine). It is generally believed that progression to end-stage renal failure is not simply a function of the primary renal insult per se but rather is related to secondary pathophysiologic processes triggered by the initial injury. The progression of chronic renal disease, for example, has been postulated by Brenner and colleagues (1982) to be a consequence of the glomerular hemodynamic response to renal injury. That is, following nephron loss, there are adaptive increases in glomerular pressures and flows that increase the single-nephron GFR of remnant viable nephrons. Although these compensatory mechanisms serve to maintain whole-kidney GFR, evidence has accumulated to suggest that, with time, these alterations are maladaptive and foster the progression of renal failure. Focal glomerulosclerosis eventually develops and may lead to tubular atrophy and interstitial fibrosis. Consequently, glomerulosclerosis in these nephrons will perpetuate the cycle of triggering further compensatory increases in the hemodynamics of less damaged nephrons, contributing, in turn, to their eventual destruction. Although the underlying mechanisms are not precisely known, compensatory increases in glomerular pressures and flows of the remnant glomeruli may result in mechanical damage to the capillaries due to increased shear stress on the endothelium and damage to the glomerular capillary wall, leading to altered permeabilities, and mesangial thickening due to increased transcapillary flux and local deposition of macromolecules (Dunn et al., 1986). Other factors likely to play a role in the pathogenesis of chronic renal failure include growth promoters and inhibitors, increased extracellular matrix deposition, ROS, lipid accumulation, and tubulointerstitial injury.

SUSCEPTIBILITY OF THE KIDNEY TO TOXIC INJURY

Incidence and Severity of Toxic Nephropathy

A wide variety of drugs, environmental chemicals, and metals can cause nephrotoxicity (Table 14-2). A large 1-year survey of all patients with ARF admitted to nephrology units revealed that in 18 percent, ARF was considered to be drug-induced (Kleinknecht et al., 1986; Fluery et al., 1990). Nephrotoxicity is a recognized clinical liability of certain classes of drugs; in particular, antibiotics represent the major class of nephrotoxic drugs, followed by angiotensin-converting enzyme inhibitors, glafenin (a European analgesic), nonsteroidal anti-inflammatory drugs (NSAIDs), and radiocontrast media. Approximately 70 percent of the patients presenting with drug-induced ARF were nonoliguric; the pathologic findings revealed acute tubular necrosis in 60 percent. Approximately 50 percent recovered completely. A myriad of risk factors appear to contribute to the incidence/severity of ARF, including genetic/hereditary factors, volume depletion, septic shock, hypotension, multiple chemical insults, age, diabetes, and preexisting renal disease. The consequences of ARF can be profound, as permanent renal damage may result and dialysis or renal transplantation may be required.

Chronic renal failure leading to end-stage renal failure has been associated with long-term abuse of analgesics. The incidence of analgesic nephropathy has been reported to be as high as 20 to 25 percent in certain countries (e.g., Switzerland). Other agents—such as lithium, cyclosporine, NSAIDs, lead, and cadmium—may produce chronic tubulointerstitial nephropathy with progressive loss of renal function.

Reasons for the Susceptibility of the Kidney to Toxicity

The unusual susceptibility of the mammalian kidney to the toxic effects of noxious chemicals can be attributed in part to the unique physiologic and anatomic features of this organ. Although the kidneys constitute only 0.5 percent of total body mass, they receive about 20 to 25 percent of the resting cardiac output. Consequently, any drug or chemical in the systemic circulation will be delivered to these organs in relatively high amounts. The processes involved in forming a concentrated urine also serve to concentrate potential toxicants in the tubular fluid. As water and electrolytes are reabsorbed from the glomerular filtrate, chemicals in the tubular fluid may be concentrated, thereby driving passive diffusion of toxicants into tubular cells. Therefore, a nontoxic concentration of a chemical in the plasma may reach toxic concentrations in the kidney. Progressive concentration of toxicants along the nephron may result in intraluminal precipitation of relatively insoluble compounds, causing ARF secondary to tubular obstruction. Finally, renal transport, accumulation, and metabolism of xenobiotics contribute significantly to the susceptibility of the kidney (and specific nephron segments) to toxic injury (see "Site-Selective Injury," below).

In addition to intrarenal factors, the incidence and/or severity of chemically induced nephrotoxicity may be related to the sensitivity of the kidney to circulating vasoactive substances. For example, nephrotoxicity due to NSAIDs is known to result in ARF if patients are suffering from hypotension, hypovolemia, and/or cardiac insufficiency (Brezis et al., 1991). Under these conditions, vasoconstrictors such as angiotensin II or vasopressin are increased. Normally, the actions of high circulating levels of vasoconstrictor hormones are counterbalanced by the actions of increased vasodilatory prostaglandins; thus, renal blood flow (RBF) and GFR are maintained. However, when prostaglandin synthesis is suppressed by NSAIDs, RBF declines markedly and ARF ensues, due to the unopposed actions of vasoconstrictors. Another example of predisposing risk factors relates to the clinical use of angiotensin-converting enzyme (ACE) inhibitors, such as captopril (De Jong and Woods, 1998). Captopril has been reported to produce ARF in patients with severe hypertension, due either to bilateral renal artery stenosis or to renal artery stenosis in a solitary kidney. Under these conditions, glomerular filtration pressure is dependent on angiotensin II–induced efferent arteriolar constriction. ACE inhibitors will block this vasoconstriction, resulting in a precipitous decline in filtration pressure and ARF.

Site-Selective Injury

Many nephrotoxicants have their primary effects on discrete segments or regions of the nephron. For example, the proximal tubule is the primary target for most nephrotoxic antibiotics, antineoplastics, halogenated hydrocarbons, mycotoxins, and heavy metals, whereas the glomerulus is the primary site for immune complexes, the loop of Henle/collecting ducts for fluoride ions, and the medulla/papilla for chronically consumed analgesic mixtures. The reasons underlying this site-selective injury are complex but can be attributed in part to site-specific differences in blood flow, transport and accumulation of chemicals, physicochemical properties of the epithelium, reactivity of cellular/molecular targets, balance of bioactivation/detoxification reactions, cellular energetics, and/or regenerative/repair mechanisms.

Glomerular Injury

The glomerulus is the initial site of chemical exposure within the nephron, and a number of nephrotoxicants produce structural injury to this segment. In certain instances, chemicals alter glomerular permeability to proteins by altering the size- and charge-selective functions. Both puromycin aminonucleoside and doxorubicin target glomerular epithelial cells, resulting in changes in size and charge selectivity and proteinuria. The decrease in charge selectivity is thought to result from a decrease in negatively charged sites, while the loss of size selectivity is thought to result from focal detachment of podocytes from the glomerular basement membrane.

Cyclosporine, amphotericin B, and gentamicin are examples of chemicals that impair glomerular ultrafiltration without significant loss of structural integrity and decrease GFR. Amphotericin B decreases GFR by causing renal vasoconstriction and decreasing the glomerular capillary ultrafiltration coefficient (K_f), an effect probably mediated through the endothelial cells. Because of its polycationic nature, the aminoglycoside gentamicin interacts with the anionic sites on the endothelial cells, decreasing K_f and GFR. Finally, cyclosporine not only causes renal vasoconstriction and vascular damage but is injurious to the glomerular endothelial cell.

Chemically induced glomerular injury may also be mediated by extrarenal factors. Circulating immune complexes may be trapped within the glomeruli; binding of complement, attraction of neutrophils, and phagocytosis may result. Neutrophils and macrophages are commonly observed within glomeruli in membranous glomerulonephritis, and the local release of cytokines and reactive oxygen species (ROS) may contribute to glomerular injury. Heavy metals (e.g., $HgCl_2$, gold, cadmium), hydrocarbons, penicillamine, and captopril can produce this type of glomerular injury. A chemical may function as a hapten attached to some native protein (e.g., tubular antigens released secondary to toxicity) or as a complete antigen—particularly if it is sequestered within the glomerulus via electrostatic interactions—and elicit an antibody response. Antibody reactions with cell-surface antigens (e.g., GBM) lead to immune deposit formation within the glomeruli, mediator activation, and subsequent injury to glomerular tissue. Volatile hydrocarbons, solvents, and $HgCl_2$ have been implicated in this type of glomerulonephritis.

Proximal Tubular Injury

The proximal tubule is the most common site of toxicant-induced renal injury. The reasons for this relate in part to the selective accumulation of xenobiotics into this segment of the nephron. For example, in contrast to the distal tubule, which is characterized by a relatively tight epithelium with high electrical resistance, the proximal tubule has a leaky epithelium, favoring the flux of compounds into proximal tubular cells. More importantly, tubular transport of organic anions and cations, low-molecular-weight proteins and peptides, GSH conjugates, and heavy metals is localized primarily if not exclusively to the proximal tubule. Thus, transport of these molecules will be greater in the proximal tubule than in other segments, resulting in proximal tubular accumulation and toxicity. Indeed, segmental differences in transport and accumulation appear to play a significant role in the onset and development of proximal tubular toxicity associated with certain drugs such as aminoglycosides, b-lactam antibiotics, and cisplatin; environmental chemicals such as ochratoxin, haloalkene S-conjugates, d-limonene, and 2,4,4-trimethylpentane; and metals such as cadmium and mercury. Although correlations between proximal tubular transport, accumulation, and toxicity suggest that the site of transport is a crucial determinant of the site of toxicity, transport is unlikely to be the sole criterion. For example, the S_2 segment is the primary site of transport and toxicity of cephaloridine, and several lines of evidence suggest a strong correlation between the transport, accumulation, and nephrotoxicity of this antibiotic. However, when a variety of cephalosporins are considered, the rank order of accumulation does not follow the rank order of nephrotoxicity; for example, renal cortical concentrations of the potent nephrotoxicant cephaloglycin are comparable to those of the relatively nontoxic cephalexin. These data suggest that site-specific transport and accumulation are necessary but not sufficient to cause proximal tubular toxicity of cephalosporins. Once taken up and sequestered by the proximal tubular cell, the nephrotoxic potential of these drugs ultimately may be dependent upon the intrinsic reactivity of the drug with subcellular or molecular targets.

In addition to segmental differences in transport, segmental differences in cytochrome P450 and cysteine conjugate b-lyase activity also are contributing factors to the enhanced susceptibility of the proximal tubule. Both enzyme systems are localized almost exclusively in the proximal tubule, with negligible activity in the glomerulus, distal tubules, or collecting ducts. Thus, nephrotoxicity requiring P450 and b-lyase–mediated bioactivation will most certainly be localized in the proximal tubule. Indeed, the site of proximal tubular bioactivation contributes at least in part to the proximal tubular lesions produced by chloroform (via cytochrome P450) and by haloalkene S-conjugates (via cysteine b-lyase).

Finally, proximal tubular cells appear to be more susceptible to ischemic injury than are distal tubular cells. Therefore, the proximal tubule likely will be the primary site of toxicity for chemicals that interfere with renal blood flow, cellular energetics, and/or mitochondrial function.

Loop of Henle/Distal Tubule/Collecting Duct Injury

Chemically-induced injury to the more distal tubular structures, compared to the proximal tubule, is an infrequent occurrence. Functional abnormalities at these sites manifest primarily as impaired concentrating ability and/or acidification defects. Drugs that have been associated with acute injury to the more distal tubular structures include amphotericin B, cisplatin, and methoxyflurane. Each of these drugs induces an ADH-resistant polyuria, suggesting that the concentrating defect occurs at the level of the medullary thick ascending limb and/or the collecting duct. However, the mechanisms mediating these drug-induced concentrating defects appear to be different. Amphotericin B is highly lipophilic and interacts with lipid sterols such as cholesterol, resulting in the formation of transmembrane channels or pores and disrupting membrane permeability (Bernardo and Branch, 1997). Thus, amphotericin effectively transforms the tight distal tubular epithelium into one that is leaky to water and ions and impairs reabsorption at these sites. The mechanisms mediating cisplatin-induced polyuria are not completely understood, but the first phase is responsive to vasopressin and inhibitors of prostaglandin synthesis (Safirstein and Defray, 1998). The second phase is not responsive to vasopressin or prostaglandin synthesis inhibitors but is associated with decreased papillary solute content. Methoxyflurane nephrotoxicity is associated with the inhibitory effects of the metabolite fluoride on solute and water reabsorption (Jarnberg, 1998). Fluoride inhibits sodium chloride reabsorption in the thick ascending limb and inhibits

ADH-mediated reabsorption of water, possibly due to disruption in adenylate cyclase.

Papillary Injury

The renal papilla is susceptible to the chronic injurious effects of abusive consumption of analgesics. The intial target is the medullary interstitial cells, followed by degenerative changes in the medullary capillaries, loops of Henle, and collecting ducts (Bach, 1997). Although the exact mechanisms underlying selective damage to the papilla by analgesics are not known, the intrarenal gradient for prostaglandin H synthase activity has been implicated as a contributing factor. This activity is greatest in the medulla and least in the cortex, and the prostaglandin hydroperoxidase component metabolizes phenacetin to reactive intermediates capable of covalent binding to cellular macromolecules. Other factors may contribute to this site-selective injury, including high papillary concentrations of potential toxicants and inhibition of vasodilatory prostaglandins, compromising renal blood flow to the renal medulla/papilla and resulting in tissue ischemia. The lack of animal models that mimic the papillary injury observed in humans has limited mechanistic research in this area (Schnellmann, 1998).

ASSESSMENT OF RENAL FUNCTION

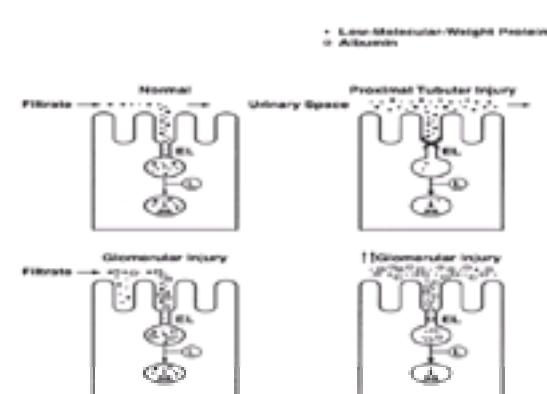
Evaluation of the effects of a chemical on the kidney can be accomplished using a variety of both in vivo and in vitro methods. Initially, nephrotoxicity can be assessed by evaluating serum and urine chemistries following treatment with the chemical in question. The standard battery of noninvasive tests includes measurement of urine volume and osmolality, pH, and urinary composition (e.g., electrolytes, glucose, protein). Although specificity is often lacking in such an assessment, urinalysis provides a relatively easy and noninvasive assessment of overall renal functional integrity and can provide some insight into the nature of the nephrotoxic insult. For example, chemically induced increases in urine volume accompanied by decreases in osmolality may suggest an impaired concentrating ability, possibly via a defect in ADH synthesis, release, and/or action. To determine whether the impaired concentrating ability is due to an altered tubular response to ADH, concentrating ability can be determined before and after an exogenous ADH challenge. Glucosuria may reflect chemically induced defects in proximal tubular reabsorption of sugars; however, because glucosuria also may be secondary to hyperglycemia, measurement of serum glucose concentrations also must be evaluated. Urinary excretion of high-molecular-weight proteins, such as albumin, is suggestive of glomerular damage, whereas excretion of low-molecular-weight proteins, such as b $_2$-microglobulin, suggests proximal tubular injury (Fig. 14-9). Urinary excretion of enzymes localized in the brush border (e.g., alkaline phosphatase, g-glutamyl transferase) may reflect brush-border damage, whereas urinary excretion of other enzymes (e.g., lactate dehydrogenase) may reflect more generalized cell damage. Enzymuria is often a transient phenomenon, as chemically induced damage may result in an early loss of most of the enzyme available. Thus, the absence of enzymuria does not necessarily reflect an absence of damage.


Figure 14-9. Mechanism of glomerular and tubular proteinuria.

In the healthy kidney, low-molecular-weight proteins are filtered by the glomerulus and reabsorbed by an endocytic mechanism to form an endosome (EL), which in turn fuses with lysosomes (L), where proteins are catabolized to their constituent amino acids (aa) (*upper left*). Following proximal tubular injury, formation and internalization of endocytotic vesicles may be impaired, resulting in decreased reabsorption and increased urinary excretion of low-molecular-weight proteins (*upper right*). In mold, glomerular injury, high-molecular-weight proteins, such as albumin, that traverse the glomerular barrier may be taken up by the proximal tubule (*bottom left*); however, with severe glomerular injury, proximal tubular transport of albumin is saturated, resulting in albuminuria (*bottom left*). [Goldstein RS, Schnellmann RG: Toxic responses of the kidney, in Klaassen CD (ed): *Casarett & Doull's Toxicology.* New York: McGraw-Hill, 1996, with permission.]

GFR can be measured directly by determining creatinine or inulin clearance. Creatinine is an endogenous compound released from skeletal muscle at a constant rate under most circumstances. Further, it is completely filtered with limited secretion. Inulin is an exogenous compound that is completely filtered with no reabsorption or secretion. Following the injection of inulin, inulin serum and urinary concentrations and urine volume are determined over time. If creatinine is being used, then serum and urinary creatinine concentrations and urine volume are determined over time. Creatinine or inulin clearance is determined by the following formula:

$$\text{Inulin clearance (mL/min)} = \frac{\text{inulin concentration in urine (mg/L)} \times \text{urine volume (mL/min)}}{\text{Inulin concentration in serum (mg/L)}}$$

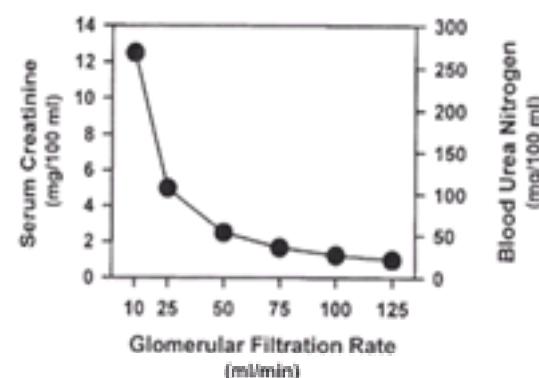
Indirect markers of GFR are serial blood urea nitrogen (BUN) and serum creatinine concentrations. However, both serum creatinine and BUN are rather insensitive indices of GFR; a 50 to 70 percent decrease in GFR must occur before increases in serum creatinine and BUN develop (Fig. 14-10). Chemically induced increases in BUN and/or serum creatinine may not necessarily reflect renal damage but rather may be secondary to dehydration, hypovolemia, and/or protein catabolism. These extrarenal events should be taken into consideration in evaluating BUN/serum creatinine as potential endpoints of renal toxicity and/or when correlating these endpoints with renal histopathology.


Figure 14-10. Relationships among glomerular filtration rate, serum creatinine, and blood urea nitrogen concentrations in the determination of renal function.

In general, approximately 50 percent of renal function must be lost before serum creatinine or blood urea nitrogen increases.
[From Tarloff JB, Kinter LB: *In vivc* methodologies used to assess renal function, in Sipes IG, McQueen CA, Gandolfi AJ (eds): *Comprehensive Toxicology.* Vol 7. Oxford, England: Elsevier, 1997, pp 99–120, with permission.]

Histopathologic evaluation of the kidney following treatment is crucial in identifying the site, nature, and severity of the nephrotoxic lesion. Assessment of chemically

induced nephrotoxicity therefore should include urinalysis, serum clinical chemistry, and histopathology to provide a reasonable profile of the functional and morphologic effects of a chemical on the kidney. Further, information on the biotransformation and toxicokinetics of the chemical should be used to direct further in vivo and in vitro studies; in particular, what metabolites are found in the kidney and what are the concentrations of parent compound and metabolites in the kidney over time.

Once a chemical has been identified as a nephrotoxicant in vivo, a variety of in vitro techniques may be used to elucidate underlying mechanisms. Tissue obtained from naive animals may be used in the preparation of isolated perfused kidneys, kidney slices, isolated suspensions of renal tubules, cells or subcellular organelles, primary cultures of renal cells, and established renal cell lines. For example, freshly prepared isolated perfused kidneys, kidney slices, and renal tubular suspensions and cells exhibit the greatest degree of differentiated functions and similarity to the in vivo situation. However, these models have limited lifespans of 2 to 24 h. In contrast, primary cultures of renal cells and established renal cell lines exhibit longer life spans (>2 weeks), but—by comparison to the in vivo condition—exhibit differentiated functions and similarity to a lesser degree; this is particularly true of immortalized renal cell lines. The reader is referred to several excellent reviews for further details on the utility and limitations of these preparations (Tarloff and Kinter, 1997 ; Ford, 1997). Such approaches may be used to distinguish between an effect on the kidney due to a direct chemical insult and one caused by extrarenal effects such as extrarenally generated metabolites, hemodynamic effects, immunologic effects, and so forth. Care must be taken to ensure that the cell type affected in the in vitro model is the same as that affected in vivo. In addition, concentrations of the nephrotoxicant to be used in in vitro preparations must be comparable to those observed in vivo, as different mechanisms of toxicity may be operative at concentrations that saturate metabolic pathways or overwhelm detoxification mechanisms. Once a mechanism has been identified in vitro, the postulated mechanism must be tested in vivo. Thus, appropriately designed in vivo and in vitro studies should provide a complete characterization of the biochemical, functional, and morphologic effects of a chemical on the kidney and an understanding of the underlying mechanisms in the target cell population(s).

BIOCHEMICAL MECHANISMS/MEDIATORS OF RENAL CELL INJURY

Cell Death

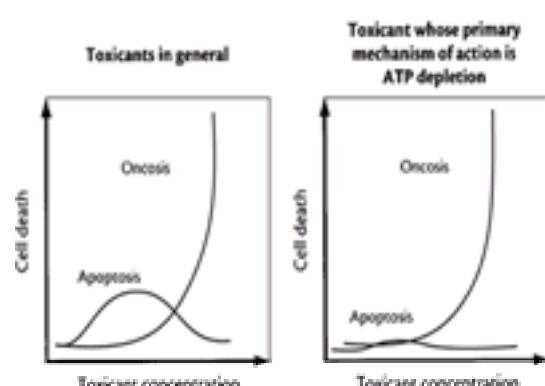
In many cases, renal cell injury may culminate in cell death. In general, cell death is thought to occur through either oncosis or apoptosis (Levin et al., 1999). The morphologic and biochemical characteristics of necrosis and apoptosis are very different. Apoptosis is a tightly controlled, organized process that usually affects scattered individual cells. The organelles retain integrity while cell volume decreases. Ultimately, the cell breaks into small fragments that are phagocytosed by adjacent cells or macrophages without producing an inflammatory response. In some cases DNA fragmentation occurs through an endonuclease-mediated cleavage of the DNA at internucleosomal linker regions, which can be visualized as a ladder-like pattern following agarose gel electrophoresis. In contrast, oncosis often affects many contiguous cells; the organelles swell, cell volume increases, and the cell ruptures with the release of cellular contents, followed by inflammation. With many toxicants, lower but injurious concentrations produce cell death through apoptosis (Fig. 14-11). As the concentration of the toxicant increases, oncosis plays a predominant role. However, because apoptosis is an ATP-dependent process, for those toxicants that target the mitochondrion, oncosis may be the predominant pathway with only limited apoptosis occurring. In general, while nephrotoxicants produce cell death through apoptosis and oncosis, it is likely that the degree of oncosis leads to renal failure.


Figure 14-11. *The general relationship between oncosis and apoptosis after nephrotoxicant exposure.*

For many toxicants, low concentrations primarily cause apoptosis and oncosis occurs principally at higher concentrations. When the primary mechanism of action of the nephrotoxicant is ATP depletion, oncosis may be the predominant cause of cell death, with limited apoptosis occurring. [Schnellmann RG, Kelly KJ: Pathophysiology of nephrotoxic acute renal failure, in Berl T, Bonventre JV (eds): *Atlas of Diseases of the Kidney*. Philadelphia: Current Medicine, 1999, p 15.6, with permission.]

Mediators of Toxicity

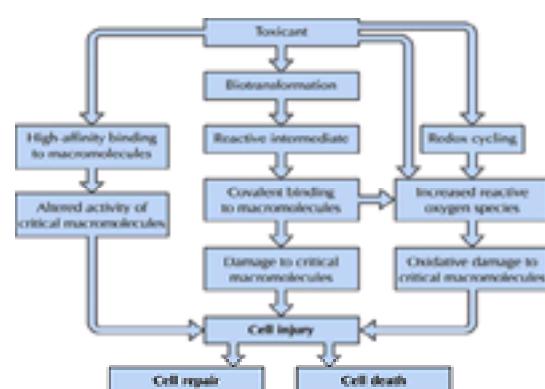
A chemical can initiate cell injury by a variety of mechanisms (Fig. 14-12). In some cases the chemical may initiate toxicity due to its intrinsic reactivity with cellular macromolecules. For example, amphotericin B reacts with plasma membrane sterols, increasing membrane permeability; fumonisin B_1 inhibits sphinganine (sphingosine) N-acyltransferase; and Hg^{2+} binds to sulfhydryl groups on cellular proteins. In contrast, some chemicals are not toxic until they are biotransformed to a reactive intermediate. Biologically reactive intermediates, also known as alkylating agents, are electron-deficient compounds (electrophiles) that bind to cellular nucleophiles (electron-rich compounds) such as proteins and lipids. For example, acetaminophen and chloroform are metabolized in the mouse kidney by cytochrome P450 to the reactive intermediates, N-acetyl-p-benzoquinonimine and phosgene, respectively (see " Chloroform " and " Acetaminophen ," below). The covalent binding of the reactive intermediate to critical cellular macromolecules is thought to interfere with the normal biological activity of the macromolecule and thereby initiate cellular injury. In other instances, extrarenal biotransformation may be required prior to the delivery of the penultimate nephrotoxic species to the proximal tubule, where it is metabolized further to a reactive intermediate.


Figure 14-12. *Covalent and noncovalent binding versus oxidative stress mechanisms of cell injury.*

Nephrotoxicants are generally thought to produce cell injury and death through one of two mechanisms, either alone or in combination. In some cases the toxicant may have a high affinity for a specific macromolecule or class of macromolecules that results in altered activity (increase or decrease) of these molecules and cell injury. Alternatively, the parent nephrotoxicant may not be toxic until it is biotransformed into a reactive intermediate that binds covalently to macromolecules and, in turn, alters their activity, resulting in cell injury. Finally, the toxicant may increase reactive oxygen species in the cells directly, after being biotransformed into a reactive intermediate or through redox cycling. The resulting increase in reactive oxygen species results in oxidative damage and cell injury. [Schnellmann RG, Kelly KJ: Pathophysiology of nephrotoxic acute renal failure, in Berl T, Bonventre JV (eds): *Atlas of Diseases of the Kidney*. Philadelphia: Current Medicine, 1999, p 15.7, with permission.]

Finally, chemicals may initiate injury indirectly by inducing oxidative stress via increased production of ROS, such as superoxide anion, hydrogen peroxide, and hydroxyl radicals. ROS can react with a variety of cellular constituents to induce toxicity. For example, ROS are capable of inducing lipid peroxidation, which may result in altered membrane fluidity, enzyme activity, and membrane permeability and transport characteristics; inactivating cellular enzymes by directly oxidizing critical protein sulfhydryl or amino groups; depolymerizing polysaccharides; and inducing DNA strand breaks and chromosome breakage. Each of these events could lead to cell injury and/or death. Oxidative stress has been proposed to contribute, at least in part, to the nephrotoxicity associated with ischemia/reperfusion injury, gentamicin, cyclosporine, cisplatin, and haloalkene cysteine conjugates (Chen et al., 1990; Groves et al., 1991; Ueda et al., 2001).

While nitric oxide is an important second messenger in a number of physiologic pathways, recent studies suggest that in the presence of oxidative stress, nitric oxide can be converted into reactive nitrogen species that contribute to cellular injury and death. For example, in the presence of superoxide anion, nitric oxide can be transformed into peroxynitrite (ONOO⁻), a strong oxidant and nitrating species (Pryor and Squadrito, 1995). Proteins, lipids, and DNA are all targets of peroxynitrite. The primary evidence for a role of peroxynitrite in renal ischemia/reperfusion injury is the formation of nitrotyrosine-protein adducts and the attenuation of renal dysfunction through the inhibition of the inducible form of nitric oxide synthase (Ueda et al., 2001).

Cellular/Subcellular and Molecular Targets

A number of cellular targets have been identified to play a role in cell death. It is generally thought that an intracellular interaction (e.g., an alkylating agent or ROS with a macromolecule) initiates a sequence of events that leads to cell death. In the case of oncosis, a "point of no return" is reached in which the cell will die regardless of any intervention. The idea of a single sequence of events is probably simplistic for most toxicants, given the extensive number of targets available for alkylating species and ROS. Rather, multiple pathways, with both distinct and common sequences of events, may lead to cell death.

Cell Volume and Ion Homeostasis

Cell volume and ion homeostasis are tightly regulated and are critical for the reabsorptive properties of the tubular epithelial cells. Toxicants generally disrupt cell volume and ion homeostasis by interacting with the plasma membrane and increasing ion permeability or by inhibiting energy production. The loss of ATP, for example, results in the inhibition of membrane transporters that maintain the internal ion balance and drive transmembrane ion movement. Following ATP depletion, Na^+,K^+-ATPase activity decreases, resulting in K^+ efflux, Na^+ and Cl^- influx, cell swelling, and ultimately cell membrane rupture. Miller and Schnellmann (1993, 1995) have proposed that ATP depletion in rabbit renal proximal tubule segments initially results in K^+ efflux and Na^+ influx followed by a lag period before Cl^- influx occurs. Cl^- influx occurs during the late stages of cell injury produced by a diverse group of toxicants and does not appear to be due to currently characterized renal Cl^- transporters. Cl^- influx may be a trigger for cell swelling, because decreasing Cl^- influx decreased cell swelling and cell death, and inhibition of cell swelling decreased cell lysis but not Cl^- influx. Meng and Reeves (2000) have reported similar findings using hydrogen peroxide as the toxicant and LLC-PK$_1$ cells.

Cytoskeleton and Cell Polarity

Toxicants may cause early changes in membrane integrity such as loss of the brush border, blebbing of the plasma membrane, or alterations in membrane polarity. These changes can result from toxicant-induced alterations in cytoskeleton components and cytoskeletal–membrane interactions, or they may be associated with perturbations in energy metabolism or calcium and phospholipid homeostasis. Marked changes in the polarity of tubular epithelium occur following an ischemic insult. Under control conditions, the tubular epithelial cell is polarized with respect to certain transporters and enzymes. During in vivo ischemia and in vitro ATP depletion there is a dissociation of Na^+,K^+-ATPase from the actin cytoskeleton and redistribution from the basolateral membrane to the apical domain in renal proximal tubule cells (Molitoris, 1997). The redistribution of this enzyme has been postulated to explain decreased Na^+ and water reabsorption during ischemic injury.

Mitochondria

Many cellular processes depend on mitochondrial ATP and thus become compromised simultaneously with inhibition of respiration. Conversely, mitochondrial dysfunction may be a consequence of some other cellular process altered by the toxicant. Numerous nephrotoxicants cause mitochondrial dysfunction (Schnellman and Griner, 1994). For example, following an in vivo exposure, $HgCl_2$ altered isolated renal cortical mitochondrial function and mitochondrial morphology prior to the appearance of tubular necrosis (Weinberg et al., 1982a). Furthermore, $HgCl_2$ produced similar changes in various respiratory parameters when added to isolated rat renal cortical mitochondria (Weinberg et al., 1982b). Different toxicants also produce different types of mitochondrial dysfunction. For example, pentachlorobutadienyl-L-cysteine initially uncouples oxidative phosphorylation in renal proximal tubular cells by dissipating the proton gradient, while TFEC does not uncouple oxidative phosphorylation but rather inhibits state 3 respiration by inhibiting sites I and II of the electron transport chain (Schnellmann et al., 1987, 1989; Wallin et al., 1987; Hayden and Stevens, 1990).

Whether toxicants target mitochondria directly or indirectly, it is clear that mitochondria play a critical role in determining whether cells die by apoptosis or oncosis. The mitochondrial permeability transition (MPT) is characterized by the opening of a high-conductance pore that allows solutes of <1500 molecular weight to pass (Lemasters, 1999). It is thought that the MPT occurs during cell injury and ultimately progresses to apoptosis if sufficient ATP is available or oncosis if ATP is depleted. Further, the release of cytochrome c following the MPT plays a key role in activating downstream caspases and executing apoptosis.

Lysosomes

Lysosomes are key subcellular targets of aminoglycosides, unleaded gasoline, and d-limonene and are believed to induce cellular injury via rupture and release of lysosomal enzymes and toxicants into the cytoplasm following excessive accumulation of reabsorbed toxicant(s) and lysosomal overload. a$_{2u}$-Globulin is normally reabsorbed in the proximal tubule and degraded in the lysosomes. a$_{2u}$-Nephropathy occurs in male rats when compounds such as d-limonene and constituents of unleaded gasoline bind to a$_{2u}$-globulin, inhibiting normal lysosomal degradation and resulting in the accumulation of a$_{2u}$-globulin in the proximal tubule. The size and number of lysosomes increase and a characteristic protein-droplet morphology is observed. Ultimately, this leads to single-cell necrosis and regenerative hyperplasia.

The aminoglycosides also induce lysosomal dysfunction following tubular reabsorption of aminoglycosides and accumulation in lysosomes (Fig. 14-13). The size and number of lysosomes increase and electron-dense lamellar structures called myeloid bodies appear. The myeloid bodies contain undegraded phospholipids and are thought to occur through the inhibition of lysosomal hydrolases and phospholipases by the aminoglycosides.

[From De Broe ME: Renal injury due to environmental toxins, drugs, and contrast agents, in Berl T, Bonventre JV (eds): Atlas of Diseases of the Kidney. Philadelphia: Current Medicine, 1999, p 11.4, with permission.]

Ca²⁺ Homeostasis

Ca^{2+} is a second messenger and plays a critical role in a variety of cellular functions. The distribution of Ca^{2+} within renal cells is complex and involves binding to anionic sites on macromolecules and compartmentation within subcellular organelles. The critical cellular Ca^{2+} pool for regulation is the free Ca^{2+} present in the cytosol. The concentration of this pool is approximately 100 nM and is maintained at this level against a large extracellular/intracellular gradient (10,000:1) by a series of pumps and channels located on the plasma membrane and endoplasmic reticulum (ER). Because the proximal tubular cells reabsorb approximately 50 to 60 percent of the filtered load of Ca^{2+}, they must maintain low cytosolic Ca^{2+} concentrations during a large Ca^{2+} flux.

Sustained elevations or abnormally large increases in cytosolic free Ca^{2+} can exert a number of detrimental effects on the cell. For example, an increase in cytosolic free Ca^{2+} can activate a number of degradative Ca^{2+}-dependent enzymes, such as phospholipases and proteinases, and can produce aberrations in the structure and function of cytoskeletal elements. While the precise role of Ca^{2+} in toxicant-induced injury remains unclear, release of ER Ca^{2+} stores may be a key step in initiating the injury process and increasing cytosolic free Ca^{2+} concentrations. For example, prior depletion of ER Ca^{2+} stores protects renal proximal tubules from extracellular Ca^{2+} influx and cell death produced by mitochondrial inhibition and hypoxia (Waters et al., 1997b). Mitochondria are known to accumulate Ca^{2+} in lethally injured cells through a low-affinity, high-capacity Ca^{2+} transport system. While this system plays a minor role in normal cellular Ca^{2+} regulation, under injurious conditions the uptake of Ca^{2+} may facilitate ROS formation and damage.

Phospholipases

Phospholipase A_2 (PLA_2) consists of a family of enzymes that hydrolyze the acyl bond at the sn-2 position of phospholipids, resulting in the release of arachidonic acid and lysophospholipid. The enzymes within this family have different biochemical characteristics, substrate preferences, and Ca^{2+} dependencies. PLA_2 activation has been suggested to play a role in various forms of cell injury through a variety of mechanisms (Cummings et al., 2000a). A supraphysiologic increase in PLA_2 activity could result in the loss of membrane phospholipids and consequently impair membrane function. The increase in PLA_2 activity may be secondary to an increase in cytosolic Ca^{2+}, because some PLA_2 enzymes translocate to membranes following increases in cytosolic free Ca^{2+}. Cell membranes are rich with polyunsaturated fatty acids and as such are susceptible to lipid peroxidation. Peroxidized lipids are predisposed to degradation by PLA_2, resulting in increased PLA_2 activity and the formation of peroxidized arachidonic acid metabolites and lysophospholipids. Lysophospholipids can be toxic to cells and alter membrane permeability characteristics and uncouple mitochondrial respiration. Furthermore, the eicosanoid products of arachidonic metabolism are chemotactic for neutrophils, which also may contribute to tissue injury.

The actual role of PLA_2 in renal cell injury has been controversial, as it is unclear whether changes in PLA_2 are a cause or consequence of cell injury or death (Cummings et al., 2000a). Further difficulties arise because inhibitors of PLA_2 are not very selective. However, Sapirstein et al. (1996) showed that cytosolic Ca^{2+}-dependent PLA_2 (cPLA₂) contributed to oxidant-induced oncosis by overexpressing cPLA₂ or secretory PLA_2 in LLC-PK₁ cells and demonstrating that cells overexpressing cPLA₂ were more susceptible to H_2O_2 toxicity, whereas overexpression of sPLA₂ did not increase H_2O_2 toxicity. In contrast, Cummings et al. (2000b) demonstrated that inhibition of Ca^{2+}-independent PLA_2 (iPLA₂) potentiates ɪ-butylhydroperoxide-induced oncosis in rabbit renal proximal tubular cells. Thus, the role of PLA_2s in oncosis depends upon the PLA_2 isoform and stimulus of injury. While the role of PLA_2s in renal cell apoptosis has received minimal attention, it has been reported that inhibition of iPLA₂ decreases cisplatin-induced proximal tubular cell apoptosis (Cummings et al., 2000c).

Endonucleases

Endonucleases have been suggested to play a role in renal cell oncosis and apoptosis. Endonuclease activation with the associated DNA cleavage producing a "ladder" pattern following gel elecrophoresis is a well-characterized response of apoptosis. In this case, the observed DNA cleavage is a very late event in the apoptotic process. Ueda et al. (1995) reported DNA damage and the activation of an endonuclease in rat renal proximal tubules undergoing oncosis following hypoxia/reoxygenation. In contrast, DNA cleavage producing a "ladder" pattern was not observed following in vitro exposure of rabbit proximal tubules to mitochondrial inhibitors, the oxidant ɪ-butylhydroperoxide, or the calcium ionophore ionomycin (Schnellmann et al., 1993). These studies suggest that endonuclease activation may occur during apoptosis and oncosis, but that endonuclease activation does not uniformly occur following renal cell injury.

Proteinases

Supraphysiologic activation of proteinases could disrupt normal membrane and cytoskeleton function and lead to cell death. One source of proteinases is the lysosomes, where proteins are normally degraded by acid hydrolases. Under conditions of cell injury, the lysosomal membrane could rupture, releasing hydrolases into the cytosol to degrade susceptible proteins. However, several studies suggest that proximal tubular cell death does not necessarily involve lysosomal rupture (Weinberg, 1993). For example, a variety of cysteine and serine proteinase inhibitors were ineffective in protecting rabbit renal proximal tubules from antimycin A, tetrafluoroethyl-ʟ-cysteine, bromohydroquinone, and ɪ-butylhydroperoxide (Schnellmann and Williams, 1998). Only E64 demonstrated any cytoprotective properties following exposure to antimycin A and TFEC, and the cytoprotection was not associated with the inhibition of lysosomal cysteine proteinases. These results suggest that nonlysosomal cysteine proteinases play an important role in cell death.

The calpains, calcium-activated neutral proteinases, are likely candidates for a role in cell death because they are cysteine proteinases; they are activated by calcium; and they have cytoskeletal proteins, membrane proteins, and enzymes as substrates. For example, calpain activity increased in rat proximal tubules subjected to hypoxia, and calpain inhibitors were cytoprotective (Edelstein et al., 1996). Further, Schnellmann and coworkers (Waters et al., 1997a) showed that calpain inhibitors with different mechanisms of action decreased cell death produced by a variety of toxicants, suggesting that calpains may play an important role in the cell death produced by a diverse range of toxicants. The mechanisms and targets of calpains in cell injury remain to be determined.

Caspases are another class of cysteine proteinases that play a role in renal cell death. A number of caspases have been identified in the rat kidney (e.g. caspases 1, 2, 3, and 6), and rat kidneys subjected to ischemia/reperfusion injury exhibit differential expression of caspases with marked increases in caspases 1 and 3 (Kaushal et al., 1998). Treatment of LLC-PK₁ cells with cisplatin resulted in caspase 3 activation and apoptosis (Zhan et al., 1999). While the caspase cascade is clearly integral in the initiation and execution of apoptosis, the role of different caspases in chemically induced renal injury requires additional experimentation.

SPECIFIC NEPHROTOXICANTS

Heavy Metals

Many metals—including cadmium, chromium, lead, mercury, platinum, and uranium—are nephrotoxic. It is important to recognize that the nature and severity of metal nephrotoxicity varies with respect to its form. For example, salts of inorganic mercury produce a greater degree of renal injury and a lesser degree of neurotoxicity than do organic mercury compounds, an effect that has been associated with the greater degree of lipophilicity of organic mercury compounds (Conner and Fowler, 1993; Zalups and Lash, 1994). In addition, different metals have different primary targets within the kidney. For example, potassium dichromate primarily affects the S_1 and S_2 segments of the proximal tubule, while mercuric chloride affects the S_2 and S_3 segments (Zalups and Lash, 1994).

Metals may cause toxicity through their ability to bind to sulfhydryl groups. For example, the affinity of mercury for sulfhydryl groups is very high and is about ten orders of magnitude higher than the affinity of mercury for carbonyl or amino groups (Ballatori, 1991). Thus, metals may cause renal cellular injury through their ability to bind to sulfhydryl groups of critical proteins within the cells and thereby inhibit their normal function.

Mercury Humans and animals are exposed to elemental mercury vapor, inorganic mercurous and mercuric salts, and organic mercuric compounds through the environment. Administered elemental mercury is rapidly oxidized in erythrocytes or tissues to inorganic mercury, and thus the tissue distribution of elemental and inorganic mercury is similar. Due to its high affinity for sulfhydryl groups, virtually all of the Hg^{2+} found in blood is bound to cells, albumin, other sulfhydryl containing proteins, glutathione, and cysteine.

The kidneys are the primary target organs for accumulation of Hg^{2+}, and the S_3 segment of the proximal tubule is the initial site of toxicity. As the dose or duration of

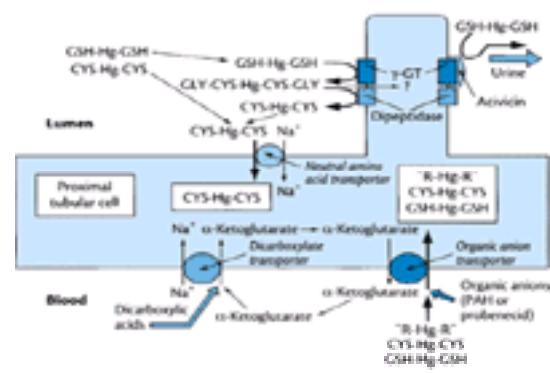
treatment increases, the S_1 and S_2 segments may be affected. Renal uptake of Hg^{2+} is very rapid with as much as 50 percent of a nontoxic dose of Hg^{2+} found in the kidneys within a few hours of exposure. Considering the fact that virtually all of the Hg^{2+} found in blood is bound to an endogenous ligand, it is likely that the luminal and/or basolateral transport of Hg^{2+} into the proximal tubular epithelial cell is through cotransport of Hg^{2+} with an endogenous ligand such as glutathione, cysteine, or albumin, or through some plasma membrane Hg^{2+}-ligand complex. Current evidence indicates that at least two mechanisms are involved in the proximal tubular uptake of Hg^{2+} (Fig. 14-14) (Zalups, 1997). One mechanism appears to involve the apical activity of g-glutamyltranspeptidase (g-GT) and a neutral amino acid transporter. Basolateral membrane transport is likely to be mediated by the organic anion transport system.


Figure 14-14. Cellular transport of Hg^{2+}.

Proximal tubular uptake of inorganic mercury is thought to be the result of the transport of Hg^{2+} conjugates [e.g., diglutathione-Hg^{2+} conjugate (GSH-Hg-GSH), dicysteine-Hg^{2+} conjugate (CYS-HG-CYS)]. At the luminal membrane, GSH-Hg-GSH is metabolized by g-GT and a dipeptidase to form CYS-HG-CYS. CYS-HG-CYS may be taken up by an amino acid transporter. At the basolateral membrane, Hg^{2+}-conjugates appear to be transported by the organic anion transporter. Uptake of Hg^{2+}-protein conjugates by endocytosis may play a minor role in the uptake of Hg^{2+}. (Courtesy of Dr. R.K. Zalups.) [Schnellmann RG, Kelly KJ: Pathophysiology of nephrotoxic acute renal failure, in Berl T, Bonventre JV (eds): *Atlas of Diseases of the Kidney*. Philadelphia: Current Medicine, 1999, p 15.7, with permission.]

The acute nephrotoxicity induced by $HgCl_2$ is characterized by proximal tubular necrosis and ARF within 24 to 48 h after administration (Zalups, 1997). Early markers of $HgCl_2$-induced renal dysfunction include an increase in the urinary excretion of brush-border enzymes such as alkaline phosphatase and g-GT, suggesting that the brush border may be an initial target of $HgCl_2$. Subsequently, when tubular injury becomes severe, intracellular enzymes such as lactate dehydrogenase and aspartate aminotransferase increase in the urine. As injury progresses, tubular reabsorption of solutes and water decreases and there is an increase in the urinary excretion of glucose, amino acids, albumin, and other proteins. Associated with the increase in injured proximal tubules is a decrease and progressive decline in the GFR. For example, GFR was reduced 35 percent in rats within 6 h of $HgCl_2$ administration and continued to decline to 32 percent and 16 percent of controls at 12 and 24 h, respectively (Eknoyan et al., 1982). The reduction in GFR results from the glomerular injury, tubular injury, and/or vasoconstriction. Interestingly, there is an early decrease in RBF secondary to the vasoconstriction. RBF may return to normal within 24 to 48 h, while GFR continues to decline. If the decline in renal function is not too severe, the remaining proximal tubular cells undergo a proliferative response and renal function returns over time.

As stated above, inorganic mercury has a very high affinity for protein sulfhydryl groups, and this interaction is thought to play an important role in the toxicity of mercury at the cellular level. Changes in mitochondrial morphology and function are very early events following $HgCl_2$ administration, supporting the hypothesis that mitochondrial dysfunction is an early and important contributor to inorganic mercury–induced cell death along the proximal tubule. Other studies have suggested that oxidative stress plays an important role in $HgCl_2$-induced renal injury. For example, Fukino and colleagues (1984) observed increased thiobarbituric acid–reactive substances, a marker of lipid peroxidation, in renal cortical homogenates following $HgCl_2$ administration, suggesting that oxidative stress did occur. Recent studies by Lund and coworkers (1993) showed that mitochondria isolated from rats treated with $HgCl_2$ exhibited elevated hydrogen peroxide formation and thus were a possible source of ROS. Finally, $HgCl_2$ increases intracellular free calcium in primary cultures of rabbit renal tubular cells (Smith et al., 1987) and may activate a variety of degradative pathways that contribute to proximal tubular injury.

Several animal studies have shown that chronic exposure to inorganic mercury results in an immunologically mediated membranous glomerular nephritis secondary to the production of antibodies against the glomerular basement membrane and the deposition of immune complexes (Zalups, 1997).

Cadmium Chronic exposure of nonsmoking humans and animals to cadmium is primarily through food and results in nephrotoxicity (Kido and Nordberg, 1998). In the workplace, inhalation of cadmium-containing dust and fumes is the major route of exposure. Cadmium has a half-life of greater than 10 years in humans and thus accumulates in the body over time. Approximately 50 percent of the body burden of cadmium can be found in the kidney. Cadmium produces proximal tubule dysfunction (S_1 and S_2 segments) and injury characterized by increases in urinary excretion of glucose, amino acids, calcium, and cellular enzymes. This injury may progress to a chronic interstitial nephritis.

Numerous studies have tried to identify markers to predict the nephrotoxic effects of cadmium in humans. These include but are not limited to urinary cadmium, calcium, amino acids, albumin, b_2-microglobulin, *N*-acetyl-b-D-glucosaminidase, and retinol-binding protein concentrations. Lauwerys and coworkers (1994) have suggested that cadmium concentrations in the urine greater than 5 and 2 nmol/mmol creatinine for adult male workers and the general population, respectively, are associated with tubular dysfunction.

A very interesting aspect of cadmium nephrotoxicity is the role metallothioneins (Klaassen et al., 1999). Metallothioneins are a family of low-molecular-weight, cysteine-rich metal-binding proteins that have a high affinity for cadmium and other heavy metals. In general, the mechanism by which metallothionein is thought to play a role in cadmium and heavy metal toxicity is through its ability to bind to a heavy metal and thereby render it biologically inactive. This assumes that the unbound or "free" concentration of the metal is the toxic species. Metallothionein production can be induced by low, nontoxic concentrations of metals. Subsequently, animals challenged with a higher dose of the metal will not exhibit toxicity compared to naive animals.

Following an oral exposure to $CdCl_2$, Cd^{2+} is thought to reach the kidneys both as Cd^{2+} and as a Cd^{2+}-metallothionein complex formed and released either from intestinal cells or hepatocytes. The Cd^{2+}-metallothionein complex is freely filtered by the glomerulus and is reabsorbed by the proximal tubule. Inside the tubular cells it is thought that lysosomal degradation of the Cd^{2+}-metallo-thionein results in the release of "free" Cd^{2+}, which, in turn, induces renal metallothionein production. Once the renal metallothionein pool is saturated, "free" Cd^{2+} initiates injury. The mechanism by which Cd^{2+} produces injury at the cellular level is not clear; however, low concentrations of Cd^{2+} have been shown to interfere with the normal function of several cellular signal transduction pathways, including inositol triphosphate, cytosolic free Ca^{2+}, and protein kinase C (Beyersmann et al., 1994; Smith et al., 1989).

Chemically Induced a_{2u}-Globulin Nephropathy

A diverse group of chemicals—including unleaded gasoline, d-limonene, 1,4-dichlorobenzene, tetrachloroethylene, decalin, and lindane—cause a a_{2u}-globulin nephropathy or hyaline droplet nephropathy (Lehman-McKeeman, 1997). This nephropathy occurs in male rats, is characterized by the accumulation of protein droplets in the S_2 segment of the proximal tubule, and results in single-cell necrosis, the formation of granular casts at the junction of the proximal tubule and the thin loop of Henle, and cellular regeneration. Chronic exposure to these compounds results in progression of these lesions and ultimately in chronic nephropathy. With compounds such as unleaded gasoline, chronic exposure results in an increased incidence of renal adenomas/carcinomas by nongenotoxic mechanisms.

As the name implies, the expression of this nephropathy requires the presence of the a_{2u}-globulin protein. a_{2u}-Globulin is synthesized in the liver of male rats and is under androgen control. Due to its low molecular weight (18.7 kDa), a_{2u}-globulin is freely filtered by the glomerulus with approximately half being reabsorbed via endocytosis in the S_2 segment of the proximal tubule. Many of the compounds that cause a_{2u}-globulin nephropathy bind to a_{2u}-globulin in a reversible manner and

decrease the ability of lysosomal proteases in the proximal tubule to breakdown a_{2u}-globulin (see above). This results in the accumulation of a_{2L}-globulin in the proximal tubule with an increase in the size and number of lysosomes and the characteristic protein-droplet morphology. A proposed mechanism of a_{2u}-globulin nephropathy is that cellular necrosis secondary to lysosomal overload leads to a sustained increase in cell proliferation, which, in turn, results in the promotion of spontaneously or chemically initiated cells to form preneoplastic and neoplastic foci (Lehman-McKeeman, 1997; Melnick, 1992).

a_{2u}-Globulin nephropathy appears to be sex- and species- specific. That is, it occurs in male rats but not female rats and in male or female mice, rabbits, or guinea pigs because they do not produce a_{2u}-globulin (Lehman-McKeeman, 1997). Furthermore, it does not occur in male Black Reiter rats that lack a a_{2u}-globulin. Considering the diversity of compounds that cause a_{2u}-globulin nephropathy and renal tumors and the fact that humans are exposed to these compounds regularly, the question arises whether humans are at risk for a_{2u}-globulin nephropathy and renal tumors when exposed to these compounds. Current data suggest that humans are not at risk because (1) humans do not synthesize a_{2u}-globulin, (2) humans secrete less proteins in general and in particular less low-molecular-weight proteins in urine than the rat; (3) the low-molecular-weight proteins in human urine are either not related structurally to a a_{2L}-globulin, do not bind to compounds that bind to a a_{2u}-globulin, or are similar to proteins in female rats, male Black Reiter rats, rabbits, or guinea pigs that do not exhibit a a_{2u}-globulin nephropathy; and (4) mice excrete a low-molecular-weight urinary protein that is 90 percent homologous to a a_{2u}-globulin, but they do not exhibit a_{2u}-globulin-nephropathy and renal tumors following exposure to a_{2u}-globulin-nephropathy–inducing agents.

Halogenated Hydrocarbons

Halogenated hydrocarbons are a diverse class of compounds and are used extensively as chemical intermediates, solvents, and pesticides. Consequently, humans are exposed to these compounds not only in the workplace but also through the environment. Numerous toxic effects have been associated with acute and chronic exposure to halogenated hydrocarbons, including nephrotoxicity (Elfarra, 1997). The three examples provided below illustrate the importance of biotransformation in the nephrotoxicity of halogenated hydrocarbons.

Chloroform Chloroform produces nephrotoxicity in a variety of species, with some species being more sensitive than others. The primary cellular target is the proximal tubule, with no primary damage to the glomerulus or the distal tubule. Proteinuria, glucosuria, and increased blood urea nitrogen levels are all characteristic of chloroform-induced nephrotoxicity. The nephrotoxicity produced by chloroform is linked to its metabolism by renal cytochrome P450 and the formation of a reactive intermediate that binds covalently to nucleophilic groups on cellular macromolecules. Cytochrome P450 biotransforms chloroform to trichloromethanol, which is unstable and releases HCl to form phosgene. Phosgene can react with (1) water to produce 2 HCl + CO_2, (2) two molecules of glutathione to produce diglutathionyl dithiocarbonate, (3) cysteine to produce 2-oxothizolidine-4-carboxylic acid, or (4) cellular macromolecules to initiate toxicity. The sex differences observed in chloroform nephrotoxicity appear to be related to differences in renal cytochrome P450 isozyme contents. For example, castration of male mice decreased renal cytochrome P450 and chloroform-induced nephrotoxicity (Smith et al., 1984). Likewise, testosterone pretreatment of female mice increased cytochrome P450 content and rendered female mice susceptible to the nephrotoxic effects of chloroform. Cytochrome P450 isozyme 2E1 is present in male mice and expressed in female mice treated with testosterone (Lock and Reed, 1997). Thus, these isozymes may play a role in chloroform-induced nephrotoxicity.

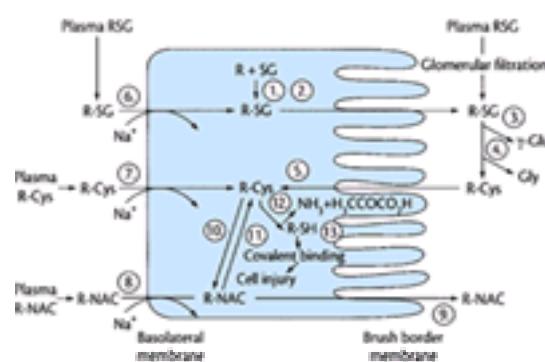
Tetrafluoroethylene Tetrafluoroethylene is metabolized in the liver by GSH- *S*-transferases to *S*-(1,1,2,2-tetrafluoroethyl)-glutathione. The GSH conjugate is secreted into the bile and small intestine where it is degraded to the cysteine *S*-conjugate (TFEC), reabsorbed, and transported to the kidney. The mercapturic acid may also be formed in the small intestine and reabsorbed. Alternatively, the glutathione conjugate can be transported to the kidney and biotransformed to the cysteine conjugate by g-GT and a dipeptidase located on the brush border (Fig. 14-15). The mercapturic acid is transported into the proximal tubule cell by the organic anion transporter while cysteine conjugates are transported by the organic anion transporter and the sodium-independent L and T transport systems. The cysteine *S*-conjugate of these compounds is thought to be the penultimate nephrotoxic species. Following transport into the proximal tubule, which is the primary cellular target for haloalkenes and haloalkanes, the cysteine *S*-conjugate is a substrate for the cytosolic and mitochondrial forms of the enzyme cysteine conjugate b-lyase. In the case of the *N*-acetyl-cysteine *S*-conjugate, the *N*-acetyl group must be removed by a deacetylase for it to be a substrate for cysteine conjugate b-lyase. The products of the reaction are ammonia, pyruvate, and a reactive thiol that is capable of binding covalently to cellular macromolecules. There is a correlation between the covalent binding of the reactive thiol of the cysteine conjugate with renal protein and nephrotoxicity. Hayden and colleagues (1991) and Bruschi and coworkers (1993) have shown that biotransformation of TFEC results in difluorothioamidyl- L-lysine-protein adducts in mitochondria and that two of the targeted proteins may belong to the heat- shock family of proteins. Hayden and colleagues (1992) have also shown that halogenated thioamide adducts of phosphatidylethanolamine are formed in mitochondria following cysteine conjugate b-lyase biotransformation of TFEC.


Figure 14-15. Renal tubular uptake and metabolism of GSH conjugates.

(1) Intracellular formation of GSH conjugates (R-SG) catalyzed by renal GSH S-transferase(s); (2) Secretion of the R-SG into the lumen; (3) g-GT-mediated catabolism of R-SG and formation of the corresponding S-cysteinylglycine conjugate; (4) formation of the corresponding cysteine conjugate (R-Cys); (5) Na^+-coupled transport of R-Cys into the renal proximal tubular cell; (6) Na^+-coupled transport of RSG across the basolateral membrane; (7) Na^+-coupled transport of R-Cys across the basolateral membrane; (8) Na^+-coupled and probenecid-sensitive transport of the mercapturate (R-NAC) across the basolateral membrane; (9) secretion R-NAC into the lumen; (10) deacetylation of R-NAC to R-Cys and (11) acetylation of R-Cys to R-NAC; (12) reactive thiol formation via b-lyase; (13) binding of the reactive thiol to cellular macromolecules and initiation of cell injury. [Schnellmann RG, Kelly KJ: Pathophysiology of nephrotoxic acute renal failure, in Berl T, Bonventre JV (eds): *Atlas of Diseases of the Kidney*. Philadelphia: Current Medicine, 1999, p 15.7, with permission.]

The nephrotoxicity produced by haloalkenes is characterized morphologically by proximal tubular necrosis, primarily affecting the S_3 segment, and functionally by increases in urinary glucose, protein, cellular enzymes, and BUN. Following in vivo and in vitro exposures to TFEC, the mitochondrion appears to be a primary target. In rabbit renal proximal tubules and isolated mitochondria, there is a marked decrease in state 3 respiration (respiration associated with maximal ATP formation) following TFEC exposure (Groves et al., 1993). Furthermore, the decrease in mitochondrial function occurs prior to the onset of cell death. Oxidative stress may also play a contributing role in TFEC-induced cell death because lipid peroxidation products were formed prior to the onset of cell death, and antioxidants and iron chelators decreased cytotoxicity (Chen et al., 1990; Groves et al., 1991).

Bromobenzene In addition to their hepatotoxic effects, bromobenzene and other halogenated benzenes also produce nephrotoxicity. The biotransformation of these compounds, like that of the haloalkenes, is critical for the expression of the nephrotoxicity. In a series of studies, Lau and Monks demonstrated that bromobenzene must be oxidized by hepatic cytochrome P450 to bromophenol and then further oxidized to bromohydroquinone (BHQ) (Lau and Monks, 1997). BHQ is conjugated to glutathione, forming 2-bromo-*bis*(glutathione-*S*-yl)hydroquinone and three positional isomers of 2-bromo-(glutathione- *S*-yl)hydroquinone. The diglutathione conjugate is approximately a thousandfold more potent than bromobenzene in producing nephrotoxicity, while it produces the same morphologic changes in the S_3 segment and increases the amount of protein, glucose, and cellular enzymes in the urine. The glutathione conjugates of BHQ are substrates for renal g-GT activity and may ultimately be converted to cysteine and *N*-acetyl-cysteine conjugates of BHQ. Lau and Monks (1997) have proposed a sequence of pathways for the renal disposition of 2-bromo-bis(cystein-*S*-yl)hydroquinone and 2-bromo-(cystein-yl)hydroquinones and identified possible toxic reactive intermediates. While the mechanisms by which these compounds produce proximal tubular cell death remains to be determined, experiments using LLC-PK1 cells as a model suggest that ROS play an important

role.

Mycotoxins

The nephrotoxicity of two mycotoxins, ochratoxin A and citrinin, found on a variety of cereal grains have been studied extensively and reviewed by Berndt (1993). Citrinin administration to rats may result in either anuric renal failure and death or nonoliguric renal failure with complete recovery within 8 days. In contrast, ochratoxin A produces renal dysfunction only after repeated injections of small doses—a condition characterized by glucosuria, ketonuria, proteinuria, and polyuria. One or both of these mycotoxins have been implicated in Balkan nephropathy in humans, although the data to support this are less than clear.

Fumonisins (mycotoxins produced by the fungus *Fusarium moniliforme* and other *Fusarium* species) are commonly found on corn and corn products and produce nephrotoxicity in rats and rabbits (Bucci et al., 1998). Histologic examination of the kidney revealed disruption of the basolateral membrane, mitochondrial swelling, increased numbers of clear and electron-dense vacuoles, and apoptosis in proximal tubular cells at the junction of the cortex and medulla. Changes in renal function included increased urine volume, decreased osmolality, and increased excretion of low- and high-molecular-weight proteins. The fumonisins are structurally similar to sphingoid bases and are thought to produce their toxicity through the inhibition of sphinganine (sphingosine) *N*-acyltransferase. Inhibition of this enzyme results in an increase in the ratio of free sphinganine to free sphingosine and a decrease in complex sphingolipids. However, the mechanism by which these sphingolipid alterations results in cell death is unknown.

Therapeutic Agents

Acetaminophen Large doses of the antipyretic and analgesic acetaminophen (APAP) are commonly associated with hepatotoxicity. However, large doses of APAP can also cause nephrotoxicity in humans and animals. APAP nephrotoxicity is characterized by proximal tubular necrosis with increases in BUN and plasma creatinine; decreases in GFR and clearance of paraaminohippurate; increases in the fractional excretion of water, sodium, and potassium; and increases in urinary glucose, protein, and brush-border enzymes. There appears to be a marked species difference in the nature and mechanism of APAP nephrotoxicity (Emeigh Hart et al., 1994; Tarloff, 1997). Morphologically, the primary targets in the mouse kidney are the S_1 and S_2 segments of the proximal tubule, while in the rat kidney the S_3 segment is the target. In the mouse, renal cytochrome P450 2E1 has been associated with APAP biotransformation to a reactive intermediate, *N*-acetyl-*p*-amino-benzoquinoneimine, that arylates proteins in the proximal tubule and initiates cell death. Two of the proteins that are targets of *N*-acetyl-*p*-amino-benzoquinoneimine are a selenium-binding protein and a glutamine synthetase (Emeigh Hart et al., 1994; Tarloff, 1997). However, the mechanism by which protein adducts initiate proximal tubular cell death and ultimately nephrotoxicity remains to be determined. While renal cytochrome P450 plays a role in APAP activation and nephrotoxicity, glutathione conjugates of APAP may also contribute to APAP nephrotoxicity. Evidence for this pathway was provided by experiments in which g-GT or organic anion transport was inhibited and APAP-induced nephrotoxicity decreased (Emeigh Hart et al., 1990).

In contrast to its effects in the mouse, a critical and early step in APAP nephrotoxicity in the rat is the conversion of APAP to *para*-aminophenol (PAP) (Tarloff, 1997). PAP is also a metabolite of phenacetin and aniline and is a known toxicant to the S_3 segment of the proximal tubule in the rat. The steps following PAP formation and the expression of nephrotoxicity are less clear. PAP or a metabolite must be further oxidized to a benzoquinoneimine or other oxidized reactive intermediate for nephrotoxicity to occur, and there is an association between covalent binding of a PAP equivalent to renal protein and nephrotoxicity. Although glutathione conjugates of PAP have been isolated from rats treated with PAP and have been shown to be nephrotoxic when administered, the exact role they play in PAP nephrotoxicity is not clear. For example, inhibition of g-GT or organic anion transport did not ameliorate PAP-induced nephrotoxicity (Anthony et al., 1993; Fowler et al., 1993), while bile duct cannulation and GSH depletion partially attenuated PAP-induced nephrotoxicity (Gartland et al., 1990).

Nonsteroidal Anti-Inflammatory Drugs (NSAIDs) NSAIDs such as aspirin, ibuprofen, naproxen, and indomethacin are extensively used as analgesics and anti-inflammatory agents and produce their therapeutic effects through the inhibition of prostaglandin synthesis. At least three different types of nephrotoxicity have been associated with NSAID administration (Bach, 1997; Tarloff, 1997; Whelton and Watson, 1998). ARF may occur within hours of a large dose of a NSAID, is usually reversible upon withdrawal of the drug, and is characterized by decreased RBF and GFR and by oliguria. When the normal production of vasodilatory prostaglandins is inhibited by NSAIDs, vasoconstriction induced by circulating catecholamines and angiotensin II are unopposed, resulting in decreased RBF and ischemia.

In contrast, chronic consumption of NSAIDs and/or APAP (>3 years) results in an often irreversible form of nephrotoxicity known as analgesic nephropathy (Bach, 1997; Elseviers and De Broe, 1998). The incidence of analgesic nephropathy varies widely in the western world, ranging from less than 1 to 18 percent of patients who present with end-stage renal disease requiring dialysis. The primary lesion in this nephropathy is papillary necrosis with chronic interstitial nephritis (see above). Initial changes are to the medullary interstitial cells and is followed by degenerative changes to the medullary loops of Henle and medullary capillaries. The mechanism by which NSAIDs produce analgesic nephropathy is not known but may result from chronic medullary/papillary ischemia secondary to renal vasoconstriction. Other studies have suggested that a reactive intermediate is formed in the cells that, in turn, initiates an oxidative stress or binds covalently to critical cellular macromolecules.

The third albeit rare type of nephrotoxicity associated with NSAIDs is an interstitial nephritis (Tarloff, 1997; Whelton and Watson, 1998) characterized by a diffuse interstitial edema with infiltration of inflammatory cells. Patients normally present with elevated serum creatinine and proteinuria. If NSAIDs are discontinued, renal function improves in 1 to 3 months.

Aminoglycosides The aminoglycoside antibiotics are so named because they consist of two or more amino sugars joined in a glycosidic linkage to a central hexose nucleus. While they are drugs of choice for many gram-negative infections, their use is primarily limited by their nephrotoxicity. The incidence of renal dysfunction following aminoglycoside administration ranges from 5 to 25 percent but seldom leads to a fatal outcome (Cojocel, 1997; De Broe, 1999; Verpooten et al., 1998).

Renal dysfunction by aminoglycosides is characterized by a nonoliguric renal failure with reduced GFR and an increase in serum creatinine and BUN. Polyuria is an early event following aminoglycoside administration and may be due to inhibition of chloride transport in the thick ascending limb (Kidwell et al., 1994). Within 24 h, increases in urinary brush-border enzymes, glucosuria, aminoaciduria, and proteinuria are observed. Histologically, lysosomal alterations are noted initially, followed by damage to the brush border, endoplasmic reticulum, mitochondria, and cytoplasm, ultimately leading to tubular cell necrosis. Interestingly, proliferation of renal proximal tubule cells can be observed early after the onset of nephrotoxicity.

Aminoglycosides are highly polar cations; they are almost exclusively filtered by the glomerulus and excreted unchanged. Filtered aminoglycosides undergo proximal tubular reabsorption by binding to anionic phospholipids in the brush border, followed by endocytosis and sequestration in lysosomes of the S_1 and S_2 segments of the proximal tubules (Fig. 14-13). Basolateral membrane binding and uptake also may occur, but this is a minor contribution to the total proximal tubular uptake of aminoglycosides. The earliest lesion observed following clinically relevant doses of aminoglycosides is an increase in the size and number of lysosomes. These lysosomes contain *myeloid bodies,* which are electron-dense lamellar structures containing undergraded phospholipids. The renal phospholipidosis produced by the aminoglycosides is thought to occur through their inhibition of lysosomal hydrolases, such as sphingomyelinase and phospholipases. While phospholipidosis plays an important role in aminoglycoside nephrotoxicity, the steps between the phospholipid accumulation in the lysosomes and tubular cell death are less clear. One hypothesis suggests that the lysosomes become progressively distended until they rupture, releasing lysosomal enzymes and high concentrations of aminoglycosides into the cytoplasm (Fig. 14-13). The released lysosomal contents can interact with various membranes and organelles and trigger cell death. Another mechanism of aminoglycoside nephrotoxicity includes a decrease in K_f and GFR (see above).

Amphotericin B Amphotericin B is a very effective antifungal agent whose clinical utility is limited by its nephrotoxicity (Bernardo and Branch, 1997). Renal dysfunction associated with amphotericin B treatment is dependent on cumulative dose and is due to both hemodynamic and tubular effects. Amphotericin B nephrotoxicity is characterized by ADH-resistant polyuria, renal tubular acidosis, hypokalemia, and either acute or chronic renal failure. Amphotericin B nephrotoxicity is unusual in that it impairs the functional integrity of the glomerulus and of the proximal and distal portions of the nephron.

Amphotericin B administration is associated with decreases in RBF and GFR secondary to renal arteriolar vasoconstriction or activation of TGF. In animals, the calcium channel blocker verapamil blocks the acute amphotericin B–induced renal vasoconstriction, suggesting that the vasoconstriction may be mediated through increased calcium levels in vascular smooth muscle cells (Tolins and Raij, 1988). However, verapamil did not completely block the acute decrease in GFR, suggesting that the decrease in GFR is not exclusively due to vasoconstriction. Thus, renal vasoconstriction is an important component in amphotericin B–induced chronic renal failure.

Some of the renal tubular cell effects of amphotericin B are due to the ability of this polyene to bind to cholesterol in the plasma membrane and form aqueous pores.

In the presence of amphotericin B, cells of the turtle and rat distal tubule do not produce a normal net outward flux of protons due to an increase in proton permeability (Steinmetz and Husted, 1982; Gil and Malnic, 1989). This results in impaired proton excretion and renal tubular acidosis. The hypokalemia observed with amphotericin B may be due to an increase in luminal potassium ion permeability in the late distal tubule and the cortical collecting duct and the loss of potassium ions in the urine.

Cyclosporine Cyclosporine is an important immunosuppressive agent and is widely used to prevent graft rejection in organ transplantation. Cyclosporine is a fungal cyclic polypeptide and acts by selectively inhibiting T-cell activation. Nephrotoxicity is a critical side effect of cyclosporine, with nearly all patients who receive the drug exhibiting some form of nephrotoxicity. Clinically, cyclosporine-induced nephrotoxicity may manifest as (1) acute reversible renal dysfunction, (2) acute vasculopathy, and (3) chronic nephropathy with interstitial fibrosis (Mason and Moore, 1997; Dieperink et al., 1998).

Acute renal dysfunction is characterized by dose-related decreases in RBF and GFR and increases in BUN and serum creatinine. These effects are lessened by reducing the dosage or by cessation of therapy. The decrease in RBF and GFR is related to marked vasoconstriction induced by cyclosporine; and it is probably produced by a number of factors, including an imbalance in vasoconstrictor and vasodilatory prostaglandin production. In particular, increased production of the vasoconstrictor thromboxane A_2 appears to play a role in cyclosporine-induced ARF. Endothelin may contribute to constriction of the afferent arteriole because endothelin receptor antagonists inhibit cyclosporine-induced vasoconstriction (Lanese and Conger, 1993). While a number of studies have explored possible direct effects of cyclosporine on tubular cells, it is still not clear whether a direct effect of cyclosporine on tubular cells plays a role in the nephrotoxicity.

Acute vasculopathy or thrombotic microangiopathy is a rather unusual nephrotoxic lesion that affects arterioles and glomerular capillaries, without an inflammatory component, following cyclosporine treatment. Hyaline and/or fibroid changes, often with fibrinogen deposition, is observed in arterioles, while thrombosis with endothelial cell desquamation affects the glomerular capillaries (Racusen and Solez, 1993). The pathogenesis of this lesion is poorly understood. While the characteristics of this lesion differ from the vascular changes of acute rejection, a variety of factors may contribute to this lesion in the clinical transplant setting.

Long-term treatment with cyclosporine can result in chronic nephropathy with interstitial fibrosis. Modest elevations in serum creatinine and decreases in GFR occur along with hypertension, proteinuria, and tubular dysfunction. Histologic changes are profound; they are characterized by arteriolopathy, global and segmental glomerular sclerosis, striped interstitial fibrosis, and tubular atrophy. These lesions may not be reversible if cyclosporine therapy is discontinued and may result in end-stage renal disease. While the mechanism of chronic cyclosporine nephropathy is not known, vasoconstriction probably plays a contributing role. Studies by Wang and Salahudeen (1994, 1995) indicated that rats treated with cyclosporine and an antioxidant lazaroid for 30 days exhibited increased GFR and RBF and less tubulointerstitial fibrosis and lipid peroxidation than rats treated with cyclosporine alone, suggesting that oxidative stress plays a role in cyclosporine nephrotoxity in rats. The marked interstitial cell proliferation and increased procollagen secretion that occurs following cyclosporine administration may contribute to the interstitial fibrosis (Racusen and Solez, 1993).

Tacrolimus (FK-506) is a new immunosuppressive agent that exhibits nephrotoxicity. At this time, the degree and incidence of nephrotoxicity and morphologic changes associated with tacrolimus exposure are similar to that exhibited with cyclosporine, suggesting similar modes of toxic action.

Cisplatin Cisplatin is a valuable drug in the treatment of solid tumors, with nephrotoxicity limiting its clinical use. The kidney is not only responsible for the majority of cisplatin excretion but is also the primary site of accumulation (Wolfgang and Leibbrant, 1997 ; Safirstein and Defray, 1998). The effects of cisplatin on the kidney are several, including acute and chronic renal failure, renal magnesium wasting, and polyuria.

ARF—characterized by decreases in RBF and GFR, enzymuria, b_2-microglobulinuria, and inappropriate urinary losses of magnesium—was identified in early clinical trials of cisplatin. Although the primary cellular target associated with ARF is the proximal tubule S_3 segment in the rat, in humans the S_1 and S_2 segments, distal tubule, and collecting ducts can also be affected. The chronic renal failure observed with cisplatin is due to prolonged exposure and is characterized by focal necrosis in numerous segments of the nephron without a significant effect on the glomerulus. Considerable effort has been expended in the development of measures to prevent cisplatin nephrotoxicity. These efforts include the use of extensive hydration and mannitol diuresis and the development of less nephrotoxic platinum compounds such as carboplatin.

The mechanism by which cisplatin produces cellular injury is not known but may involve metabolites of cisplatin. Interestingly, the *trans* isomer of cisplatin is not nephrotoxic even though similar concentrations of platinum are observed in the kidney after dosing. Thus, it is not the platinum atom per se that is responsible for the toxicity but rather the geometry of the complex or a metabolite. The antineoplastic and perhaps the nephrotoxic effects of cisplatin may be due to its intracellular hydrolysis to the reactive mono-chloro-mono-aquo-diammine-platinum or diaquo-diammine-platinum species and the ability of these metabolites to alkylate purine and pyrimidine bases.

In vitro studies using primary cultures of mouse proximal tubular cells revealed that the type of cell death produced by cisplatin is dependent on the concentration (Lieberthal et al., 1996). At cisplatin concentrations less than 100 mM, the primary form of cell death is apoptosis. As the concentration increases above 100 mM, a greater percentage of the cells die by oncosis. Using rabbit renal proximal tubule cells, Courjault et al. (1993) showed that while DNA synthesis, protein synthesis, glucose transport, Na^+, K^+-ATPase activity, and cell viability were all inhibited by cisplatin, DNA synthesis was the most sensitive. These results suggest that cisplatin may produce nephrotoxicity through its ability to inhibit DNA synthesis as well as transport functions. The lack of complete return of renal function following cisplatin treatment in vivo may result from the interference of cisplatin with the normal proliferative response that occurs after injury.

Radiocontrast Agents Iodinated contrast media are used for the imaging of tissues, with two major classes of compounds currently in use. The ionic compounds, diatrizoate derivatives, are (1) ionized at physiologic pH, (2) not significantly bound to protein, (3) restricted to the extracellular space, (4) almost entirely eliminated by the kidney, and (5) freely filtered by the glomerulus and neither secreted nor reabsorbed. These agents have a very high osmolality (>1200 mOsm/L) and are potentially nephrotoxic, particularly in patients with existing renal impairment, diabetes, or heart failure or who are receiving other nephrotoxic drugs. The newer contrast agents (e.g., iotrol, iopamidol) are nonionic owing to the addition of an organic side chain, their low osmolality, and their lower nephrotoxicity. The nephrotoxicity of these agents is due to both hemodynamic alterations (vasoconstriction) and tubular injury (via ROS) (Bakris, 1997; Porter and Kremer, 1998).

CHAPTER 15

TOXIC RESPONSES OF THE RESPIRATORY SYSTEM

Hanspeter R. Witschi and Jerold A. Last

Initially, lung injury caused by chemicals was primarily associated with certain professions and occupations. In his classic treatise of 1713, the Italian physician Bernardino Ramazzini provided detailed and harrowing accounts of the sufferings of miners, whose ailments had been known and described since antiquity. Two of Ramazzini's quotations are noteworthy. With regard to miners of metals, he stated that "the lungs and brains of that class of workers are badly affected, the lungs especially, since they take in with the air mineral spirits and are the first to be keenly aware of injury." Ramazzini also was aware of the important concept of exposure: "They (workers who shovel, melt, and cast and refine mined material) are liable of the same diseases, though in less acute form, because they perform their tasks in open air." Thus, exposure to chemicals by inhalation can have two effects: on the lung tissues and on distant organs that are reached after chemicals enter the body by means of inhalation. Indeed, the term *inhalation toxicology* refers to the route of exposure, whereas *respiratory tract toxicology* refers to target-organ toxicity, in this case abnormal changes in the respiratory tract produced by airborne (and on occasion blood-borne) agents. We now know of numerous lung diseases prompted by occupational exposures, many crippling and some fatal. Examples include black lung in coal miners, silicosis and silicotuberculosis in sandblasters and tunnel miners, and asbestosis in shipyard workers and asbestos miners. Occupational exposures to asbestos or metals such as nickel, beryllium, and cadmium can also cause lung cancer. In the twentieth century, it has become obvious that disease caused by airborne agents may not be limited to certain trades. The ubiquitous presence of airborne chemicals is a matter of concern, since "air pollution" adversely affects human health and may be an important contributor to mortality (Zemp et al., 1999).

To better understand environmental lung disease, we need more precise knowledge about the doses of toxic inhalants delivered to specific sites in the respiratory tract and an understanding of the extent to which repeated and often intermittent low-level exposures eventually may initiate and propagate chronic lung disease. Lung tissue can be injured directly or secondarily by metabolic products from organic compounds. However, the most important effect of many toxic inhalants is to place an undue oxidative burden on the lungs. Observations made in humans and animals provide strong evidence that the sequelae of oxidative stress may be instrumental in initiating and propagating ailments such as chronic bronchitis, emphysema, interstitial disorders (fibrosis), and cancer (Crapo et al., 1992).

Respiratory tract toxicology is a field in which collaboration involving epidemiologists, physiologists studying human lung function, toxicologists, and cell and molecular biologists has become close and fruitful. Epidemiologists now use a variety of pulmonary function tests to assess decrements in lung function in workers and populations exposed to air pollutants. These tests have been adapted for animal studies and are used to examine the mechanisms responsible for the pulmonary effects of air pollutants. When similar data can be obtained in both experimental animals and human subjects (for example, studies of mucociliary clearance of particles or responsiveness to bronchoconstrictive agents), these direct comparisons assist in extrapolating from animals to humans. Progress has been made in understanding some of the mechanisms that underlie the response of the lungs to toxic agents. In response to toxic insult, pulmonary cells are known to release a variety of potent chemical mediators that may critically affect lung function. Biochemical data from the study of cells taken from exposed animals and in vitro exposure of cells in culture are also useful in assessing the toxic potential of many agents. Recently, molecular techniques, such as in situ hybridization and immunostains, have been applied to analyze production of chemical mediators and other important macromolecules produced by specific cell types in response to inhaled toxicants. Bronchoalveolar lavage is now widely exploited in experimental animals and human subjects to examine respiratory airways' contents (cellular and acellular) after exposure. This chapter discusses how pulmonary toxicologists profit from these methods to study the biochemical, structural, and functional changes produced by the inhalation of pollutant gases and particles.

LUNG STRUCTURE AND FUNCTION

Nasal Passages

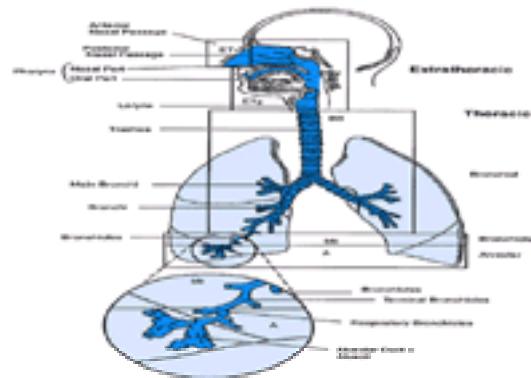
Figure 15-1 shows a schematic overview of the different regions of the respiratory tract. Air enters the respiratory tract through the nasal and oral regions. Many species, particularly small laboratory rodents, are obligatory nose breathers, in whom air passes almost exclusively through the nasal passages. Other species, including humans, monkeys, and dogs, can inhale air both through the nose and through the mouth (oronasal breathers). Air is warmed and humidified while passing through the nose. The nasal passages function as a filter for particles, which may be collected by diffusion or impaction on the nasal mucosa. Highly water-soluble gases are absorbed efficiently in the nasal passages, which reach from the nostril to the pharynx. The nasal turbinates thus form a first defensive barrier against many toxic inhalants.


Figure 15-1. Schematic drawing of the anatomical regions of the respiratory tract.

(From International Commission on Radiological Protection, Human Respiratory Tract Model for Radiological Protection. ICRP Publication 66; *Ann ICRP*. Oxford: Pergamon Press, 1994, p 24.)

The nasal passages are lined by distinctive epithelia: stratified squamous epithelium in the vestibule, nonciliated cuboidal/columnar epithelium in the anterior chamber, ciliated pseudostratified respiratory epithelium, and olfactory epithelium. The greater part of the internal nasal passages is covered by respiratory epithelium containing goblet cells, ciliated cells, nonciliated columnar cells, cuboidal cells, brush cells, and basal cells. Located in the superior part is the olfactory epithelium, which contains sensory cells. Nerve endings in the nasal passages are associated mostly with the fifth cranial (trigeminal) nerve.

Nasal epithelia are competent to metabolize foreign compounds (Fanucchi et al., 1999). Nasal tissue has been found to activate nitrosamines to mutagenic compounds. P-450 isozymes 1A1, 2B1, and 4B1 have been localized in the nose of several species by immunohistochemical procedures. The nasal cavity is thus a ready target site for metabolite-induced lesions. The olfactory epithelium appears to be particularly vulnerable. Metabolism by the olfactory epithelium may play a role in providing or preventing access of inhalants directly to the brain; for example, inhaled xylene may be converted to metabolites that move to the brain by axonal transport.

Conducting Airways

The proximal airways—the trachea and bronchi—have a pseudostratified epithelium containing ciliated cells and two types of nonciliated cells: mucous and serous cells. Mucous cells (and glandular structures) produce respiratory tract mucus, a family of high-molecular-weight glycoproteins with a sugar content of 80 percent or more that coat the epithelium with a viscoelastic sticky protective layer that traps pollutants and cell debris. Serous cells produce a fluid in which mucus may be dissolved. The action of the respiratory tract cilia, which beat in synchrony under the control of the central nervous system (CNS), continuously drives the mucous layer toward the pharynx, where it is removed from the respiratory system by swallowing or expectoration. The mucous layer is also thought to have antioxidant, acid-neutralizing, and free radical–scavenging functions that protect the epithelial cells (Cross et al., 1998).

Conducting airways have a characteristic branched bifurcating structure, with successive airway generations containing approximately twice the number of bronchi with a progressively decreasing internal diameter. Thus, the conducting airways contain a continuously increasing total surface area from the trachea to the distal airways. Bifurcations have flow dividers at branch points that serve as sites of impaction for particles, and successively narrower diameters also favor the collection of gases and particles on airway walls. Eventually a transition zone is reached where cartilaginous airways (bronchi) give way to noncartilaginous airways (bronchioles), which in turn give way to gas-exchange regions, respiratory bronchioles, and alveoli. Mucus-producing cells and glands give way to Clara cells in the bronchiolar epithelium. There are important structural and cellular differences between the conductive airways of humans and these of many commonly studied laboratory animals, as discussed later in this chapter.

Gas-Exchange Region

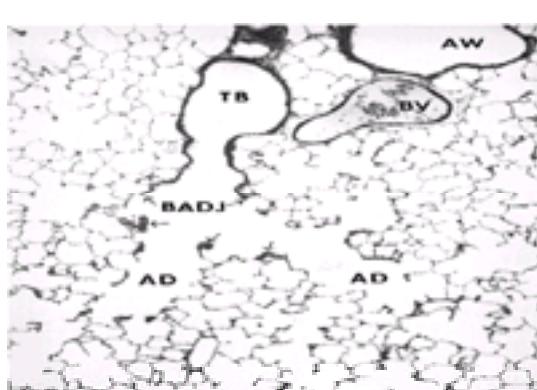
Human lungs are divided into five lobes: the superior and inferior left lobes and the superior, middle, and inferior right lobes. In small laboratory animals such as rats, mice, and hamsters, the left lung consists of a single lobe, whereas the right lung is divided into four lobes: cranial, middle, caudal, and ancillary. In the guinea pig and rabbit, the left lung is divided into two lobes. Dogs have two left and four right lobes. The lung can be further subdivided at the periphery of the bronchial tree into distinct anatomic bronchopulmonary segments, then into lobules, and finally into acini. An acinus includes a terminal bronchiole and all its respiratory bronchioles, alveolar ducts, and alveolar sacs. An acinus may be made up of two to eight ventilatory units. A ventilatory unit is defined as an anatomic region that includes all alveolar ducts and alveoli distal to each bronchiolar-alveolar duct junction (Mercer and Crapo, 1991). The ventilatory unit is important because it represents the smallest common denominator when the distribution of inhaled gases to the gas-exchanging surface of the lung is modeled (Fig. 15-2).


Figure 15-2. Centriacinar region (ventilatory unit) of the lung.

An airway and an arteriole [blood vessel (BV)] are in close proximity to the terminal bronchiole (TB) opening into alveolar ducts (AD) at the bronchiole–alveolar duct junction (BADJ). A number of the alveolar septal tips (*arrows*) close to the BADJ are thickened after a brief (4-h) exposure to asbestos fibers, indicating localization of fiber deposition. Other inhalants, such as ozone, produce lesions in the same locations. (Photograph courtesy of Dr. Kent E. Pinkerton, University of California, Davis.)

Gas exchange occurs in the alveoli, which represent approximately 80 to 90 percent of the total parenchymal lung volume; adult human lungs contain an estimated 300 million alveoli. The ratio of total capillary surface to total alveolar surface is slightly less than 1. Within the alveolar septum, capillaries are organized in a single sheet. Capillaries, blood plasma, and formed blood elements are separated from the air space by a thin layer of tissue formed by epithelial, interstitial, and endothelial components (Pinkerton et al., 1991).

Type I and type II alveolar cells represent approximately 25 percent of all the cells in the alveolar septum (Fig. 15-3). Type III epithelial cells, also called brush cells, are relatively rare. Type I cells cover a large surface area (approximately 90 percent of the alveolar surface). They have an attenuated cytoplasm and appear to be poor in organelles but probably are as metabolically competent as are the more compact type II cells. Preferential damage to type I cells by various agents may be explained by the fact that they constitute a large percentage of the total target (surface of the epithelium). Type II cells are cuboidal and show abundant perinuclear cytoplasm. They produce surfactant and, in case of damage to the type I epithelium, may undergo mitotic division and replace damaged cells. The shape of type I and type II cells is independent of alveolar size and is remarkably similar in different species. A typical rat alveolus (14,000 mm^2 surface) contains an average of two type I

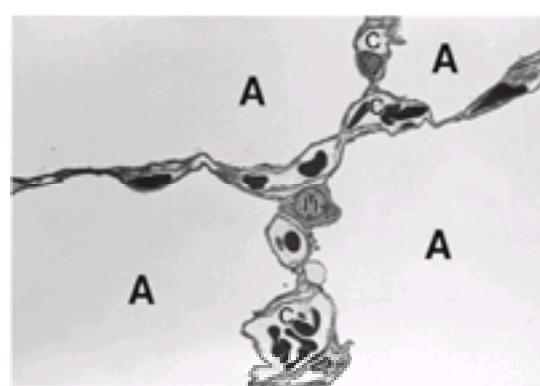
cells and three type II cells, whereas a human alveolus with a surface of 200,000 to 300,000 mm^2 contains 32 type I cells and 51 type II cells (Pinkerton et al., 1991).


Figure 15-3. Micrograph of four alveoli **(A)** *separated by the alveolar septum.*

The thin air-to-blood tissue barrier of the alveolar septal wall is composed of squamous alveolar type I cells and occasional alveolar type II cells (II), a small interstitial space, and the attenuated cytoplasm of the endothelial cells that form the wall of the capillaries (C). (Photograph courtesy of Dr. Kent E. Pinkerton, University of California, Davis.)

The mesenchymal interstitial cell population consists of fibroblasts that produce collagen and elastin, as well as other cell matrix components and various effector molecules. Pericytes, monocytes, and lymphocytes also reside in the interstitium and so do macrophages before they enter the alveoli. Endothelial cells have a thin cytoplasm and cover about one-fourth of the area covered by type I cells. Clara cells are located in the terminal bronchioles and have a high content of xenobiotic metabolizing enzymes.

Gas Exchange

The principal function of the lung is gas exchange, which consists of ventilation, perfusion, and diffusion. The lung is superbly equipped to handle its main task: bringing essential oxygen to the organs and tissues of the body and eliminating its most abundant waste product, CO_2 (Weibel, 1983).

Ventilation During inhalation, fresh air is moved into the lung through the upper respiratory tract and conducting airways and into the terminal respiratory units when the thoracic cage enlarges and the diaphragm moves downward; the lung passively follows this expansion. After diffusion of oxygen into the blood and that of CO_2 from the blood into the alveolar spaces, the air (now enriched in CO_2) is expelled by exhalation. Relaxation of the chest wall and diaphragm diminishes the internal volume of the thoracic cage, the elastic fibers of the lung parenchyma contract, and air is expelled from the alveolar zone through the airways. Any interference with the elastic properties of the lung, for example, the decrease in elastic fibers that occurs in emphysema, adversely affects ventilation, as do decreases in the diameters of or blockage of the conducting airways, as in asthma.

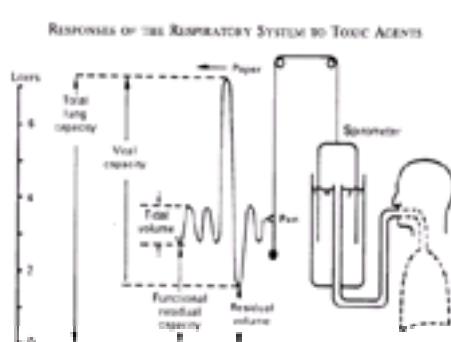
The total volume of air in an inflated human lung, approximately 5700 cm^3, represents the total lung capacity (TLC). After a maximum expiration, the lung retains approximately 1200 cm^3 of air, the residual volume (RV). The air volume moved into and out of the lung with a maximum inspiratory and expiratory movement, which is called the vital capacity (VC), is thus approximately 4500 cm^3. Under resting conditions, only a fraction of the vital capacity, the tidal volume (TV), is moved into and out of the lung. In resting humans, the TV measures approximately 500 cm^3 with each breath (Fig. 15-4). The respiratory frequency, or the number of breaths per minute, is approximately 12 to 20. If an augmented metabolic demand of the body requires the delivery of increased amounts of oxygen—for example, during heavy and prolonged exercise—both the TV and the respiratory rate can be greatly increased. The amount of air moved into and out of the human lung may increase to up to 60 L/min. Increased ventilation in a polluted atmosphere increases the deposition of inhaled toxic material. For this reason, it is often stated that people, particularly children, should not exercise during episodes of heavy air pollution.


Figure 15-4. Lung volumes.

Note that the functional residual capacity and residual volume cannot be measured with spirometer but require special procedures (e.g., nitrogen or helium outwash). (From West JB: *Respiratory Physiology—The Essentials.* Baltimore: Williams & Wilkins, 1994, with permission.)

The TLC, as well as the ratio of RV to VC, changes when the lung is diseased. In emphysema, the alveoli overextend and more air is trapped. While the TLC may stay the same or even increase, the volume of air that is actually moved during breathing is diminished. This results in decreased VC with a concomitant increase in RV. If part of the lung collapses or becomes filled with edema fluid, TLC and VC are reduced. Pulmonary function tests give quantitative information on such changes.

Perfusion The lung receives the entire output from the right ventricle, approximately 70 to 80 cm^3 of blood per heartbeat, and thus may be exposed to substantial amounts of toxic agents carried in the blood. An agent placed onto or deposited under the skin (subcutaneous injection) or introduced directly into a peripheral vein (intravenous injection) travels through the venous system to the right ventricle and then comes into contact with the pulmonary capillary bed before distribution to other organs or tissues in the body.

Diffusion Gas exchange takes place across the entire alveolar surface. Contact to airborne toxic agent thus occurs over a surface (approximately 140 m^2) that is second only to the small intestine (approximately 250 m^2) and considerably larger than the skin (approximately 1.75 m^2), two other organs that are in direct contact with the outside world. A variety of abnormal processes may thicken the alveolar septum and adversely affect the diffusion of oxygen to the erythrocytes. Such processes may include collection of liquid in the alveolar space and an abnormal thickening of the pulmonary epithelium. It is often seen as a result of chronic toxicity because of an abnormal accumulation of tissue constituents in the interstitial space through proliferation of interstitial cells. Increased formation and deposition of extracellular substances such as collagen or because of the interstitial accumulation of edema fluid has similar consequences.

GENERAL PRINCIPLES IN THE PATHOGENESIS OF LUNG DAMAGE CAUSED BY CHEMICALS

Oxidative Burden

An important type of injury to the lung is thought to be caused by an undue oxidative burden that often is mediated by free radicals, such as those generated by ozone, NO_2, tobacco smoke, and lung defense cells (Witschi, 1997a). Evidence for the role of free radicals in lung damage includes a wide variety of observations. Numerous studies have reported increases in the activity of free radical–scavenging enzymes in the lungs of animals exposed to O_3, NO_2, and other toxicants, indirectly supporting this hypothesis. Treatment with various hydroxyl radical scavengers can protect rats from pulmonary edema induced by high doses of thiourea and otherwise lethal levels of gamma irradiation.

Theories of lung oxidant toxicity relate to the formation of reactive and unstable free radicals, with subsequent chain reactions leading to uncontrolled destructive oxidation. Recent work has emphasized the pivotal roles of superoxide, nitric oxide, peroxynitrate, hydroxyl radicals, and perhaps singlet oxygen in mediating tissue damage. Reduction of O_2 to active O_2 metabolites normally occurs as a by-product of cellular metabolism during both microsomal and mitochondrial electron transfer reactions; considerable amounts of superoxide anion are generated by NADPH cytochrome P450 reductase reactions. Because these oxidant species are potentially cytotoxic, they may mediate or promote the actions of various pneumotoxicants. Such mechanisms have been proposed for paraquat- and nitrofurantoin-induced lung injury. When cellular injury of any type occurs, the release of otherwise contained cellular constituents such as microsomes and flavoproteins into the extracellular space may lead to extracellular generation of deleterious reactive O_2 species.

Among mammalian cells, neutrophils, monocytes, and macrophages seem particularly adept at converting molecular O_2 to reactive O_2 metabolites; this probably is related to their phagocytosis and antimicrobial activities. As a by-product of this capability, toxic O_2 species are released (possibly by the plasmalemma itself) into surrounding tissues. As most forms of toxic pulmonary edema are accompanied by phagocyte accumulation in the lung microcirculation (pulmonary leukostasis) and parenchyma, oxidative damage may represent a significant component of all types of pneumotoxic lung injury accompanied by a phagocyte-mediated inflammatory component.

Chemotactic and phagocytic "activation" processes result in a substantial increase in the release of potent oxidants by stimulated phagocytes; these radicals cause oxidative damage to the surrounding tissues. A key role of hydrogen peroxide as the mediator of the extracellular cytotoxic mechanism of "activated" phagocytes has been well documented. Phenomena occurring at the phagocyte surface, such as those which may occur in endogenous lung phagocytes after exposure to dusts and toxic gases, or in circulating phagocytes before their accumulation in the lung or after their attachment to normal or damaged lung endothelium seem to be important in determining their degree of enhanced oxidative activity, which is otherwise at a much lower basal level in the unstimulated cell. It also has been long appreciated that phagocytes may cause lysosomal enzyme release and tissue damage.

The fact that oxidative processes are complex is suggested by the finding that phagocytic production of active oxygen species causes inactivation of proteinase inhibitors and degranulation of mast cells. The production of oxygen radicals by phagocytes is enhanced not only by interactions of cell surface membranes with various appropriate stimuli but also by hyperoxia. Platelets (and platelet microthrombi) also have the ability to generate activated O_2 species.

The lung can respond with specific defense mechanisms that may be acquired over time and may be stimulated by constant exposure to numerous species of airborne microorganisms as well as by a variety of low- and high-molecular-weight antigenic materials. The immune system can mount either cellular or humorally mediated responses to these inhaled antigens. Direct immunologic effects occur when inhaled foreign material sensitizes the respiratory system to further exposure to the same material. The mammalian lung has a well-developed immune system. Lymphocytes reside in the hilar or mediastinal lymph nodes, lymphoid aggregates, and lymphoepithelial nodules as well as in aggregates or as single cells throughout the airways. Bronchoconstriction and chronic pulmonary disease can result from the inhalation of materials that appear to act wholly or partly through an allergic response. In some instances, these reactions are caused by spores of molds or bacterial contaminants. Frequently, chemical components of the sensitizing dusts or gases are responsible for the allergic response. Low-molecular-weight compounds can act as haptens that combine with native proteins to form a complex that is recognized as an antigen by the immune system. Further exposure to the sensitizing compound can result in an allergic reaction that is characterized by the release of various inflammatory mediators that produce an early and/or a late bronchoconstrictor response. Such a response is observed in sensitized workers exposed to toluene diisocyanate (TDI), a chemical widely used in the manufacture of polyurethane plastics (Karol et al., 1994).

Indirect immune effects occur when exposure to air pollutants either suppresses or enhances the immune response to other materials. Both sulfur dioxide (SO_2) and ozone can boost the response of the respiratory system to inhaled foreign material, at least in experimental animals (guinea pigs). It is not known whether these effects occur in humans, but they form the bases for concerns about increased susceptibility of asthmatic individuals to air pollutants such as ozone and sulfur dioxide.

Toxic Inhalants, Gases, and Dosimetry

The sites of deposition of gases in the respiratory tract define the pattern of toxicity of those gases. Water solubility is the critical factor in determining how deeply a given gas penetrates into the lung. Highly soluble gases such as SO_2 do not penetrate farther than the nose and are therefore relatively nontoxic to animals, especially obligatory nose breathers such as the rat. Relatively insoluble gases such as ozone and NO_2 penetrate deeply into the lung and reach the smallest airways and the alveoli (centriacinar region), where they can elicit toxic responses. Mathematical models of gas entry and deposition in the lung that are based solely on the aqueous solubility of a gas predict sites of lung lesions fairly accurately. These models may be useful for extrapolating findings made in laboratory animals to humans (Kimbell and Miller, 1999; Medinsky et al., 1999). Very insoluble gases such as CO and H_2S efficiently pass through the respiratory tract and are taken up by the pulmonary blood supply to be distributed throughout the body.

Particle Deposition and Clearance

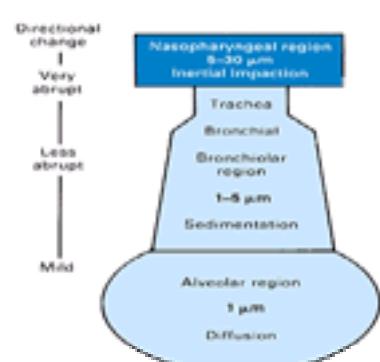
The site of deposition of solid particles or droplets in the respiratory tract, along with their chemical makeup, is important. Particle size is usually the critical factor that determines the region of the respiratory tract in which a particle or an aerosol will be deposited. Deposition of particles on the surface of the lung and airways is brought about by a combination of lung anatomy and the patterns of airflow in the respiratory system (Raabe, 1999; Miller, 1999) (Fig. 15-5).


Figure 15-5. Parameters influencing particle deposition.

[From Casarett LJ: The vital sacs: Alveolar clearance mechanisms in inhalation toxicology, in Blood FR (ed): *Essays in Toxicology.* Vol 3. New York: Academic Press, 1972, with permission.]

Particle Size Inhaled aerosols are most frequently polydisperse in regard to size. The size distribution of many aerosols approximates a log-normal distribution that may be described by the *median* or *geometric mean* and the *geometric standard deviation*. A plot of the frequency of occurrence of a given size against the log of the size produces a bell-shaped probability curve. Particle data frequently are handled by plotting the cumulative percentage of particles smaller than a stated size on log-probability paper. This results in a straight line that may be fitted by eye or mathematically. In actual practice, it is not unusual to have some deviation from a straight line at the largest or smallest particle sizes measured. The geometric mean is the 50 percent size as the mean bisects the curve. The geometric standard

deviation (sg) is calculated as

$$sg = 84.1\% \text{ size}/50\% \text{ size}$$

The sg of the particle size distribution is a measure of the polydispersity of the aerosol. In the laboratory, values for sg of 1.8 to 3.0 are encountered frequently. In the field, values for sg may range up to 4.5. An aerosol with a sg below 1.2 may be considered monodisperse.

The median diameter that is determined may reflect the number of particles, as in the count median diameter (CMD), or reflect mass, as in the mass median aerodynamic diameter (MMAD). The larger the number and mass of particles capable of penetrating the lung, the greater the probability of a toxic effect. The size distribution in relation to other factors, such as particle shape and surface area, also may be of interest. Surface area is of special importance when toxic materials are adsorbed on the surfaces of particles and thus are carried to the lung.

Particles that are nonspherical in shape are frequently characterized in terms of equivalent spheres on the basis of equal mass, volume, or aerodynamic drag. The MMAD takes into account both the density of the particle and aerodynamic drag. It represents the diameter of a unit density sphere with the same terminal settling velocity as the particle, regardless of its size, shape, and density. Aerodynamic diameter is the proper measurement for particles that are deposited by impaction and sedimentation. For very small particles, which are deposited primarily by diffusion, the critical factor is particle size, not density. It must be kept in mind that the size of a particle may change before its deposition in the respiratory tract. Materials that are hygroscopic, such as sodium chloride, sulfuric acid, and glycerol, take on water and grow in size in the warm, saturated atmosphere of the lower respiratory tract.

Deposition Mechanisms Deposition of particles occurs primarily by interception, impaction, sedimentation, and diffusion (Brownian movement). Interception occurs only when the trajectory of a particle brings it near enough to a surface so that an edge of the particle contacts the airway surface. Interception is important for the deposition of fibers. Whereas fiber diameter determines the probability of deposition by impaction and sedimentation, interception is dependent on fiber length. Thus, a fiber with a diameter of 1 mm and a length of 200 mm will be deposited in the bronchial tree primarily by interception rather than impaction.

As a result of inertia, particles suspended in air tend to continue to travel along their original path. In a bending airstream, such as at an airway bifurcation, a particle may be impacted on the surface. At relatively symmetrical bifurcations, which typically occur in the human lung, the deposition rate is likely to be high for particles that move in the center of the airway. Generalizations regarding the site of deposition of particles of a given size are problematic. However, in the average adult, most particles larger than 10 mm in aerodynamic diameter are deposited in the nose or oral pharynx and cannot penetrate to tissues distal to the larynx. Recent data have shown that very fine particles (0.01 mm and smaller) are also trapped relatively efficiently in the upper airways by diffusion. Particles that penetrate beyond the upper airways are available to be deposited in the bronchial region and the deeper-lying airways. Therefore, the alveolar region has significant deposition efficiencies for particles smaller than 5 mm and larger than 0.003 mm.

Sedimentation brings about deposition in the smaller bronchi, the bronchioles, and the alveolar spaces, where the airways are small and the velocity of airflow is low. As a particle moves downward through air, buoyancy and the resistance of air act on the particle in an upward direction while gravitational force acts on the particle in a downward direction. Eventually, the gravitational force equilibrates with the sum of the buoyancy and the air resistance, and the particle continues to settle with a constant velocity known as the terminal settling velocity. Sedimentation is not a significant route of particle deposition when the aerodynamic diameter is below 0.5 mm.

Diffusion is an important factor in the deposition of submicrometer particles. A random motion is imparted to these particles by the impact of gas molecules. This brownian motion increases with decreasing particle size, and so diffusion is an important deposition mechanism in the nose and in other airways and alveoli for particles smaller than about 0.5 mm.

An important factor in particle deposition is the pattern of breathing. During quiet breathing, in which the TV is only two to three times the volume of the anatomic dead space (i.e, the volume of the conducting airways where gas exchange does not occur), a large proportion of the inhaled particles may be exhaled. During exercise, when larger volumes are inhaled at higher velocities, impaction in the large airways and sedimentation and diffusion in the smaller airways and alveoli increase. Breath holding also increases deposition from sedimentation and diffusion. Factors that modify the diameter of the conducting airways can alter particle deposition. In patients with chronic bronchitis, the mucous layer is greatly thickened and extended peripherally and may partially block the airways in some areas. Jets formed by air flowing through such partially occluded airways have the potential to increase the deposition of particles by impaction and diffusion in the small airways. Irritant materials that produce bronchoconstriction tend to increase the tracheobronchial deposition of particles. Cigarette smoking has been shown experimentally to produce such an effect.

Particle Clearance The clearance of deposited particles is an important aspect of lung defense. Rapid removal lessens the time available to cause damage to the pulmonary tissues or permit local absorption. The specific mechanisms available for the removal of particles from the respiratory tract vary with the site of the deposition. It is important to emphasize that clearance of particles from the respiratory tract is not synonymous with clearance from the body. Depending on the specific clearance mechanism used, particles are cleared to (1) the stomach and gastrointestinal (GI) tract; (2) the lymphatics and lymph nodes, where they may be dissolved and enter the venous circulation; or (3) the pulmonary vasculature. The only mechanisms by which the respiratory system can truly remove deposited particles from the body are coughing and blowing the nose.

Nasal Clearance Particles deposited in the nose are cleared by various mechanisms, depending on their site of deposition and solubility in mucus. The anterior portion of the nose is lined with relatively dry squamous epithelium, and so particles deposited there are removed by extrinsic actions such as wiping and blowing. The other regions of the nose are largely covered by a mucociliary epithelium that propels mucus toward the glottis, where it is swallowed. Insoluble particles generally are cleared from this region in healthy adults and swallowed within an hour of deposition. Particles that are soluble in mucus may dissolve and enter the epithelium and/or blood before they can be mechanically removed. Uncertainties still remain about the clearance of particles that are deposited on olfactory regions or areas that are damaged by acute infection, chronic illnesses, or toxic injury.

Tracheobronchial Clearance The mucous layer covering the tracheobronchial tree is moved upward by the beating of the underlying cilia. This mucociliary escalator transports deposited particles and particle-laden macrophages upward to the oropharynx, where they are swallowed and pass through the GI tract. Mucociliary clearance is relatively rapid in healthy individuals and is completed within 24 to 48 h for particles deposited in the lower airways. Infection and other injuries can greatly impair clearance.

Pulmonary Clearance There are several primary ways by which particulate material is removed from the lower respiratory tract once it has been deposited:

1. Particles may be directly trapped on the fluid layer of the conducting airways by impaction and cleared upward, in the tracheobronchial tree via the mucociliary escalator.
2. Particles may be phagocytized by macrophages and cleared via the mucociliary escalator.
3. Particles may be phagocytized by alveolar macrophages and removed via the lymphatic drainage.
4. Material may dissolve from the surfaces of particles and be removed via the bloodstream or lymphatics.
5. Small particles may directly penetrate epithelial membranes.

Minutes after particles are inhaled, they may be found in alveolar macrophages. Many alveolar macrophages are ultimately transported to the mucociliary escalator. It is possible that macrophages are carried to the bronchioles with the alveolar fluid that contributes to the fluid layer in the airways. Other particles may be sequestered in the lung for very long periods, often in macrophages located in the interstitium.

ACUTE RESPONSES OF THE LUNG TO INJURY

Airway Reactivity

Large airways are surrounded by bronchial smooth muscles, which help maintain airway tone and diameter during expansion and contraction of the lung. Bronchial smooth muscle tone is normally regulated by the autonomic nervous system. Reflex contraction occurs when receptors in the trachea and large bronchi are stimulated by irritants such as cigarette smoke and air pollutants. Bronchoconstriction can be provoked by cholinergic drugs such as acetylcholine, a phenomenon that serves as the basis for a sensitive measure of whether a toxicant can cause bronchoconstriction in animals or humans primed by a prior dose of an acetylcholinelike agent

(bronchoprovocation testing). These agents bind to cell surface receptors (cholinergic receptors) and trigger an increase in the intracellular concentration of cyclic guanosine monophosphate (cGMP), which in turn facilitates smooth muscle contraction. The actions of cGMP can be antagonized by cyclic adenosine monophospate (cAMP), which has bronchodilatory activity, and can be increased by agents that bind to beta-adrenergic receptors on the cell surface. Other important mediators of airway smooth muscle tone include histamine, various prostaglandins and leukotrienes, substance P, and nitric oxide. The bronchial smooth muscles of individuals with asthma contract with much less provocation than do those of normal subjects. Bronchoconstriction causes a decrease in airway diameter and a corresponding increase in resistance to airflow. Characteristic associated symptoms include wheezing, coughing, a sensation of chest tightness, and dyspnea. Exercise potentiates these problems. A major cause of concern about ambient air pollution is whether asthmatic individuals represent a population that is particularly susceptible to the adverse health effects of sulfur dioxide, ozone, nitrogen dioxide, other respiratory irritant gases, and respirable particles. Since the major component of airway resistance usually is contributed by large bronchi, inhaled agents that cause reflex bronchoconstriction are generally irritant gases with moderate solubility. Demonstrations of the bronchoconstrictive effects of gases in laboratory animals often are performed in guinea pigs, which seem to represent a natural animal model of asthmatic humans with respect to innate airway reactivity.

Pulmonary Edema

Toxic pulmonary edema represents an acute, exudative phase of lung injury that generally produces a thickening of the alveolar-capillary barrier. Edema fluid, when present, alters ventilation-perfusion relationships and limits diffusive transfer of O_2 and CO_2 even in otherwise structurally normal alveoli. Edema is often a sign of acute lung injury.

The biological consequences of toxic pulmonary edema not only induce acute compromise of lung structure and function but also may include abnormalities that remain after resolution of the edematous process. After exposure to some toxic agents in which the alveolar-capillary surface is denuded (such as alloxan), recovery is unlikely, whereas in situations of more modest injury (such as histamine administration), full recovery is readily achievable. Between these two extremes there are forms of severe lung injury accompanied by amplified inflammatory damage and/or exaggerated restorative-reparative processes (e.g., after paraquat ingestion). In these severe forms, the extensive interstitial and intraalveolar inflammatory exudate resolves via fibrogenesis, an outcome that may be beneficial or damaging to the lung. Accumulation and turnover of inflammatory cells and related immune responses in an edematous lung probably play a role in eliciting both mitogenic activity and fibrogenic responses.

Pulmonary edema is customarily quantified in experimental animals by some form of gravimetric measurement of lung water content. Very commonly, the wet (undesiccated) weight of the whole lung or that of a single lung lobe is determined. This value is often normalized to the weight of the animal from which the lung was taken. Alternatively, some investigators determine lung water content by weighing whole lungs or lung slices before and after complete drying in an oven or desiccator. Commonly used methods for expressing such data include (1) percentage water content [100 × (wet weight – dry weight)/(wet weight)], (2) percentage dry weight [100 × (dry weight)/(wet weight)], and (3) water content [(milliliters of water)/(dry weight)].

Mechanisms of Respiratory Tract Injury

Airborne agents can contact cells lining the respiratory tract from the nostrils to the gas-exchanging region. The sites of interaction of toxicants in the respiratory tract have important implications for evaluation of the risk to humans posed by inhalants. For example, rats have much more nasal surface on a per body weight basis than do humans. Measurement of DNA-protein cross-links formed in nasal tissue by the highly reactive gas formaldehyde has demonstrated that rats, which readily develop nasal tumors, have many more DNA cross-links per unit of exposure (concentration of formaldehyde × duration of exposure) than do monkeys. Because the breathing pattern of humans resembles that of monkeys more than that of rats, it was concluded that extrapolation of tumor data from rats to humans on the basis of formaldehyde concentration may overestimate doses of formaldehyde to humans. Patterns of animal activity can affect dose to the lung; nocturnally active animals such as rats receive a greater dose per unit of exposure at night than during the day, whereas humans show the opposite diurnal relationships of exposure concentration to dose.

Certain gases and vapors stimulate nerve endings in the nose, particularly those of the trigeminal nerve (Alarie et al., 1998). The result is holding of the breath or changes in breathing patterns, to avoid or reduce further exposure. If continued exposure cannot be avoided, many acidic or alkaline irritants produce cell necrosis and increased permeability of the alveolar walls. Other inhaled agents can be more insidious; inhalation of HCl, NO_2, NH_3, or phosgene may at first produce very little apparent damage in the respiratory tract. The epithelial barrier in the alveolar zone, after a latency period of several hours, begins to leak, flooding the alveoli and producing a delayed pulmonary edema that is often fatal.

A different pathogenetic mechanism is typical of highly reactive molecules such as ozone. It is unlikely that ozone as such can penetrate beyond the layer of fluid covering the cells of the lung. Instead, ozone lesions are propagated by a cascade of secondary reaction products, such as aldehydes and hydroxyperoxides produced by ozonolysis of fatty acids and other substrates in the lung's lining fluid, and by reactive oxygen species arising from free radical reactions. Reactive oxygen species also have been implicated in pulmonary bleomycin toxicity, pulmonary oxygen toxicity, paraquat toxicity, and the development of chronic lesions such as the fibrogenic and carcinogenic effects of asbestos fibers.

Metabolism of foreign compounds can be involved in the pathogenesis of lung injury. The balance of activation and detoxification plays a key role in determining whether a given chemical ultimately will cause damage. The lung contains most of the enzymes involved in xenobiotic metabolism that have been identified in other tissues, such as the liver (Buckpitt et al., 1997). While the overall levels of these enzymes tend to be lower in lung than in liver, they often are highly concentrated in specific cell populations of the respiratory tract. Moreover, their specific content of particular cytochrome P450 isozymes may be much higher in lung. Thus, the turnover of a substrate for a lung P450 may be far more rapid than occurs in liver. Many isozymes of the cytochrome P450 complex have been identified in and isolated from the lungs of rabbits, rats, hamsters and humans. Cytochrome P450 1A1 is present in low amounts in normal rat and rabbit lungs but is highly inducible by polycyclic aromatic hydrocarbons, flavones, and mixtures of polyhalogenated biphenyls. This isozyme also is present in human lungs and is thought to be involved in the metabolic activation of the polycyclic aromatic hydrocarbons that are present in cigarette smoke. By inference, this P450 isozyme may play a role in the pathogenesis of lung cancer. Attempts have been made to use the expression of cytochrome P450 1A1 as a biomarker of exposure and sensitivity to cigarette smoke in humans, although the precise relationships remain unclear. Cytochrome P450 2B1, which is readily inducible in rat liver by phenobarbital, is not inducible in lung tissue. Other isozymes identified in human lung are cytochrome P450 2F1, 4B1, and 3A4. Further microsomal enzymes found in the lung include NADPH cytochrome P450 reductase, epoxide hydrolase, and flavin-containing monoxygenases. Finally, two important cytosolic enzymes involved in lung xenobiotic metabolism are glutathione-*S*-transferase and glutathione peroxidase. Adult human lungs appear to contain several forms of glutathione- *S*-transferase.

Mediators of Lung Toxicity

Advances in cell culture techniques (Leikauf and Driscoll, 1993) have allowed investigators to examine the role of specific signal molecules in toxicant-induced lung damage; this is a very active area of research. Such studies are often guided by results obtained by analysis of cytokines and other mediators in lung lavage fluid from animals or human volunteers exposed to inhaled toxic agents.

For example, interleukin 1 beta (IL-1b), transforming growth factor beta (TGF-b), and tumor necrosis factor alpha (TNF-a) have all been implicated in the cascade of reactions that is thought to be responsible for the pathogenesis of pulmonary fibrosis (Zhang and Phan, 1999). Similarly, several of the nine described members of the interleukin family, especially IL-1, IL-2, IL-5 and IL-8, are thought to be essential components of the lung's response to epithelial cell injury. Various specific prostaglandins, especially PGE_2, and leukotrienes have been implicated in intracellular signaling pathways in the lung. The roles of cell surface adhesion molecules and their interaction with cell matrix components and with control of inflammatory cell migration (particularly neutrophil influx to the lung) have been studied intensively.

Analysis of normal lung homogenates suggests that the lung contains large amounts of endogenous cytokines and inflammatory mediators, far more than enough for these potent compounds to elicit effects. Thus, these agents must be compartmentalized in a healthy lung to control their potent bioactivity. How these processes are regulated normally, what exactly goes wrong with homeostasis in a damaged lung, the temporal and geographic relationship of different cytokines in the amplification of an initial injurious event, and detailed mechanisms of resolution of lung injury are not well understood and represent the current focus of much research on mechanisms of lung injury by toxic agents. The reader is referred to reviews of these topics (Massague, 1998; Barnes et al., 1998) for more details on specific mediators and toxic agents in this rapidly changing research area.

Cell Proliferation

The effects of toxicants on the lung may be reversible or irreversible. Postexposure progression of lung fibrosis has been demonstrated in rats exposed to ozone, mice exposed to cyclophosphamide, and hamsters exposed to bleomycin or bleomycin plus oxygen. The mechanisms for exacerbating lung damage or repairing such damage during a postexposure period in which filtered air alone is inhaled are not obvious. Examination of the time course and cellular components of reepithelialization of the alveolar ducts and walls during the postexposure period would be especially important in this regard. Research on the postexposure effects of inhaled toxicants is an important area for further study.

The normal adult lung is an organ for which under normal circumstances very few cells appear to die and to be replaced. When damaged by a toxic insult, the lung parenchyma is capable to repair itself in an efficient manner. Type I cell damage is followed by proliferation of type II epithelial cells which eventually transform into new type I cells; in the airways, the Clara cells proliferate and divide following injury. The migration of mobile blood cells such as leukocytes across the pulmonary capillaries into the alveolar lumen may also trigger a mitotic response. Other cells in the alveolar zone, such as capillary endothelial cells, interstitial cells, and alveolar macrophages, also proliferate. The result is a normal looking organ again although on occasion excessive proliferation of fibroblasts may result in lung disease. In general, however, the lung appears to have a high capacity to repair itself and thus to deal with the many toxic insults presented by the environment (Witschi, 1997b).

CHRONIC RESPONSES OF THE LUNG TO INJURY

Fibrosis

Defined clinically, lung fibrosis refers to the type of interstitial fibrosis that is seen in the later stages of idiopathic pulmonary fibrosis (also called *cryptogenic fibrosing alveolitis* in the United Kingdom). In this disease, the hallmark of pulmonary fibrosis seen by the pathologist is increased focal staining of collagen fibers in the alveolar interstitium. Fibrotic lungs from humans with acute or chronic pulmonary fibrosis contain increased amounts of collagen as evaluated biochemically, in agreement with the histological findings.

In lungs damaged by toxicants, the response resembles adult or infant respiratory distress syndrome more closely than it resembles chronic interstitial fibrosis. Excess lung collagen is usually observed not only in the alveolar interstitium but also throughout the centriacinar region, including the alveolar ducts and respiratory bronchioles. The relationship between increased collagen deposition around small airways and lung mechanics is not understood either theoretically or empirically.

At least 19 genetically distinct collagen types are known to occur in all mammals, most of which have been found in normal lungs or to be synthesized by isolated lung cells. Two types predominate in the lung, representing about 90 percent or more of the total lung collagen. Type I and type III collagen are major interstitial components and are found in the normal lungs of all mammals in an approximate ratio of 2:1. Type I collagen is the material that stains histologically as "collagen," whereas type III collagen is appreciated histologically as reticulin. Some types of toxicant-induced pulmonary fibrosis, including that induced by O_3, involve abnormalities in the type of collagen made. For example, there is an increase in type I collagen relative to type III collagen in patients with idiopathic pulmonary fibrosis. Similar shifts have been demonstrated in the lungs of adults and infants dying of acute respiratory distress syndrome. It is not known whether shifts in collagen types, compared with absolute increases in collagen content, account for the increased stiffness of fibrotic lungs. Type III collagen is much more compliant than is type I; thus, an increasing proportion of type I relative to type III collagen may result in a stiffer lung, as is observed in pulmonary fibrosis. Changes in collagen cross-linking in fibrotic lungs also may contribute to the increased stiffness. It is unclear whether the observed increase in stainable collagen is due solely to the increase in the collagen content of the lungs observed biochemically or whether altered collagen types or cross-linking might also contribute to the histological changes.

Increased collagen type I:type III ratios also have been observed in newly synthesized collagen in several animal models of acute pulmonary fibrosis. Although the mechanism for this shift in collagen types is unknown, there are many possible explanations. Clones of fibroblasts responsive to recruitment and/or proliferation factors may preferentially synthesize type I collagen compared with the action of the fibroblasts normally present. Alterations in the extracellular matrix resulting from inflammatory mediators secreted by various effector cells also may cause the fibroblasts to switch the collagen phenotype that is synthesized.

Collagen associated with fibrosis also may be abnormal with respect to cross-linking. Alterations in cross-links in experimental silicosis and bleomycin-induced fibrosis have been described. As in the case of alterations in collagen type ratios, it is unclear whether the mechanisms can be ascribed to changes in the clones of fibroblasts that actively synthesize collagen or to changes in the milieu that secondarily affect the nature of the collagen made by a given population of lung fibroblasts.

Emphysema

In many ways emphysema can be viewed as the opposite of fibrosis in terms of the response of the lungs to an insult: the lungs become larger and too compliant rather than becoming smaller and stiffer. Destruction of the gas-exchanging surface area results in a distended, hyperinflated lung that no longer effectively exchanges oxygen and carbon dioxide as a result of both loss of tissue and air trapping. The currently accepted pathological definition of emphysema is "a condition of the lung characterized by abnormal enlargement of the airspaces distal to the terminal bronchiole, accompanied by destruction of the walls, without obvious fibrosis" (Snider et al., 1985). The major cause of human emphysema is, by far, cigarette smoke inhalation, although other toxicants also can elicit this response. A feature of toxicant-induced emphysema is severe or recurrent inflammation, especially alveolitis with release of proteolytic enzymes by participating leukocytes.

A unifying hypothesis that explains the pathogenesis of emphysema has emerged from studies by several investigators. Early clinical research on screening blood protein phenotypes identified a rare mutation giving rise to a hereditary deficiency of the serum globulin alpha $_1$-antitrypsin. Homozygotes for this mutation had no circulating levels of this protein, which can prevent the proteolytic activity of serine proteases such as trypsin. Thus, alpha $_1$-antitrypsin (now called alpha$_1$-antiprotease) is one of the body's main defenses against uncontrolled proteolytic digestion by this class of enzymes, which includes elastase. There is a clinical association between the genetic lack of this important inhibitor of elastase and the development of emphysema at an extraordinarily young age. Further studies in smokers led to the hypothesis that neutrophil (and perhaps alveolar macrophage) elastases can break down lung elastin and thus cause emphysema; these elastases usually are kept in check by alpha $_1$-antiprotease that diffuses into the lung from the blood. As the individual ages, an accumulation of random elastolytic events can cause the emphysematous changes in the lungs that are normally associated with aging. Toxicants that cause inflammatory cell influx and thus increase the burden of neutrophil elastase can accelerate this process. In accordance with this hypothesis are a large number of experimental studies in animals instilled intratracheally with pancreatic or neutrophil elastase or with other proteolytic enzymes that can digest elastin in which a pathological condition develops that has some of the characteristics of emphysema, including destruction of alveolar walls and airspace enlargement in the lung parenchyma.

An additional clue to the pathogenesis of emphysema is provided by the observation that mice with defects in genes that code for elastin and collagen modifying enzymes develop emphysema (O'Byrne and Postma, 1999). These observations suggest that problems with elastin synthesis may play an important role in the pathogenesis of emphysema, and that in its simplest form the elastase-antiprotease model alone cannot fully explain the detailed biochemical mechanisms that underlie the etiology of emphysema.

Asthma

Asthma is becoming increasingly prevalent in the United States and Europe, especially in crowded urban areas. This disease is characterized clinically by attacks of shortness of breath, which may be mild or severe. It is caused by narrowing of the large conducting airways (bronchi) either upon inhalation of provoking agents or for unknown causes. There are well-established links between occupational and environmental exposure to antigens or to chemicals that can act as haptens and in the pathogenesis of asthma. There are histopathologic components that are common between asthma and pulmonary fibrosis, but in this case the disease is centered in and around the large conducting airways rather than the centriacinar region of the lung parenchyma. There may be common mechanisms, especially with regard to the role of inflammatory cells and the cytokines and growth factors they secrete (Barnes et al., 1998). The clinical hallmark of asthma is increased airway reactivity: the smooth muscle around the large airways contract in response to exposure to irritants. The extreme sensitivity of guinea pigs (as opposed to rats or mice) to inhaled irritants such as ozone or SO_2 may be an example of an animal model of the human asthmatic subject (Barnes et al., 1998).

Lung Cancer

Lung cancer, an extremely rare disease around the turn of the century, is now the leading cause of death from cancer among men and women. Retrospective and,

more conclusively, prospective epidemiologic studies unequivocally show an association between tobacco smoking and lung cancer. It has been estimated that approximately 80 to 90 percent of lung cancers (and several other cancers, such as cancer of the bladder, esophagus, oral cavity, and pancreas) are caused by cigarette smoking. Average smokers have a 10-fold and heavy smokers a 20-fold increased risk of developing lung cancer compared with nonsmokers. Quitting the habit will reduce the risk (Wingo et al., 1999).

Inhalation of asbestos fibers and metallic dusts or fumes—such as arsenic, beryllium, cadmium, chromium, and nickel, encountered in smelting and manufacturing operations— has been associated with cancer of the respiratory tract. Workers who manufacture chloromethyl ether or mustard gas also have an increased risk of developing lung cancers, as do workers exposed to effluent gases from coke ovens. Radon gas is a known human lung carcinogen. Formaldehyde is a probable human respiratory carcinogen. Silica, human-made fibers, and welding fumes are suspected carcinogens (International Agency for Research on Cancer, 1987, 1993). Smokers who inhale radon or asbestos fibers increase their risk of developing lung cancer severalfold, suggesting a synergistic interaction between the carcinogens. To what extent common air pollutants such as ozone, nitrogen dioxide, sulfur dioxide, and fumes emanating from power plants, oil refineries, and Diesel fuel–powered trucks and cars contribute to the development of lung cancer in the general population remains an open question. Some evidence suggests that respirable particulates suspended in polluted air are a risk factor (Beeson et al., 1998). Indoor air pollution, including environmental tobacco smoke, increases the risk of developing lung cancer in nonsmokers (National Cancer Institute, 1999).

Human lung cancers may have a latency period of 20 to 40 years, making the relationship to specific exposures difficult to establish. Many lung cancers in humans originate from the cells lining the airways (lung cancer originating from such sites is often referred to as bronchogenic carcinoma), but during the last two decades a significant increase in peripheral adenocarcinomas has occurred. Compared with cancer in the lung, cancer in the upper respiratory tract is less common. Malignant lesions of the nasal passages, which are seen frequently in experimental animals, are comparatively rare in humans. They are associated with certain occupations, including work with chromate, nickel, mustard gas, isopropyl alcohol, the manufacture of wooden furniture, and boot and shoe manufacture. Possible carcinogens include hexavalent chromium compounds, metallic nickel and nickel subsulfide, nickel oxide, formaldehyde, and certain wood and leather dusts.

The potential mechanisms of lung carcinogenesis have been studied extensively by means of analysis of tumor material and in studies of human bronchial cells maintained in culture. Damage to DNA is thought to be a key mechanism. An activated carcinogen or its metabolic product, such as alkyldiazonium ions derived from N-nitrosamines, may interact with DNA. Persistence of O^6-alkyldeoxyguanosine in DNA appears to correlate with carcinogenicity (Hecht, 1999). However, tumors do not always develop when adducts are present, and adduct formation may be a necessary but not sufficient condition for carcinogenesis. DNA damage caused by active oxygen species is another potentially important mechanism. Ionizing radiation leads to the formation of superoxide, which is converted through the action of superoxide dismutase to hydrogen peroxide. In the presence of Fe and other transition metals, hydroxyl radicals may be formed which then cause DNA strand breaks. Cigarette smoke contains high quantities of active oxygen species and other free radicals. Additional oxidative stress may be placed on the lung tissue of smokers by the release of superoxide anions and hydrogen peroxide by activated macrophages, metabolism of carcinogens, and lipid peroxidation caused by reactive aldehydes.

In laboratory animals, spontaneously occurring malignant lung tumors are uncommon unless the animals reach a very advanced age. Exposure to carcinogens by the inhalation route or by intratracheal instillation or systemic administration readily produces lung tumors in many laboratory species, such as mice, rats, hamsters, and dogs. There are several differences between lung tumors in animals and bronchogenic cancer in humans. In animals, particularly rodents, most tumors are in the periphery rather than arising from the bronchi. The incidence of benign lung tumors such as adenomas is often very high, and carcinomas seem to require more time to develop. Lung tumors in animals do not metastasize as aggressively, if they do so at all, as do human lung cancers (Hahn, 1997). Cancer of the nasal passages is readily induced in experimental animals in inhalation studies.

Because lung tumors in mice and rats are often seen in carcinogenesis bioassays, they deserve special mention. Murine lung tumors are mostly benign-appearing adenomas originating from alveolar type II cells or bronchiolar Clara cells. They can progress to adenocarcinomas and invade lymphatics and blood vessels. Certain mouse strains, such as strain A and the Swiss-Webster mouse, have a high incidence of spontaneously occurring lung tumors. These animals respond with increased numbers of tumors to the inhalation or injection of many carcinogens. Other strains are much more resistant. Lung tumors in strain A mice have become valuable tools for studing the genetic factors that determine susceptibility (Malkinson, 1998). They contain frequent mutations in the K-ras gene, a mutation also found frequently in human lung cancers (Graziano et al., 1999). Methylating nitrosamines (NNK and DMN) produce mutations consistent with the formation of O^6-methylguanine and ethylating nitrosamines (ENU and DEN) and mutations consistent with the formation of O^4-ethylthymidine. In strains less susceptible than the A/J mouse, chemicals such as tetranitromethane, 1,3-butadiene, DMN, and NNK generate tumors with mutations consistent with the result of DNA adduct formation, whereas other chemicals (acetylaminofluorene, methylene chloride) do not produce tumors with carcinogen-specific mutations.

Lung tumors in rats exposed to airborne carcinogens consist mostly of peripheral adenocarcinomas and squamous cell carcinomas. In addition, rat lungs on occasion contain lesions that are characterized by an epithelium surrounding a space filled with keratin. The mass may compress the adjacent lung parenchyma and occasionally invades it. These lesions are classified by some pathologists as bona fide tumors, whereas other pathologists characterize this type of lesion as a cyst filled with keratin. Classification of such a lesion as a tumor is important because these lesions often are found in long-term tests in animals that have been exposed to agents that are not considered carcinogens, such as carbon black, titanium dioxide, and certain human-made fibers (ILSI, 2000).

AGENTS KNOWN TO PRODUCE LUNG INJURY IN HUMANS

The prevention and treatment of acute and chronic lung disease will eventually be based on a knowledge of the cellular and molecular events that determine lung injury and repair. During the past 20 years, a large body of evidence has accumulated. Table 15-1 lists common toxicants that are known to produce acute and chronic lung injury in humans. In the following sections, a few examples of our current understanding of lung injury at the mechanistic level are discussed, with emphasis on agents directly responsible for human lung disease.

Table 15-1 Industrial Toxicants That Produce Lung Disease

Airborne Agents That Produce Lung Injury in Humans

Asbestos The term "asbestos" describes silicate minerals in fiber form. The most commonly mined and commercially used asbestos fibers include the serpentine chrysotile asbestos and the amphiboles crocidolite, anthophyllite, amosite, actinolite, and tremolite. Exposure to asbestos fibers occurs in mining operations and in the construction and shipbuilding industries, where asbestos was at one time widely used for its highly desirable insulating and fireproofing properties. During the last few years, concern about asbestos in older buildings has led to the removal of asbestos-based insulating material; abatement workers may now represent an additional population at risk.

Asbestos causes three forms of lung disease in humans: asbestosis, lung cancer, and malignant mesothelioma. Asbestosis is characterized by a diffuse increase of collagen in the alveolar walls (fibrosis) and the presence of asbestos fibers, either free or coated with a proteinaceous material (asbestos bodies). Malignant mesothelioma (a tumor of the cells covering the surface of the visceral and parietal pleura), a tumor that otherwise occurs only extremely rarely in the general population, is unequivocally associated with asbestos exposure. There is some discrepancy between human observations and animal data. In animal experiments, chrysotile produces mesothelioma much more readily than do the amphibole fibers. In humans, amphibole fibers are implicated more often even when the

predominant exposure is to chrysotile asbestos. Chrysotile breaks down much more readily than do the amphiboles. It is possible that in small laboratory animals chrysotile fibers, even if broken down, are retained longer relative to the life span of the animal than they are in humans, thus explaining the higher rate of mesothelioma development.

The hazards associated with asbestos exposure depend on fiber length. Fibers 2 mm in length may produce asbestosis; mesothelioma is associated with fibers 5 mm long, and lung cancer with fibers larger than 10 mm. Fiber diameter is another critical feature. Fibers with diameters larger than approximately 3 mm do not readily penetrate into the peripheral lung. For the development of mesothelioma, fiber diameter must be less than 0.5 mm, since thinner fibers may be translocated from their site of deposition via the lymphatics to other organs, including the pleural surface.

Once asbestos fibers have been deposited in the lung, they may become phagocytized by alveolar macrophages. Short fibers are completely ingested and subsequently removed via the mucociliary escalator. Longer fibers are incompletely ingested, and the macrophages become unable to leave the alveoli. Activated by the fibers, macrophages release mediators such as lymphokines and growth factors, which in turn attract immunocompetent cells or stimulate collagen production. Asbestos-related lung disease thus may be mediated through the triggering of an inflammatory sequence of events or the production of changes that eventually lead to the initiation (DNA damage caused by reactive molecular species) or promotion (increased rate of cell turnover in the lung) of the carcinogenic process.

The surface properties of asbestos fibers appear to be an important mechanistic element in toxicity. The protection afforded by superoxide dismutase or free radical scavengers in asbestos-related cell injury in vitro suggests that the generation of active oxygen species and concomitant lipid peroxidation are important mechanisms in asbestos toxicity. The interaction of iron on the surface of asbestos fibers with oxygen may lead to the production of hydrogen peroxide and the highly reactive hydroxyl radical, events that have been associated with asbestos toxicity (Timblin et al., 1999).

Silica Silicosis in humans may be acute or chronic; this distinction is important conceptually because the pathological consequences are manifested quite differently. Acute silicosis occurs only in subjects exposed to a very high level of aerosol containing particles small enough to be respirable (usually less than 5 mm) over a relatively short period, generally a few months to a few years. These patients have worsening dyspnea, fever, cough, and weight loss. There is rapid progression of respiratory failure, usually ending in death within a year or two. No known treatment modality influences the relentless course of acute silicosis.

Chronic silicosis has a long latency period, usually more than 10 years. Uncomplicated silicosis is almost entirely asymptomatic; little alteration is shown on routine pulmonary function tests even after the disease is radiographically demonstrable. The x-ray picture presents fibrotic nodules, generally in the apical portion of lung. The hilar lymph nodes have peripheral calcifications known as eggshell calcifications. Simple silicosis may progress into complicated silicosis, which is defined as the presence of conglomerate nodules larger than 1 cm in diameter. These nodules usually occur in the upper and midlung zones. At an advanced stage they may be surrounded by emphysematous bullae. Chronic silicosis is associated with an increased incidence of tuberculosis.

Crystalline silica is a major component of the earth's crust; after oxygen, silicon is the most common element. As a pure mineral, silicon exists primarily in the form of its dioxide, silica (SiO_2), which has a crystalline form in which a central silicon atom forms a tetrahedron with four shared oxygen atoms. The three principal crystalline isomeric forms are quartz, tridymite, and cristobalite. The tetrahedral structure is linked to fibrogenic potential. Stishovite, a rare crystalline variant without the tetrahedral conformation, is biologically inert. Amorphous forms of silica such as kieselguhr and vitreous silica have very low fibrogenic potential. The ubiquitous presence of silica has made it an occupational hazard ever since humans began shaping tools from stone, and silicosis remains a significant industrial hazard throughout the world in occupations such as mining and quarrying, sandblasting, and foundry work. The main factors that affect the pathogenicity of silica both in vivo and in vitro, in addition to its structure, are particle size and concentration. Many studies have examined the relationship of silica particle size to fibrogenicity. In studies with humans, the most fibrogenic particle size appears to be about 1 mm (range 0.5 to 3mm). In animal experiments (rats, hamsters), the comparable values appear to be 1 to 2 mm (range 0.5 to 5 mm). In animal models, there appears to be a direct relationship between the concentration of silica dust to which an animal is exposed and the intensity and rapidity of the histologic reaction in the lung.

The pathophysiological basis of pulmonary fibrosis in chronic silicosis is probably better understood than is the etiology of any other form of lung fibrosis. The role of pulmonary alveolar macrophages in the ingestion of silica as an initiating event has been established. Apparently, as part of the cytotoxic response of a macrophage to silica ingestion, the macrophage may release cytokines and other substances that cause fibroblasts to replicate and/or increase their rate of collagen biosynthesis. The role of inflammatory cells other than alveolar macrophages in this process is unknown. Also not understood is the role of the host's immune response and the roles of lymphocyte factors in stimulating fibroblast proliferation and/or collagen synthesis by fibroblasts in lung fibrogenesis (Varani and Ward, 1997).

Lung Overload Caused by Particles Investigators studying the kinetics of the pulmonary clearance of particles have observed a slowing of the rate of alveolar clearance when deposited lung burdens are high. At about the same time, investigators evaluating inhaled particles in carcinogenesis bioassays observed excess tumors in animals that inhaled very high concentrations of apparently inert so-called nuisance dusts, which were included in such experiments as negative controls. From these observations came a unifying hypothesis (Morrow, 1992) that clearance mechanisms in the deep lung depending predominantly if not completely on phagocytosis and migration of pulmonary alveolar macrophages can be overwhelmed by quantities of respirable dusts far in excess of physiologic loads. As a consequence, lung burdens of these dusts persist for months or years, and completely unphysiologic mechanisms of disease pathogenesis may come into play. In rats, lung tumors have been produced by particles such as Diesel exhaust that carry mutagens and carcinogens on their surface, but also by inert carbon black particles. The issue of whether particle overloading defines a threshold in such experiments remains unresolved.

Naphthalene Naphthalene occurs in tars and petroleum and is a widely used precursor chemical for synthetic tanning agents, phthalic acid anhydride, carbaryl, and 2-naphthol. It is present in ambient air. Smokers inhale substantial amounts of naphthalene in cigarette smoke. In experimental animals, inhaled or parenterally administered naphthalene has shown remarkable species and tissue specificity: it produces extensive and selective necrosis in the bronchiolar epithelium of the mouse but much less necrosis in rats and hamsters.

Animals treated with small doses of naphthalene or inhibitors of microsomal oxidases show little or no tissue damage, implicating metabolism in the toxicity of this chemical. Metabolism to the oxide is mediated through cytochrome P450 1A1 and 2F2. Naphthalene epoxides may subsequently be conjugated with glutathione and form adducts that presumably are not toxic. It is also possible that the epoxides undergo rearrangement to 1-naphthol with subsequent metabolism to quinones, which are potentially toxic compounds. In rats and other species, probably including humans, conversion of naphthalene is less stereospecific and rates of formation of the epoxide are much slower than in mice. This may explain the species differences that were noted previously (Franklin et al., 1993).

Oxygen Oxygen toxicity is mediated though increased production of partially reduced oxygen products such as superoxide anion, perhydroperoxy and hydroxyl radicals, peroxynitrite and possibly singlet molecular oxygen. In infants who are given oxygen therapy after birth, a syndrome known as bronchopulmonary dysplasia may develop. Lung pathology is characterized by necrotizing bronchiolitis, fibroblast proliferation, squamous metaplasia of the bronchial lining, and destruction of alveolar ducts. In animals exposed to 95 to 100% oxygen, diffuse pulmonary damage develops and is usually fatal after 3 to 4 days. There is extensive damage to the cells of the alveolar-capillary septum. Type I epithelial cells and capillary endothelial cells develop necrotic changes. Capillary damage leads to leakage of proteinaceous fluid and formed blood elements into the alveolar space. Hyaline membranes formed by cellular debris and proteinaceous exudate are a characteristic sign of pulmonary oxygen toxicity. In animals returned to air after the development of acute oxygen toxicity, there is active cell proliferation (Frank, 1997).

Blood-Borne Agents That Cause Pulmonary Toxicity in Humans

Paraquat The bipyridylium compound paraquat, a widely used herbicide, produces extensive lung injury when ingested by humans. In patients who survive the first few days of acute paraquat poisoning, progressive and eventually fatal lung lesions can develop. Paraquat lung disease is characterized by diffuse interstitial and intraalveolar fibrosis. The initial damage consists of widespread necrosis of both type I and type II epithelial cells of the alveolar region. Extensive proliferation of fibroblasts in the alveolar interstitium and the largely collapsed alveoli follows. Paraquat accumulates in the cells of the lung through the polyamine uptake system. Once inside the cells, paraquat continuously cycles from its oxidized form to the reduced form, with the concomitant formation of active oxygen species. A mechanistic hypothesis to explain paraquat toxicity involves oxidation of cellular NADPH and eventual depletion of the NADPH content of pulmonary cells (Smith, 1997).

Monocrotaline Monocrotaline (MCT) is a pyrrolizidine alkaloid, one of many structurally related naturally occurring products of plants that have been identified in grains, honey and herbal teas. These compounds produce liver toxicity (hepatocellular necrosis and veno-occlusive disease). Although the hepatic metabolism of the pyrrolidine alkaloids is usually completed by 24 h, the administration of a single dose of monocrotaline is known to initiate a delayed lung injury. This pulmonary lesion is characterized by a remodeling of the vascular bed with hyperplasia of capillary endothelial cells, thickening of the arterial media, formation of microthrombi, and eventually capillary occlusion with resulting hypertension of the pulmonary arterial system and hypertrophy of the right side of the heart.

Monocrotaline propagates changes in the contractile response of arterial smooth muscle, changes in smooth muscle Na/K-ATP- ase activity, release of platelet factors, and decreased serotonin transport by vascular endothelial cells (Wilson et al., 1992). Monocrotaline is metabolized in the liver by cytochrome P450 3A to a highly reactive pyrrole, a bifunctional alkylating agent, where some of the reactive pyrrole forms nontoxic conjugates with either glutathione or cysteine. A percentage of the remaining pyrrole is released from the liver and travels to other organs, such as the lung and possibly the kidney, via red blood cells (RBCs), where it initiates endothelial injury. It had been previously shown that RBCs circulated through an isolated perfused buffer containing [^{14}C]MCT, subsequently washed and recirculated through an isolated lung preparation could transfer electrophiles to pulmonary tissues. Recent evidence has indicated that the pyrrole is conjugated to the RBCs, mainly to the bb-chains of hemoglobin (Laméé et al., 1997). These pyrrole adducts may be particularly susceptible to removal from globin chains following either enzymatic degradation or environmental changes observed during circulation through hepatic and pulmonary tissues and consequently interact with key target proteins.

Bleomycin Bleomycin, a mixture of several structurally similar compounds, is a widely used cancer chemotherapeutic agent. Pulmonary fibrosis, often fatal, represents the most serious form of toxicity. The sequence of damage includes necrosis of capillary endothelial and type I alveolar cells, edema formation and hemorrhage, delayed (after 1 to 2 weeks) proliferation of type II epithelial cells, and eventually thickening of the alveolar walls by fibrotic changes.

In many tissues, the cytosolic enzyme bleomycin hydrolase inactivates bleomycin. In lung and skin, two target organs for bleomycin toxicity, the activity of this enzyme is low compared with that in other organs. Bleomycin stimulates the production of collagen in the lung. Before increased collagen biosynthesis, steady-state levels of mRNA coding for fibronectin and procollagens are increased, presumably subsequent to a bleomycin-mediated release of cytokines such as TGF-b and TNF. Bleomycin also combines with Fe(II) and molecular oxygen; when it combines with DNA, single- and double-strand breaks are produced by a free radical reaction (Hoyt and Lazo, 1997).

Cyclophosphamide and 1,3-Bis-(2-Chloroethyl)-1-Nitrosourea (BCNU) Cyclophosphamide is widely used as an anticancer and immunosuppressive agent. The undesirable side effects include hemorrhagic cystitis and pulmonary fibrosis. Cyclophosphamide is metabolized by the cytochrome P450 system to two highly reactive metabolites: acrolein and phosphoramide mustard. In the lung, cooxidation with the prostaglandin-H synthase system, which has high activity in the lung, is a possibility. Although the exact mechanism of action for causing lung damage has not been established, studies with isolated lung microsomes have shown that cyclophosphamide and its metabolite acrolein initiate lipid peroxidation. Carmustine (BCNU) is an effective chemotherapeutic agent that exerts its antitumor properties by reacting with cellular macromolecules and forms inter- and intrastrand cross-links with DNA. In humans, a dose-related pulmonary toxicity is often noticed first by a decrease in diffusion capacity. Pulmonary fibrosis caused by this drug can be fatal. The mechanism of action is not entirely clear. It is possible that BCNU inhibits pulmonary glutathione disulfide reductase, an event that may lead to a disturbed GSH/GSSG state in pulmonary cells. Eventually, this state leaves the cell unable to cope with oxidant stress. High concentrations of oxygen in the inspired air may enhance the pulmonary toxicity of BCNU and also that of the other anticancer drugs known to affect lung tissue: cyclophosphamide and bleomycin. Several other chemotherapeutic agents can produce lung damage and pulmonary toxicity in patients treated with these drugs can be a significant problem (Ramu and Kehrer, 1997).

Cationic Amphophilic Drugs Several drugs with similar structural characteristics that are called cationic amphophilic drugs (CADs) produce pulmonary lipidosis. The antiarrhythmic amiodarone and the anorexic chlorphentermine elicit such changes in humans. Pulmonary lipidosis is characterized by the intracellular presence, particularly in macrophages, of large concentric membranous structures now known to be secondary lysosomes. CADs inhibit phospholipases A and B, presumably because these drugs combine with phospholipids and form indigestible complexes. Degradation of pulmonary surfactant is impaired, and the material accumulates in phagocytic cells. In humans, amiodarone may cause dyspnea and cough. In animals and humans, the condition is fully reversible on drug withdrawal (Reasor, 1997).

METHODS FOR STUDYING LUNG INJURY

Inhalation Exposure Systems

The generation of a gas available in high purity as a compressed "tank gas," for example, SO_2, O_2, or NO_2, is relatively straightforward, and metering and dilution produce appropriate concentrations for exposure. Monitoring and quantifying gaseous pollutants require either expensive detectors that need frequent calibration (and usually a computer to process the tremendous amount of data generated) or very labor intensive wet chemical analysis procedures after sampled gases from the chambers are bubbled through traps. Particle generation is difficult, and specialized references must be consulted (Wong, 1999).

Exposure chambers must allow for the rapid attainment of the desired concentrations of toxicants, maintenance of desired levels homogeneously throughout the chamber, adequate capacity for experimental animals, and minimal accumulation of undesired products associated with animal occupancy (usually ammonia, dander, heat, and carbon dioxide). Modern chambers tend to be fabricated from inert materials (usually glass, stainless steel, and Teflon) and have flow patterns that are designed to promote mixing and homogeneity of the chamber atmosphere and prevent a buildup of undesirable contaminants. A major concern with regard to exposure to acid aerosols has been the putative buildup of ammonia in chambers because of microbial action on animal excreta. Thus, maximal loading factors and sanitation also must be considered in chamber usage. As a general rule, the total body volume of the animals should not exceed 5 percent of the chamber volume. Nose-only exposure chambers avoid some of these problems. Finally, concern for the environment and the safety of facility personnel suggest prudence in how chambers are exhausted.

In inhalation studies, selection of animals with a respiratory system similar to that of humans is particularly desirable. The respiratory system of monkeys most closely resembles that of humans. However, the availability and cost of animals and the necessity for special facilities for housing monkeys and performing long-term exposures, along with ethical considerations, including the confinement of primates in small exposure chambers for prolonged periods, severely limit the use of primates. Rats are widely used, although fundamental differences in respiratory anatomy (for example, lack of respiratory bronchioles) and function (rats are obligate nose breathers) can complicate the extrapolation of effects to humans. Guinea pigs and rabbits have been used to predict the response of humans to sulfuric acid (Amdur, 1989).

Pulmonary Function Studies

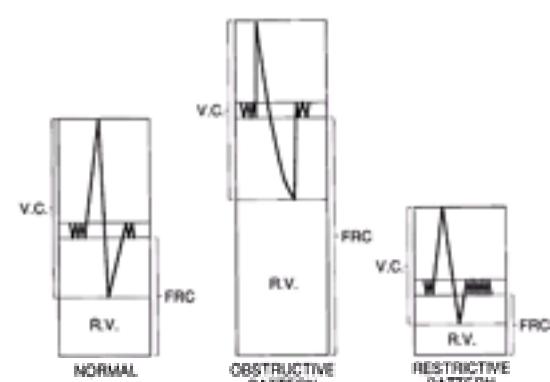
Numerous tests are available with which to study pulmonary function and gas exchange in humans and experimental animals. Commonly used tests include measurement of VC, TLC, functional residual volume, TV, airway resistance, and maximum flow (Fig. 15-6). Additional tests evaluate the distribution of ventilation, lung and chest wall compliance, diffusion capacity, and the oxygen and carbon dioxide content of the arterial and venous blood (Costa et al., 1991).


Figure 15-6. Typical lung volume measurements from individuals with normal lung function, obstructive airways disease, or restrictive lung disease.

Note that there is (1) a slowing of forced expiration in addition to gas trapping (an increase in residual volume) in obstructive disease and (2) a general decrease in lung volumes in restrictive disease. Note that the measurements read from left to right.

Many pulmonary function tests require active collaboration by the subject examined, for example, the so-called FEV_1 (forced expiratory volume) during the first second of an active exhalation. This is an easy test to administer to humans, does not require sophisticated equipment or a hospital setting, and is completely noninvasive. The subject is asked first to inhale deeply and then to exhale the air as quickly as possible. The test is often used in epidemiological studies or controlled clinical studies designed to assess the potential adverse effects of air pollutants. A reduction in FEV_1 is usually indicative of impaired ventilation such as that found in restrictive (increased lung stiffness) or obstructive (obstructed airflow) lung disease. Experimental animals, by contrast, cannot be made to maximally inhale or exhale at the investigator's will. In experimental animals, FEV_1 can be obtained, but the test is done under anesthesia. Expiration is forced by applying external pressure to the thorax or negative pressure to the airways.

Analysis of breathing patterns has been widely used to assess the effects of irritants. This technique allows one to differentiate between sensory or upper airway irritants and "pulmonary" irritants. Highly water soluble irritants such as ammonia, chlorine, and formaldehyde produce upper respiratory tract irritation, whereas less soluble gases such as nitrogen dioxide and ozone generate pulmonary irritation. The sensory irritant pattern has been described as slowing down respiratory frequency while increasing TV. Pulmonary irritants usually increase respiratory frequency and decrease minute volume. The result is rapid, shallow breathing.

Analysis of volume-pressure curves of the lung provides some indication of lung compliance. Compliance (volume/ pressure) is measured as the slope of the volume-pressure curve; it gives some indication of the intrinsic elastic properties of the lung parenchyma and, when measured in vivo, the thoracic cage. This is a comparatively easy test to perform in animals, requiring little specialized apparatus. Cannulation of the excised lungs and attachment to a syringe and manometer to measure volume and pressure are all that is needed. Volume-pressure curves can be obtained from lungs filled with air or physiological saline. The latter test is much more sensitive to structural changes in lung parenchyma, as the effects of surfactant are eliminated in a saline-filled lung.

To accomplish proper oxygenation of venous blood and elimination of CO_2, the gases have to diffuse across the air-blood barrier. Gas exchange may be hindered by the accumulation of fluids or cellular elements in the alveoli (edema, pneumonic infiltrates), thickening of the alveolar wall (fibrosis), insufficient ventilation of the alveolar region (emphysema), or insufficient presence of oxygen transport elements (reduced alveolar blood volume or reduced amount of hemoglobin in the blood). Gas exchange can be evaluated by measuring the arterial partial pressure of both oxygen and CO_2. In experimental animals, the collection of arterial blood may require the presence of indwelling catheters.

In general, blood gas analysis is a comparatively insensitive assay for disturbed ventilation because of the organism's buffering and reserve capacities. While it is a useful tool in clinical medicine, only the most severe obstructive or restrictive pulmonary alterations cause signs of impaired gas exchange in animals. Measurement of diffusion capacity with CO, a gas that binds with 250 times higher affinity to hemoglobin than does oxygen, is more sensitive. The test is comparatively easy to perform in both humans and laboratory animals and is widely used in toxicology studies.

Morphologic Techniques

The pathology of acute and chronic injury may be described after examination of the respiratory tract by gross inspection and under the microscope. Morphologic evaluation should not be limited to the peripheral lung; nasal passages, the larynx, and major airways must be examined as carefully as is the lung parenchyma. For example, formaldehyde produces nasal tumors but not deep lung tumors in the rat. In hamsters exposed to cigarette smoke, cancerous changes are found in the larynx but not in the more distal airways.

Careful consideration must be given to tissue fixation and preparation. Nasal passages must be flushed with fixative. After decalcification, cross sections should be cut at multiple levels; the regional distribution of lesions may vary from agent to agent. Proper fixation of the lung is done by vascular perfusion with fixative through the pulmonary artery or by instillation of fixative through the trachea. Perfusion fixation does not dislodge material (lining fluid, deposited particles) or cells in the lumen of the airways or the alveoli from their original position. Fixation by instillation does this, but it also keeps the alveoli open. It is done under controlled pressure, usually 30 cm H_2O, and is required if semiquantitative or quantitative measurements will be made. The choice of fixative depends on how the lung will be further analyzed. Formalin-based fixatives are satisfactory for routine histopathology, whereas the use of more sophisticated techniques such as electron microscopy, immunohistochemistry, and in situ hybridization require careful selection of the fixative.

Ordinary paraffin sections of respiratory tract tissue are suitable for routine histopathologic analysis; gross pathological changes such as inflammation and the presence of cancerous tissue can be detected easily. Plastic or epon sections about 1 mm thick are required for proper identification of different cell types lining the airways or alveoli and for recognition of cytoplasmic changes in damaged Clara cells. Other structural alterations, such as degenerative changes or necrosis of type I epithelial cells or capillary endothelial cells, usually are detected by transmission electron microscopy (TEM). TEM is essential for an unequivocal identification of cells in the alveolar interstitium and is used mainly in morphometric analysis of the lung. Scanning electron microscopy allows visualization of the surface of interior lung structures, reveals alterations in the tissue surface, and detects rearrangement of the overall cell population. Confocal microscopy, consisting of a laser microscope coupled to a computer, allows examination of thick sections and discovery of specific cell types deep within the tissue; it is an ideal tool for three-dimensional reconstruction of normal and damaged lung.

Morphometry, the quantitative description of structure, refers to a quantitative analysis of tissue (Gehr et al., 1993). Measurements made in two dimensions on photographs taken under the microscope allow one to measure areas, the thickness of a structure, and numerical density. With the help of appropriate formulas, values such as the volume occupied by a specific cell population in the entire lung parenchyma can be calculated. The method is particulalry useful for the detection of subtle toxic effects in the lung parenchyma (Witschi et al., 1999).

Additional tools for the study of toxic lung injury include immunohistochemistry, in situ hybridization, and analysis of cell kinetics. Antibodies to a variety of enzymes, mediators, and other proteins are available. It is possible to identify cell types that carry certain enzymes and their anatomic locations. This information is important for mechanistic studies. In situ hybridization allows one to visualize anatomic sites where a specific gene product is expressed, for example, collagen production in a fibrotic lung. This technique is especially important in an organ such as the lung where there are more than 40 morphologically distinct cell types present. Ascribing a given metabolic capability to a specific cell type requires evaluation of gene expression and/or protein production in specific cells in situ. Flow cytometry is valuable in the study of cell populations prepared from the lung. The technique requires dissociation of the lung parenchyma into its individual cell populations. Different lung cells then can be identified and isolated.

Pulmonary Lavage

Pulmonary edema and/or pulmonary inflammation appear to be obligatory early events in acute and chronic lung injury. Markers of these processes generally are chosen to reflect lung edema or cellular changes in the lung. The most popular of these types of assays have quantified various parameters in lung lavage fluid from animals exposed to pneumotoxic substances. Generally, the lungs of exposed and control animals are washed with multiple small volumes of isotonic saline This technique has the further advantage of allowing direct comparisons with data accessible from normal human volunteers or patients undergoing bronchopulmonary lavage for therapeutic purposes. Current emphasis seems to be on the measurement of polymorphonuclear leukocytes, macrophages, and monocytes (and their phagocytotic capabilities) in the cellular fraction and the measurement of lactate dehydrogenase (and its substituent isoenzymes), *N*-acetylglucosaminidase, acid or alkaline phosphatase, other lysosomal hydrolases, lavageable total protein and/or albumin, and sialic acid. Although such measurements have often formed the basis of mechanistic interpretations, we really do not have a rigorous theoretical understanding of the exact source of any of these parameters.

Measurement of apparent changes in the permeability of the air-blood barrier by quantification of intravenously injected tracer in lung lavage fluid is another useful index of lung damage. The movement of low-molecular-weight tracers such as [^{51}Cr] EDTA across the blood-air barrier occurs rapidly (within 10 min of IV injection). High-molecular-weight tracers such as radiolabeled albumin also have been used for this purpose.

In Vitro Approaches

In vitro systems are particularly suited for the study of mechanisms that cause lung injury. The following systems are widely used (Postlethwait and Bidani, 1997).

Isolated Perfused Lung The isolated perfused lung method is applicable to lungs from many laboratory animal species (rabbit, rat, mouse, guinea pig). The lung, in situ or excised, is perfused with blood or a blood substitute through the pulmonary arterial bed. At the same time, the lung is actively (through rhythmic inflation-deflation cycles with positive pressure) or passively (by creating negative pressure with an "artificial thorax" in which the lung is suspended) ventilated. Toxic

agents can be introduced into the perfusate or the inspired air. Repeated sampling of the perfusate allows one to determine the rate of metabolism of drugs and the metabolic activity of the lung.

Lung Explants and Slices Slices and explants from the conducting airways or the lung parenchyma allow one to examine biochemical and morphologic changes in the lung parenchyma without intervening complications from cells migrating into the tissue (e.g., leukocytes). If the lung is first inflated with agar, the alveolar spaces remain open in the explant. Slices prepared in this way can be kept viable for several weeks, and the mechanisms of development of chronic lesions can be studied.

Microdissection Many inhalants act in circumscribed regions of the respiratory tract, such as the terminal bronchioles, a region especially rich in metabolically highly competent Clara cells. Microdissection of the airways consists of the stripping of small bronchi and terminal bronchioli from the surrounding parenchyma and maintenance of the isolated airways in culture. Specific biochemical reactions predominantly located in the cells of the small airways can then be studied with biochemical or morphologic techniques.

Organotypic Cell Culture Systems Tissue culture systems have been developed in which epithelial cells maintain their polarity, differentiation, and normal function similar to what is observed in vivo. Epithelial cell surfaces are exposed to air (or a gas phase containing an airborne toxic agent), while the basal portion is bathed by a tissue culture medium. Epithelial cells may be seeded on top of a suitable supporting material (e.g., collagen or nitrocellulose membranes) with mesenchymal cells seeded on the other side to observe epithelial cell–fibroblast interactions.

Isolated Lung Cell Populations Many specific lung cell types have been isolated and maintained as primary cultures in vitro. Alveolar macrophages are easily obtained from human and animal lungs by lavage. Their function can be examined in vitro with or without exposure to appropriate toxic stimuli. Type II alveolar epithelial cells are isolated after digestion of the lung. Direct isolation of type I epithelial cells has also been successful. Systems for the isolation and culture of Clara cells and neuroepithelial cells are available. Lung fibroblasts are easily grown and have been studied in coculture with epithelial cells. Multiple primary cell cultures and cell lines have been established from lung tumors found in experimental animals and humans. Isolated cell techniques suffer from possible enzymatic digestion of critical cellular components. Caution should be exercised in the final interpretation of experiments utilizing this approach.

CHAPTER 16

TOXIC RESPONSES OF THE NERVOUS SYSTEM

Douglas C. Anthony, Thomas J. Montine, William M. Valentine, and Doyle G. Graham

OVERVIEW OF THE NERVOUS SYSTEM

Neurotoxicants and toxins have been extensively studied, both because of their toxic effects on humans and because of their utility in the study of the nervous system (NS). Many insights into the organization and function of the NS are based on observations derived from the action of neurotoxicants. The binding of exogenous compounds to membranes has been the basis for the definition of specific receptors within the brain; an understanding of the roles of different cell types in the function of the NS has stemmed from the selectivity of certain toxicants in injuring only certain cell types; and important differences in basic metabolic requirements of different subpopulations of neurons have been inferred from the effects of toxicants.

It is estimated that millions of people worldwide are exposed to known neurotoxicants each year, a fact underscored by repeated outbreaks of neurologic disease (Federal Register, 1994). An even larger potential problem is the incomplete information on many compounds that may have neurotoxic effects. Unknown is the extent to which neurologic disability may be related to chronic low-level exposures, nor do we understand the overall impact of environmental contaminants on brain function.

In order to study neurotoxicologic diseases, one must understand some of the anatomy, physiology, development, and regenerative capacity of the NS. These complex functions can be reduced to several generalities that allow a basic understanding of the actions of neurotoxicants. These general principles include (1) the privileged status of the NS with the maintenance of a biochemical barrier between the brain and the blood, (2) the importance of the high energy requirements of the brain, (3) the spatial extensions of the NS as long cellular processes and the requirements of cells with such a complex geometry, (4) the maintenance of an environment rich in lipids, and (5) the transmission of information across extracellular space at the synapse. Each of these features of the NS carries with it specialized metabolic requirements and unique vulnerabilities to toxic compounds.

Blood-Brain Barrier

The NS is protected from the adverse effects of many potential toxicants by an anatomic barrier. In 1885, Ehrlich, while studying the distribution of dyes in the body, noticed that although other tissues became stained, the brain and spinal cord did not develop the color of the dyes. This observation pointed to the existence of an interface between the blood and the brain, or a "blood-brain barrier." Most of the brain, spinal cord, retina, and peripheral NS maintain this barrier with the blood, with a selectivity similar to the interface between cells and extracellular space. The principal basis of the blood-brain barrier is thought to be specialized endothelial cells in the brain's microvasculature, aided, at least in part, by interactions with glia (Kniesel and Wolburg, 2000).

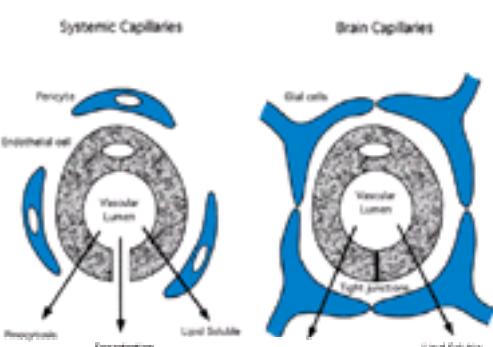
Among the unique properties of endothelial cells in the NS is the presence of tight junctions between cells (Kniesel and Wolburg, 2000; Rubin and Staddon, 1999), compared to the 4-nm gaps between endothelial cells outside the NS. To gain entry to the NS, molecules must pass through the cell membranes of endothelial cells of the brain rather than between endothelial cells, as they do in other tissues (Fig. 16-1). The blood-brain barrier also contains xenobiotic transporters, such as the multidrug-resistant protein, which transports some xenobiotics that have diffused through endothelial cells back into the blood. Aside from molecules that are actively transported in the brain, the penetration of toxicants or their metabolites into the NS is largely related to their lipid solubility and to their ability to pass through the plasma membranes of the cells forming the barrier (Pardridge, 1999; Stewart, 2000). There are important exceptions to this general rule. In the mature NS, the spinal and autonomic ganglia as well as a small number of other sites within the brain, called *circumventricular organs,* do not contain specialized endothelial tight junctions and are not protected by blood-tissue barriers. This discontinuity of the barrier allows entry of the anticancer drug doxorubicin into the sensory ganglia and forms the basis for the selective neurotoxicity of this compound to ganglionic neurons (Spencer, 2000). The blood-brain barrier is incompletely developed at birth and even less so in premature infants. This predisposes the premature infant to brain injury by toxins, such as unconjugated bilirubin, that later in life are excluded from the NS (Lucey et al., 1964).


Figure 16-1. Schematic diagram of the blood-brain barrier.

Systemic capillaries are depicted with intercellular gaps, or fenestrations, which permit the passage of molecules incapable of crossing the endothelial cell. There is also more abundant pinocytosis in systemic capillaries, in addition to the transcellular passage of lipid soluble compounds. In brain capillaries, tight junctions between endothelial cells and the lack of pinocytosis limit transport to compounds with active transport mechanisms or those which pass through cellular membranes by virtue of their lipid solubility.

In addition to this interface with blood, the brain, spinal cord, and peripheral nerves are also completely covered with a continuous lining of specialized cells that limits the entry of molecules from adjacent tissue. In the brain and spinal cord, this surface is the meningeal surface; in peripheral nerves, each fascicle of nerve is surrounded by perineurial cells.

Energy Requirements

Neurons and cardiac myocytes are highly dependent upon aerobic metabolism. These cells share the property of conduction of electrical impulses, and their dependence on aerobic respiration emphasizes the high metabolic demand associated with the maintenance and repetitive reinstitution of ion gradients. Membrane depolarizations and repolarizations occur with such frequency that these cells must be able to produce large quantities of high-energy phosphates even in a resting state. That the energy requirements of the brain are related to membrane depolarizations is supported by the fact that hyperactivity, as in epileptic foci, increases the energy requirements by as much as five times (Plum and Posner, 1985). The dependence on a continual source of energy, in the absence of energy reserves, places the neuron in a vulnerable position. To meet these high energy requirements, the brain utilizes aerobic glycolysis and, therefore, is extremely sensitive to even brief interruptions in the supply of oxygen or glucose.

The systemic exposure to toxicants that inhibit aerobic respiration, such as cyanide, or to conditions that produce hypoxia, such as carbon monoxide (CO) poisoning, leads to the earliest signs of dysfunction in the myocardium and neurons. Damage to the NS under these conditions is a combination of direct toxic effects on neurons and secondary damage from systemic hypoxia or ischemia. For example, acute CO poisoning damages those structures in the central nervous system (CNS) that are most vulnerable to hypoxia: the neurons in specific regions of the basal ganglia and hippocampus, certain layers of the cerebral cortex, and the cerebellar Purkinje cells. Experiments utilizing several different laboratory animal species have shown that systemic hypotension is the best predictor of these lesions following CO poisoning; however, CO poisoning also may produce white matter damage, and this leukoencephalopathy may result from a primary effect of CO in the CNS (Penny, 1990). As in the case of acute CO intoxication, survivors of cyanide poisoning may develop lesions in the CNS that are characteristic of systemic hypoxic or ischemic injury, and experiments in rats and monkeys have led to the conclusion that global hypoperfusion, rather than direct histotoxicity, is the major cause of CNS damage (Auer and Benveniste, 1997). 3-Nitropropionic acid (3-NP), a naturally occurring mycotoxin, is an irreversible inhibitor of succinate dehydrogenase that produces adenosine triphosphate (ATP) depletion in cerebral cortical explants and is associated with motor disorders in livestock and humans that have ingested contaminated food (Ludolf et al., 1991, 1992). Some investigators removed the complication of systemic toxicity by directly injecting 3-NP into specific regions of the brain. They have observed neuron degeneration mediated in part by excitotoxic mechanisms (Brouillet et al., 1993). These examples demonstrate the exquisite sensitivity of neurons to energy depletion and also underscore the complex relationships between direct neurotoxicity and the effects of systemic toxicity on the NS.

Axonal Transport

Some forms of intercellular communication are conducted through the vascular system as hormones, which transmit information to remote sites through the bloodstream. Some information, however, is too vital to be conducted in such a diffuse and slow manner, and the NS can be envisioned as a remedy to the obstacle of space in intercellular communication. Impulses are conducted over great distances at rapid speed and provide information about the environment to the organism in a coordinated manner that allows an organized response to be carried out at a specific site. However, the intricate organization of such a complex network places an unparalleled demand on the cells of the NS. Single cells, rather than being spherical and a few micrometers in diameter, are elongated and may extend over a meter in length!

The anatomy of such a complex cellular network creates features of metabolism and cellular geometry that are peculiar to the NS. The two immediate demands placed on the neuron are the maintenance of a much larger cellular volume and the transport of intracellular materials over great distances. Although the length of neurons may exceed 200,000 times the dimensions of most other cells, the cellular volume has not undergone a similar increase due to the unique attribute of very fine cylindrical extensions of the cell to span the long distances. In the form of long delicate axons, the neuron spans large distances but maintains less cytoplasmic volume and cell surface. Even so, the volume of the axon is much greater than the volume of the cell body. If one considers the lower motor neuron in humans, the cell body is located in the spinal cord and the axon extends to the site of innervation of a muscle at a distant location. In spite of the smaller diameter of the axon, the tremendous distances traversed by the axon translate to an axonal volume that is hundreds of times greater than that of the cell body itself (Schwartz, 1991). This places a great burden on the neuron to provide protein synthetic machinery for such a cytoplasmic volume. The cellular machinery is readily visible in large neurons through the light microscope as the Nissl substance, which is formed by clusters of ribosomal complexes for the synthesis of proteins (Parent, 1996). That this is a reflection of an unusual protein synthetic burden may be surmised from the fact that neurons are the only cell type with such a Nissl substance.

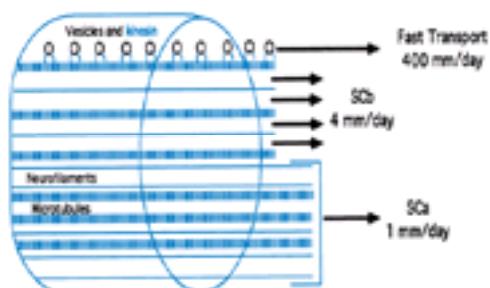
In addition to the increased burden of protein synthesis, the neuron is dependent on the ability to distribute materials over the distances encompassed by its processes. While analogous systems exist in all cell types and are referred to as cytoplasmic streaming, in the NS this process occurs over much greater distances and is referred to as axonal transport. Protein synthesis occurs in the cell body, and the protein products are then transported to the appropriate site through the process of axonal transport. The assembly of the cytoskeleton at tremendous distances from their site of synthesis in the cell body represents a formidable challenge (Nixon, 1998). Through studies of the movement of radiolabeled amino acid precursors, several major components of axonal transport are known (Grafstein, 1995). The fastest component is referred to as *fast axonal transport* and carries a large number of proteins from their site of synthesis in the cell body into the axon. Many of these proteins are associated with vesicles (Grafstein, 1995) and migrate through the axon at a rate of 400 mm/day (Fig. 16-2). This process has been known for some time to be dependent on ATP, but it was not until the description of a microtubule-associated ATPase activity that there rapidly emerged the concept of microtubule-associated motor proteins. These proteins, kinesin and dynein being the prototypes of a class of microtubule-associated motors, provide both the mechanochemical force in the form of a microtubule-associated ATPase and the interface between microtubules as the track and vesicles as the cargo. Vesicles are transported rapidly in an anterograde direction by kinesin, and they are transported in a retrograde direction by dynein (Schnapp and Reese, 1989). While this mechanism of cytoplasmic transport toward the cell periphery and back toward the nucleus appears to be a general feature of cells, the process is amplified within the NS by the distances encompassed by the axonal extensions of neurons. In the axon, multiple waves of transport can be detected in the fast component of axonal transport (Mulugeta et al., 2000).


Figure 16-2. Schematic diagram of axonal transport.

Fast axonal transport is depicted as spherical vesicles moving along microtubules with intervening microtubule-associated motors. The slow component A (SCa) represents the movement of the cytoskeleton, composed of neurofilaments and microtubules. Slow component b (SCb) moves at a faster rate than SCa and includes soluble proteins, which are apparently moving between the more slowly moving cytoskeleton.

The transport of some organelles, including mitochondria, constitutes an intermediate component of axonal transport, moving at 50 mm/day (Grafstein, 1995). As with the fast component, the function is apparently the continuous replacement of organelles within the axon. The slowest component of axonal transport represents the movement of the cytoskeleton itself, rather than the movement of enzymes or organelles through the cytosol (Fig. 16-2). The cytoskeleton is composed of structural elements, including microtubules formed by the association of tubulin subunits and neurofilaments formed by the association of three neurofilament protein subunits. Dynamic exchange of subunits of the filamentous structure has now been observed with high-resolution microscopy of living cells, indicating that stationary filamentous structures exchange subunits that move rapidly once dissociated (Wang et al., 2000). Each of the elements of the cytoskeleton moves along the length of the axon at a specific rate. Overall, slow component A (SCa), so named to distinguish this wave of movement from another slow component of axonal transport, slow component B (SCb) (Hoffman and Lasek, 1975), is composed of the movement of the axonal cytoskelton in an anterograde direction.

Neurofilaments and microtubules move at a rate of approximately 1 mm/day and make up the majority of SCa, the slowest-moving component of axonal transport. Subunit structures appear to migrate and reassemble in a process that is dependent on nucleoside triphosphates, kinases, and phosphatases (Koehnle and Brown,

1999; Nixon, 1998). Moving at only a slightly more rapid rate of 2 to 4 mm/day is SCb, which is composed of many proteins (Grafstein, 1995). Included in SCb are several structural proteins, such as the component of microfilaments (actin) and several microfilament-associated proteins (M2 protein and fodrin), as well as clathrin and many soluble proteins.

This continual transport of proteins from the cell body through the various components of forward-directed, or anterograde, axonal transport is the mechanism through which the neuron provides the distal axon with its complement of functional and structural proteins. Some vesicles are also moving in a retrograde direction and undoubtedly provide the cell body with information concerning the status of the distal axon. The evidence for such a dynamic interchange of materials and information stems not only from the biochemical detection of these components of axonal transport but also from the observations of the effects of terminating this interchange by severing the axon from its cell body. The result of transection of an axon is that the distal axon is destined to degenerate, a process known as axonal degeneration which is unique to the NS. The cell body of the neuron responds to the transection of the axon as well and undergoes a process of chromatolysis, a response of the cell body to degeneration of the axon.

Axonal Degeneration Current concepts of axonal degeneration were initially derived from the transection of nerve, first reported by Augustus Waller over a hundred years ago. Accordingly, the recognized sequence of events that occur in the distal stump of an axon following transection are referred to as *Wallerian degeneration*. Because the axonal degeneration associated with chemical agents and some disease states is thought to occur through a similar sequence of events, it is often referred to as *Wallerian-like* axonal degeneration.

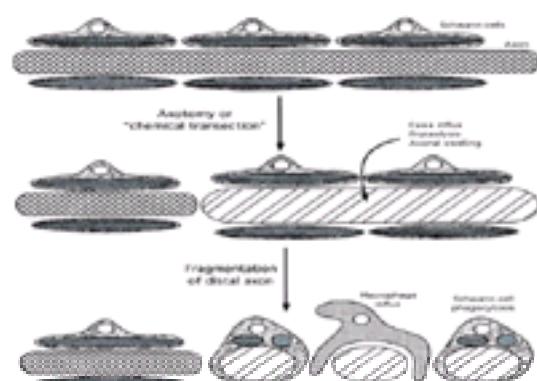
Following axotomy, there is degeneration of the distal nerve stump, followed by generation of a microenvironment supportive of regeneration. This process proceeds through a sequence of changes involving the distal axon, ensheathing glial cells and the blood nerve barrier. Initially there is a period during which the distal stump survives and maintains relatively normal structural, transport, and conduction properties. The duration of survival is proportional to the length of the axonal stump (Chaudry and Cornblath, 1992), and this relationship appears to be maintained across species. An exception has been noted in the C57/BL6/01a mouse, in which transected nerve fibers function electrically for 14 to 28 days (Lunn et al., 1989). Although the underlying reason for slow degeneration in this mutant is unknown, the trait is transmitted by a dominant gene on chromosome 4 (Lyon et al., 1993) and is an intrinsic property of the neuron that does not involve macrophages or Schwann cells (Glass et al., 1993). Terminating the period of survival is an active proteolysis that digests the axolemma and axoplasm, leaving only a myelin sheath surrounding a swollen degenerate axon (Fig. 16-3). Digestion of the axon appears to be an all-or-none event effected through endogenous proteases (Schaefler and Zimmerman, 1984) that appear to be activated through increased levels of intracellular free Ca $^{2+}$ (George et al., 1995). Although it is established that degeneration of the most terminal portion of the axon occurs first, whether degeneration of the remainder of the stump occurs from proximal to distal, distal to proximal, or simultaneously along its entire length remains a matter of debate. The active proteolysis phase occurs so rapidly in mammals that it has been difficult to define a spatial distribution.


Figure 16-3. Schematic diagram of axonal degeneration.

Following axotomy, or chemical injury of an axon, the distal portion of the axon undergoes a process of axonal degeneration. Initial stages of axonal swelling are followed by fragmentation of the distal axon and phagocytosis by resident Schwann cells and an influx of macrophages, which are largely derived from the circulation.

Schwann cells respond to loss of axons by decreasing synthesis of myelin lipids, down-regulating genes encoding myelin proteins, and dedifferentiating to a premyelinating mitotic Schwann cell phenotype (Stoll and Muller, 1999). The proliferating Schwann cells align along the original basal lamina, which creates a tubular structure referred to as a band of Bungner. In addition to providing physical guidance for regenerating axons, these tubes provide trophic support from nerve growth factor, brain-derived nerve growth factor, insulin-like growth factor, and corresponding receptors produced by the associated Schwann cells. Resident macrophages distributed along the endothelium within the endoneurium and the denervated Schwann cells assist in clearing myelin debris, but the recruitment of hematogenous macrophages accounts for the removal of the majority of myelin. Infiltrating macrophages express complement receptor 3, and the presence of complement 3 on the surface of degenerating myelin sheaths facilitates opsonization. In contrast to the proteolysis of the axon, processing of myelin breakdown products proceeds in an established proximal-to-distal progression. Another essential role of recruited circulating macrophages is the secretion of interleukin-1, which is responsible for stimulating production of nerve growth factor by Schwann cells.

Investigations have shown that degeneration of the distal axonal stump after transection is an active, synchronized process that can be delayed experimentally through decreasing temperature, preventing the entry of extracellular Ca $^{2+}$ or inhibiting proteolysis by calpain II (George et al., 1995). Accompanying events in glial cells and macrophages direct and facilitate the sprouting neurite originating from the surviving proximal axon that also undergoes changes in protein expression resembling a less differentiated state. The facilitation of regeneration in the peripheral nervous system by Schwann cells distinguishes it from the central nervous system (CNS), in which oligodendrocytes secrete inhibitory factors that impede neurite outgrowth. Eventually, though, even in the peripheral nervous system (PNS), if axonal contact is not restored, Schwann cell numbers will decrease, bands of Bungner will disappear, and increased fibroblast collagen production will render regeneration increasingly unlikely.

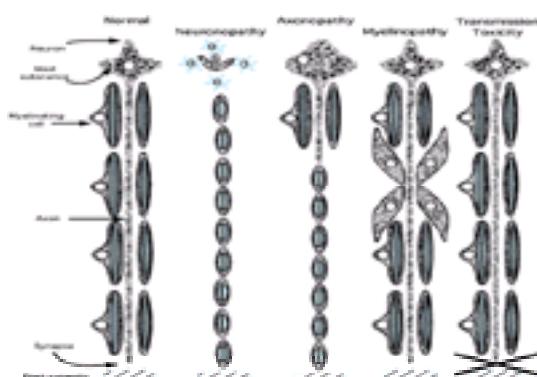
These dynamic relationships between the neuronal cell body and its axon are important in understanding the basic pathological responses to axonal and neuronal injuries caused by neurotoxicants. When the neuronal cell body has been lethally injured, it degenerates, along with all of its cellular processes. This process is a *neuronopathy* and is characterized by the loss of the cell body and all of its processes, with no potential for regeneration. However, when the injury is at the level of the axon, the axon may degenerate while the neuronal cell body continues to survive, a condition known as an "axonopathy" (Fig. 16-4). In this setting, there is a potential for regeneration and recovery from the toxic injury as the axonal stump sprouts and regenerates. Since axonal transport is the process by which the neuron supplies proteins to the distal portions of the axon, axonal transport systems have become of major interest in attempts to understand the toxic degeneration of axons.


Figure 16-4. Patterns of neurotoxic injury.

A neuronopathy results from the death of the entire neuron. Astrocytes often proliferate in response to the neuronal loss, creating both neuronal loss and gliosis. When the axon is the primary site of injury, the axon degenerates, while the surviving neuron shows only chromatolysis with margination of its Nissl substance and

nucleus to the cell periphery. This condition is termed an axonopathy. Myelinopathies result from disruption of myelin or from selective injury to the myelinating cells. To prevent cross-talk between adjacent axons, myelinating cells divide and cover the denuded axon rapidly; however, the process of remyelination is much less effective in the CNS than in the PNS. Some compounds do not lead to cell death but exert their toxic effects by interrupting the process of neurotransmission, either through blocking excitation or by excessive stimulation.

Myelin Formation and Maintenance

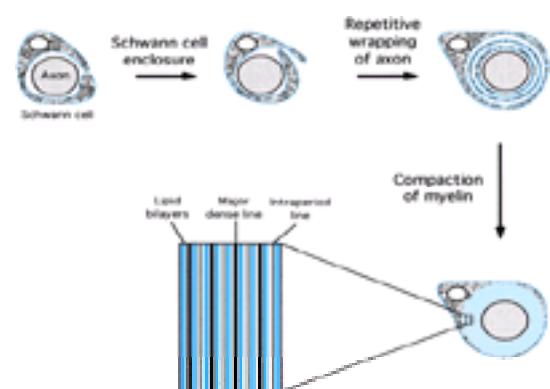
Myelin is formed in the CNS by oligodendrocytes and in the PNS by Schwann cells. Both of these cell types form concentric layers of lipid-rich myelin by the progressive wrapping of their cytoplasmic processes around the axon in successive loops (Fig. 16-5). Ultimately, these cells exclude cytoplasm from the inner surface of their membranes to form the major dense line of myelin (Quarles et al., 1997; Monuki and Lemke, 1995; Parent, 1996). In a similar process, the extracellular space is reduced on the extracellular surface of the bilayers, and the lipid membranes stack together, separated only by a proteinaceous intraperiod line existing between successive layers.


Figure 16-5. Schematic diagram of myelination.

Myelination begins when a myelinating cell encircles an axon, either Schwann cells in the peripheral nervous system or oligodendrocytes in the central nervous system. Simple enclosure of the axon persists in unmyelinated axons. Myelin formation proceeds by a progressive wrapping of multiple layers of the myelinating cell around the axon, with extrusion of the cytoplasm and extracellular space to bring the lipid bilayers into close proximity. The intracellular space is compressed to form the major dense line of myelin, and the extracellular space is compressed to form the intraperiod line.

The formation and maintenance of myelin requires metabolic and structural proteins that are unique to the NS. Myelin basic protein, an integral protein of CNS myelin, is closely associated with the intracellular space (at the major dense line of myelin) (Quarles et al., 1997; Monuki and Lemke, 1995), and an analogous protein, P1 protein, is located in the PNS. On the extracellular surface of the lipid bilayers is the CNS protein, proteolipid protein, at the intraperiod line of myelin. Mutation of this protein in several species, including humans, or overexpression of the wild-type gene in transgenic mice, results in disorders in which myelin of the CNS does not form normally (Pham-Dinh et al., 1991; Readhead et al., 1994).

There are a variety of hereditary disorders in which myelin is either poorly formed from the outset or is not maintained after its formation. In addition to mutation of proteolipid protein, there are a variety of inherited abnormalities of myelin proteins and myelin-specific lipid catabolism. These genetic defects have provided some insight into the special processes required to maintain the lipid-rich environment of myelin. It is now known that the maintenance of myelin is dependent on a number of membrane-associated proteins and on metabolism of specific lipids present in myelin bilayers. In the context of toxic exposures, it is easy to imagine how some toxic compounds interfere with this complex process of the maintenance of myelin and result in the toxic "myelinopathies" (Fig. 16-4). In general, the loss of myelin, with the preservation of axons is referred to as *demyelination*.

Neurotransmission

Intercellular communication is achieved in the NS through the synapse. Neurotransmitters released from one axon act as the first messenger. Binding of the transmitter to the postsynaptic receptor is followed by modulation of an ion channel or activation of a second messenger system, leading to changes in the responding cell. In the case of neuromuscular transmission, acetylcholine crosses the synaptic cleft to bind the cholinergic receptor of the myocyte and leads to muscle contraction.

The process of neurotransmission is targeted by a variety of therapeutic drugs and is a major component of the science of neuropharmacology. In addition, there are a variety of toxic compounds that interact directly with the process of neurotransmission, hence forming the basis of neurotransmitter-associated toxicity. To a certain extent, many of the toxic effects associated with neurotransmitters is related to the dose. While a desirable effect may occur, with some agonists or antagonists acting at a neurotransmitter receptor site, excessive effect may result in neurotoxicity. The therapeutic index, in general, is a measure of the margin between the desirable and toxic effects of a compound. Thus, the very processes targeted by many clinical neuropharmacologic strategies and drug designs are also the targets of certain neurotoxic compounds.

Development of the Nervous System

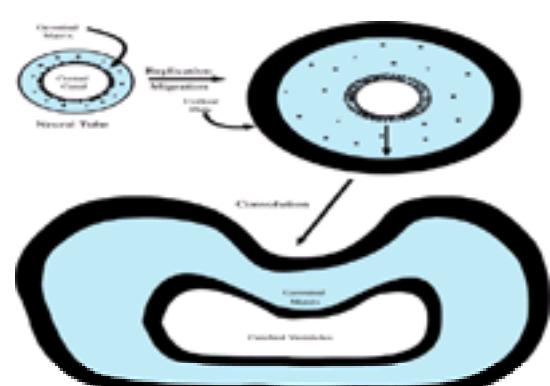
Replication, migration, differentiation, myelination, and synapse formation are the basic processes that underlie development of the NS. Both neuronal and glial precursors replicate in a discrete zone near the inner surface of the neural tube (Fig. 16-6). This germinal mantle, a collection of cells near the ventricular system, gives rise to successive waves of neurons, which migrate toward the outer surface of the brain to form the cerebral cortex, as well as other neurons, supportive astrocytes, and myelinating oligodendrocytes. Each wave of cells migrates from the germinal mantle in a precisely ordered sequence both in utero and in early postnatal life. Myelination begins in utero and continues through childhood (Kinney and Armstrong, 1997). Synaptic connectivity, the basis of neurologic function, is a dynamic process throughout life.


Figure 16-6. Development of the central nervous system.

Initially a tube of committed neuroepithelial cells around a central lumen (the neural tube), the central nervous system develops by replication of cells within the periventricular germinal matrix and migration of waves of neurons toward the surface. The basic tube structure persists in the spinal cord with its central canal.

However, in the forebrain, the tube becomes extensively convoluted to form the gyrations of the brain.

Development of the brain during childhood provides a certain resilience toward injuries. Much of this is due to the fact that the younger brain has greater plasticity, an ability of one portion of the NS to assume the function of an injured area. The brain of a child may compensate partially for an injury that would result in much greater disability in an adult (Goldberger and Murray, 1985). This plasticity of the immature NS appears to derive from the ability of dendrites to arborize and form new synapses. It is both curious and tragic that this capacity wanes with age.

This regenerative ability notwithstanding, the immature NS is especially vulnerable to certain agents. Ethanol exposure during pregnancy can result in abnormalities in the fetus, including abnormal neuronal migration, abnormal facial development, and diffuse abnormalities in the development of neuronal processes, especially the dendritic spines (Stoltenburg-Didinger and Spohre, 1983). While the exposure may be of little consequence to the mother, it can be devastating to the fetus. There is an effect on NMDA glutamate receptors and excessive activation of GABA receptors, with induction of apoptosis throughout the brain (Ikonomidou et al., 2000). The clinical result of fetal alcohol exposure is often mental retardation, with malformations of the brain and delayed myelination of white matter (Riikonen et al., 1999). Although there remains a great deal of uncertainty concerning the molecular basis of this developmental aberration, it occurs in a variety of experimental animals, and it appears that acetaldehyde, a product of ethanol catabolism, can produce migration defects in developing animals similar to those that occur in the fetal alcohol syndrome (O'Shea and Kaufman, 1979).

FUNCTIONAL MANIFESTATIONS OF NEUROTOXICITY

A variety of methods are available to investigate the deleterious effects of neurotoxicants. A complete biochemical or molecular mechanism for all toxicants is the ultimate goal of neurotoxicology, and it is from this perspective that the remainder of this chapter presents specific neurotoxic agents. One hastens to note that a vast ignorance lies between our current knowledge and this objective. The foremost priority is the identification of potential neurotoxicants. It is here that behavioral methods continue to make great achievements. In most instances, mechanistic data have accrued following functional assessment of exposed populations.

The strength of functional assessment has been exploited by many investigators and regulatory agencies that now employ functional test batteries as a means for screening potentially neurotoxic compounds (Tilson, 1993). A group or "battery" of behavioral tests is typically performed to evaluate a variety of neurologic functions, and its validity has been established by collaborative intergroup measures (Moser et al., 1997a). These *functional observational batteries* (FOBs) have the advantage over biochemical and pathologic measures that they permit evaluation of a single animal over longitudinal studies to determine the onset, progression, duration, and reversibility of a neurotoxic injury. In addition, repeated exposures may lead to tolerance in behavioral measures. Tilson has proposed two distinct tiers of functional testing of neurotoxicants: a first tier in which FOBs or motor activity tests may be used to identify the presence of a neurotoxic substance, and a second tier that involves characterization of the effects of the compound on sensory, motor, autonomic, and cognitive functions (Tilson, 1993). The second tier is critical, since it is in this phase that the validity of behavioral tests is established, and behavioral changes are correlated with physiologic, biochemical, and pathologic identification of neurotoxic injury (Becking et al., 1993). Problems exist in the cross-species extrapolation of behavioral abnormalities from experimental animals to humans (Winneke, 1992). Nonetheless, comparisons of defined protocols of FOBs with limited numbers of compounds (Moser et al., 1997b,c) suggest that these methods can identify neurotoxic compounds reliably. Ultimately, neurotoxicants identified by behavioral methods are evaluated at a cellular and molecular level to provide an understanding of the events in the NS that cause the neurologic dysfunction detected by observational tests.

MECHANISMS OF NEUROTOXICITY

Efforts to understand the mechanism of action of individual neurotoxic compounds have begun with the identification of the cellular target. In the nervous system, this has most often been one of four targets: the neuron, the axon, the myelinating cell, or the neurotransmitter system. As a result, neurotoxic compounds may be identified which cause neuronopathies, axonopathies, myelino-pathies, or neurotransmitter-associated toxicity (Fig. 16-4). This is the classification system that is utilized here to organize the discussion of neurotoxic compounds and their mechanisms of action.

Neuronopathies

Certain toxicants are specific for neurons, or sometimes a particular group of neurons, resulting in their injury or, when intoxication is severe enough, their death. The loss of a neuron is irreversible and includes degeneration of all of its cytoplasmic extensions, dendrites and axons, and of the myelin ensheathing the axon (Fig. 16-4). Although the neuron is similar to other cell types in many respects, some features of the neuron are unique, placing it at risk for the action of cellular toxicants. Some of the unique features of the neuron include a high metabolic rate, a long cellular process that is supported by the cell body, and an excitable membrane that is rapidly depolarized and repolarized. Because many neurotoxic compounds act at the site of the cell body, when massive loss of axons and myelin are discovered in the PNS or CNS, the first question is whether the neuronal cell bodies themselves have been destroyed.

Although a large number of compounds are known to result in toxic neuronopathies (Table 16-1), all of these toxicants share certain features. Each toxic condition is the result of a cellular toxicant that has a predilection for neurons, most likely due to one of the neuron's peculiar vulnerabilities. The initial injury to neurons is followed by apoptosis or necrosis, leading to permanent loss of the neuron. These agents tend to be diffuse in their action, although they may show some selectivity in the degree of injury of different neuronal subpopulations or at times an exquisite selectivity for such a subpopulation. The expression of these cellular events is often a diffuse encephalopathy, with global dysfunctions; however, the symptomatology reflects the injury to the brain, so neurotoxicants that are selective in their action and affect only a subpopulation of neurons may lead to interruption of only a particular functionality.

Table 16-1 Compounds Associated with Neuronal Injury (Neuronopathies)

Doxorubicin Although it is the cardiac toxicity that limits the quantity of doxorubicin (Adriamycin) that can be given to cancer patients, doxorubicin also injures neurons in the PNS, specifically those of the dorsal root ganglia and autonomic ganglia (Spencer, 2000). This selective vulnerability of peripheral ganglion cells is particularly dramatic in experimental animals, where it has been well documented. Doxorubicin is an anthracycline antibiotic derivative whose antineoplastic properties derive from its ability to intercalate in double-stranded DNA, interfering with transcription. Because all neurons are dependent on the ability to transcribe DNA, it is quite interesting that the neurotoxicity of doxorubicin is so limited in its extent. The particular vulnerability of sensory and autonomic neurons appears to reflect the lack of protection of these neurons by a blood-tissue barrier within ganglia. If the blood-brain barrier is temporarily opened by the use of mannitol, the toxicity of doxorubicin is expressed in a much more diffuse manner, with injury of neurons in the cortex and subcortical nuclei of the brain (Spencer, 2000).

Methyl Mercury The neuronal toxicity of organomercurial compounds, such as methyl mercury, was tragically revealed in large numbers of poisonings in Japan and Iraq. The residents of Minamata Bay in Japan, whose diet was largely composed of fish from the bay, were exposed to massive amounts of methyl mercury when mercury-laden industrial effluent was rerouted into the bay (Kurland et al., 1960; Takeuchi et al., 1962). Methyl mercury injured even more people in Iraq, with more than 400 deaths and 6000 people hospitalized. In this epidemic, as well as in several smaller ones, the effects occurred after the consumption of grain that had been

dusted with methyl mercury as an inexpensive pesticide (Bakir et al., 1973).

The clinical picture varies both with the severity of exposure and the age of the individual at the time of exposure. In adults, the most dramatic sites of injury are the neurons of the visual cortex and the small internal granular cell neurons of the cerebellar cortex, whose massive degeneration results in blindness and marked ataxia. In children, particularly those exposed to methyl mercury in utero, the neuronal loss is widespread, and in settings of greatest exposure, it produces profound mental retardation and paralysis (Reuhl and Chang, 1979). Studies on primates exposed in utero also have demonstrated abnormal social development (Burbacher et al., 1990). Recent studies in rats show that the neurons that are most sensitive to the toxic effects of methyl mercury are those that reside in the dorsal root ganglia, perhaps again reflecting the vulnerability of neurons not shielded by blood-tissue barriers (Schionning et al., 1998).

The mechanism of methyl mercury toxicity has been the subject of intense investigation. However, it remains unknown whether the ultimate toxicant is methyl mercury or the liberated mercuric ion. While Hg^{2+} is known to bind strongly to sulfhydryl groups, it is not clear that MeHg results in cell death through sulfhydryl binding. A variety of aberrations in cellular function have been noted, including impaired glycolysis, nucleic acid biosynthesis, aerobic respiration, protein synthesis (Cheung and Verity, 1985), and neurotransmitter release (Atchison and Hare, 1994). In addition, there is evidence for enhanced oxidative injury (LeBel et al., 1992) and altered calcium homeostasis (Marty and Atchison, 1997). It seems likely that MeHg toxicity is mediated by numerous reactions and that no single critical target will be identified. As these toxic events occur, the injured neurons eventually die. Exposure to methyl mercury leads to widespread neuronal injury and subsequently to a diffuse encephalopathy. However, there is relative selectivity of the toxicant for some groups of neurons over others. The distribution of neuronal injury does not appear to be related to the tissue distribution of either methyl mercury or ionic mercury but rather to particular vulnerabilities of these neurons.

Trimethyltin Organotins are used industrially as plasticizers, antifungal agents, or pesticides. Intoxication with trimethyltin has been associated with a potentially irreversible limbic-cerebellar syndrome in humans and similar behavioral changes in primates (Besser et al., 1987; Reuhl et al., 1985). Trimethyltin gains access to the nervous system where, by an undefined mechanism, it leads to diffuse neuronal injury. Many neurons of the brain begin to accumulate cytoplasmic bodies composed of Golgi-like structures, followed by cellular swelling and necrosis (Bouldin et al., 1981). The hippocampus is particularly vulnerable to this process. Following acute intoxication, the cells of the fascia dentata degenerate; with chronic intoxication, the cells of the corpus ammonis are lost. Ganglion cells and hair cells of the cochlea are similarly sensitive (Liu and Fechter, 1996). Several hypotheses seek the mechanism of trimethyltin neurotoxicity, including energy deprivation and excitotoxic damage. The role of stannin, a protein present in trimethyltin-sensitive neurons (Toggas et al., 1992), remains to be established, though the gene has been sequenced and is highly conserved between species (Dejneka et al., 1998).

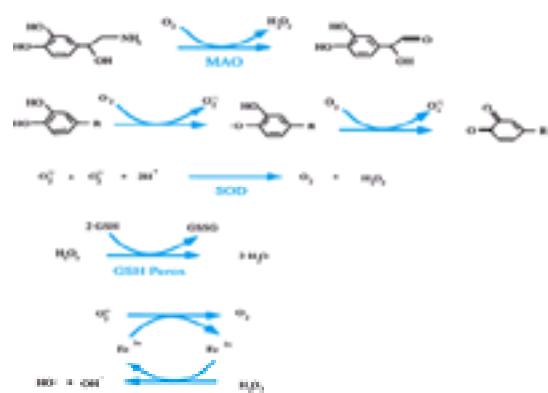
Dopamine, 6-Hydroxydopamine, and Catecholamine Toxicity The progressive loss of catecholaminergic neurons that occurs with age has been postulated to derive from the toxicity of the oxidation products of catecholamines, especially dopamine, as well as from the products of the partial reduction of oxygen. The oxidation of catecholamines by monoamine oxidase (MAO) yields H_2O_2, a known cytotoxic metabolite. The metal ion–catalyzed autoxidation of catecholamines, especially dopamine, results in the production of catecholamine-derived quinones as well as superoxide anion (O_2^-), H_2O_2 from O_2^- dismutation, and the hydroxyl radical ($\cdot$OH) from the Fenton reaction (Fig. 16-7) (Cohen and Heikkila, 1977; Graham et al., 1978). Cellular glutathione affords protection from the flux of quinones, glutathione peroxidase from H_2O_2, and superoxide dismutase from O_2^-. Among the naturally occurring catecholamines, dopamine is the most cytotoxic, because of both its greater ease of autoxidation and the greater reactivity of its orthoquinone oxidation product (Graham, 1978). There is evidence that the mercapturate of dopamine may play a major role in dopaminergic neurodegeneration (Zhang et al., 2000b).


Figure 16-7. Catecholamine oxidation and activated oxygen species.

Both the enzyme-catalyzed oxidation of catecholamines, here illustrating the action of monoamine oxidase (MAO) on norepinephrine, and the nonenzymatic oxidation of catecholamines generate activated oxygen species, including hydrogen peroxide and superoxide. There are intracellular enzymes that handle the flux of superoxide (superoxide dismutase, SOD) and hydrogen peroxide (glutathione peroxidase, GSH Perox). The hydroxyl radical (OH$\cdot$) is a highly reactive molecule that may react with lipids, proteins, and nucleic acids. Although originally thought to arise through the direct reaction of peroxide (H_2O_2) and superoxide (O_2^{-}), it appears that the only likely source of hydroxyl radical is through the metal-catalyzed Fenton reaction (with cycling of Fe^{3+} and Fe^{2+}). In addition, the autoxidation of catecholamines generates the semiquinone and the catecholamine-derived quinone, which is a strong electrophile and reacts with available sulfhydryls.

An analog of dopamine, 6-hydroxydopamine, is extremely potent in leading to a chemical sympathectomy. This compound fails to cross the blood-brain barrier, so its site of action is limited to the periphery after systemic administration. In addition, it does not cross into peripheral nerves and gains access to nerves only at their terminals. 6-Hydroxydopamine is actively transported into nerve terminals, employing the uptake mechanism utilized by the structurally similar catecholamines in sympathetic terminals. The uptake of 6-hydroxydopamine results in an injury to sympathetic neurons due to oxidation of this catecholamine analog similar to what occurs with dopamine (Fig. 16-7) (Graham, 1978). The result is selective destruction of sympathetic innervation (Malmfors, 1971). The sympathetic fibers degenerate, resulting in an uncompensated parasympathetic tone, a slowing of the heart rate, and hypermotility of the gastrointestinal system. It is noteworthy that neurobiologists employ 6-hydroxydopamine to destroy specific groups of catecholaminergic neurons. For example, stereotaxic injection of 6-hydroxydopamine into the caudate nucleus, which is rich in dopaminergic synapses, leads to neurite degeneration; if it is injected into the substantia nigra, the cell bodies of the dopamine neurons are destroyed (Marshall et al., 1983). The mechanism of toxicity of 6-hydroxydopamine appears to derive from its autoxidation and production of reactive oxygen species (Storch et al., 2000). Support for this mechanism is provided in the observation that overexpression of either Cu,Zn-superoxide dismutase or glutathione peroxidase in transgenic mice provides protection from the toxicity of 6-hydroxydopamine (Bensadoun et al., 1998; Asanuma et al., 1998).

MPTP Because of a chemist's error, people who injected themselves with a meperidine derivative, or synthetic heroin, also received a contaminant, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). Over hours to days, dozens of these patients developed the signs and symptoms of irreversible Parkinson's disease (Langston and Irwin, 1986), some becoming almost immobile with rigidity. Autopsy studies have demonstrated marked degeneration of dopaminergic neurons in the substantia nigra, with degeneration continuing many years after exposure (Langston et al., 1999).

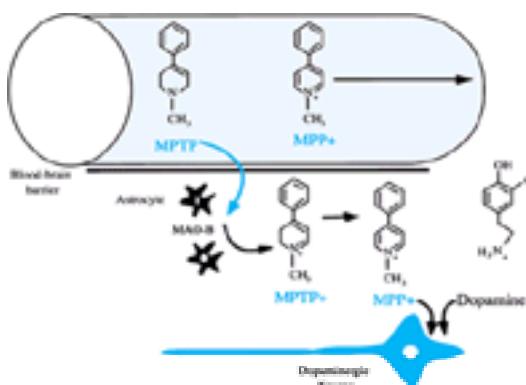
It is surprising not only that a compound like MPTP is neurotoxic but also that MPTP is a substrate for the B isozyme of monoamine oxidase (MAO-B). It appears that MPTP, an uncharged species at physiologic pH, easily crosses the blood-brain barrier and diffuses into cells, including astrocytes. The MAO-B of astrocytes catalyzes the two-electron oxidation to yield $MPDP^+$, the corresponding dihydropyridinium ion. A further two-electron oxidation yields the pyridinium ion, MPP^+ (Fig. 16-8). MPP^+ enters dopaminergic neurons of the substantia nigra via the dopamine uptake system, resulting in injury or death of the neuron. Noradrenergic neurons of the locus ceruleus are also vulnerable to repeated exposures of MPTP (Langston and Irwin, 1986), although they are less affected by single exposures than the dopaminergic neurons. Once inside neurons, MPP^+ acts as a general mitochondrial toxin, blocking respiration at complex I (DiMonte and Langston, 2000). MPP^+ may also lead to the production of activated oxygen species, and MPP^+results in the release of dopamine from vesicles to the higher pH environment of the cytosol where it undergoes autoxidation (Lotharius and O'Malley, 2000). Mice deficient in either Cu,Zn-superoxide dismutase or glutathione peroxidase show increased vulnerability to MPTP neurotoxicity (Zhang et al., 2000a), while overexpression of manganese superoxide dismutase attenuates the toxicity (Klivenyi et al., 1998). Metallothionein-I and -II, by contrast, do not play a role in protecting against MPTP (Rojas and Klaassen, 1999). It should be noted that the general toxicity of MPP^+ itself is great when it is administered to animals, although systemic exposure to MPP^+ does not result in neurotoxicity because it does not cross the blood-brain barrier.


Figure 16-8. Diagram of MPTP toxicity.

MPP+, either formed elsewhere in the body following exposure to MPTP or injected directly into the blood, is unable to cross the blood-brain barrier. In contrast, MPTP gains access and is oxidized in situ to MPDP+ and MPP+. The same transport system that carries dopamine into the dopaminergic neurons also transports the cytotoxic MPP+.

Although not identical, MPTP neurotoxicity and Parkinson's disease are strikingly similar. The symptomatology of each reflects a disruption of the nigrostriatal pathway: masked facies, difficulties in initiating and terminating movements, resting "pill-rolling" tremors, rigidity, and bradykinesias are all features of both conditions. Pathologically, there is an unusually selective degeneration of neurons in the substantia nigra and depletion of striatal dopamine in both diseases (Di Monte and Langston, 2000). However, PET studies employing [$^{(18)}$F]-fluorodopa show that while patients with idiopathic Parkinson's disease demonstrate greater loss of dopaminergic function in the putamen than the caudate nucleus, the loss from these two nuclei was the same in patients who had taken MPTP (Snow et al., 2000).

Environmental Factors Relevant to Neurodegenerative Diseases It has been observed that individuals exposed to insufficient MPTP to result in immediate parkinsonism have developed early signs of the disease years later (Calne et al., 1985). This observation presents the possibility that the onset of a neurotoxic problem may follow toxic exposure by many years. It does not seem likely that an early sublethal injury to dopaminergic neurons later becomes lethal. Rather, smaller exposures to MPTP may cause a decrement in the population of neurons within the substantia nigra. Such a loss would most likely be silent, because the symptoms of Parkinson's disease do not develop until approximately 80 percent of the substantia nigra neurons are lost. These individuals with a diminished number of neurons may be more vulnerable to further loss of dopaminergic neurons. The neurologic picture of Parkinson's disease develops at an earlier age than in unexposed individuals, as a further loss of catecholaminergic neurons occurs during the process of aging.

The relationship between MPTP intoxication and parkinsonism has stimulated investigations into the role that environmental and occupational exposures may play in the pathogenesis of Parkinson's disease. While several families with early-onset Parkinson's disease demonstrate autosomal dominant inheritance, with identification of candidate genes (Polymeropoulos et al., 1997; Agundez et al., 1995; Kurth et al., 1993), twin studies indicate that environmental exposures play a more significant role than genetics in the vast majority of Parkinson's disease patients, particularly those with late-onset disease (Tanner et al., 1999; Kuopio et al., 1999). Epidemiologic studies implicate exposure to herbicides, pesticides, and metals as risk factors for Parkinson's disease (Gorell et al., 1998, 1999; Liou et al., 1997). Several studies suggest that dithiocarbamates also play an important role (Miller, 1982; Ferraz et al., 1988; Bachurin et al., 1996).

Some studies suggest that cigarette smoking may have a protective effect against both Alzheimer's disease and Parkinson's disease, but alternative explanations have been offered (Riggs, 1992). An epidemic of dialysis-related dementia with some pathologic resemblance to Alzheimer's disease appears to have been related to aluminum in the dialysate, and its removal has prevented further instances of dialysis dementia. However, there is no substantial evidence to date that aluminum is in any way related to sporadic Alzheimer's disease in the general population (Letzel et al., 2000).

Axonopathies

The neurotoxic disorders termed *axonopathies* are those in which the primary site of toxicity is the axon itself. The axon degenerates, and with it the myelin surrounding that axon; however, the neuron cell body remains intact (Fig. 16-4). John Cavanagh coined the term *dying-back neuropathy* as a synonym for *axonopathy* (Cavanagh, 1964). The concept of "dying back" postulated that the focus of toxicity was the neuronal cell body itself and that the distal axon degenerated progressively from the synapse, back toward the cell body with increasing injury. It now appears that, in the best-studied axonopathies, a different pathogenetic sequence occurs; the toxicant results in a "chemical transection" of the axon at some point along its length, and the axon distal to the transection, biologically separated from its cell body, degenerates.

Because longer axons have more targets for toxic damage than shorter axons, one would predict that longer axons would be more affected in toxic axonopathies. Indeed, such is the case. The involvement of long axons of the CNS, such as ascending sensory axons in the posterior columns or descending motor axons, along with long sensory and motor axons of the PNS, prompted Spencer and Schaumburg (1976) to suggest that the toxic axonopathies in which the distal axon was most vulnerable be called *central peripheral distal axonopathies,* which, though cumbersome, accurately depicts the pathologic sequence.

A critical difference exists in the significance of axonal degeneration in the CNS compared with that in the PNS: peripheral axons can regenerate whereas central axons cannot. In the PNS, glial cells and macrophages create an environment supportive of axonal regeneration, and Schwann cells transplanted to the CNS maintain this ability. In the CNS, release of inhibitory factors from damaged myelin and astrocyte scarring actually interfere with regeneration (Qui, 2000). Interestingly, when this glial interference is removed through transplantation of CNS neurons to the PNS, the neurons are capable of extending neurites. But there appears to be more than just glial interference to account for the lack of CNS regeneration. The observation that embryonic neurons can overcome glial interference when placed into the adult NS is consistent with the development of an intrinsic sensitivity to inhibitory factors during maturation. Therefore, the inability of the CNS to regenerate appears to be due to both unfavorable environmental glial factors and properties of the mature neuron. The clinical relevance of the disparity between the CNS and PNS is that partial recovery—or, in mild cases, complete recovery—can occur after axonal degeneration in the PNS, whereas the same event is irreversible in the CNS.

Axonopathies can be considered to result from a chemical transection of the axon. The number of axonal toxicants is large and increasing in number (Table 16-2); however, they may be viewed as a group, all of which result in the pathologic loss of distal axons with the survival of the cell body. Because the axonopathies pathologically resemble the actual physical transection of the axon, axonal transport appears to be a likely target in many of the toxic axonopathies. Furthermore, as these axons degenerate, the result is most often the clinical condition of peripheral neuropathy, in which sensations and motor strength are first impaired in the most distal extent of the axonal processes, the feet and hands. With time and continued injury, the deficit progresses to involve more proximal areas of the body and the long axons of the spinal cord. The potential for regeneration is great when the insult is limited to peripheral nerves and may be complete in axonopathies in which the initiating event can be determined and removed.

Table 16-2 Compounds Associated with Axonal Injury (Axonopathies)

Gamma-Diketones Since the late 1960s and early 1970s, it has been appreciated that humans develop a progressive sensorimotor distal axonopathy when exposed to high concentrations of a simple alkane, *n*-hexane, day after day in work settings (Yamamura, 1969) or after repeated intentional inhalation of hexane-containing glues. This axonopathy can be reproduced in its entirety in rats and larger species after weeks to months of exposure to *n*-hexane or its oxidative metabolites (Krasavage et al., 1980).

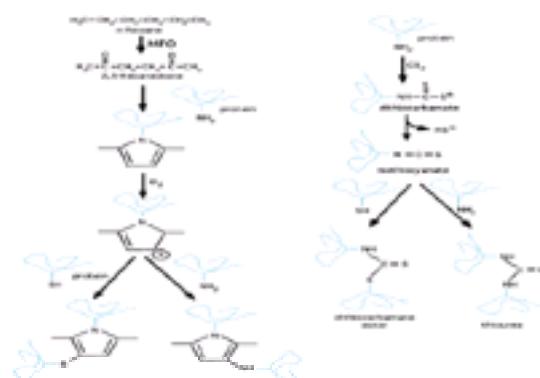
The subsequent observation that methyl *n*-butyl ketone (2-hexanone) resulted in a neuropathy identical to that caused by *n*-hexane prompted elucidation of the metabolism of these two 6-carbon compounds. The w-1 oxidation of the carbon chain (Fig. 16-9) results ultimately in the g-diketone, 2,5-hexanedione (HD). That HD is the ultimate toxic metabolite of both *r*-hexane and methyl *n*-butyl ketone is shown by the fact that other g-diketones or g-diketone precursors are similarly neurotoxic, while a- and b-diketones are not (Krasavage et al., 1980).


Figure 16-9. Molecular mechanisms of protein cross-linking in the neurofilamentous neuropathies.

Both 2,5-hexanedione, produced from hexane via w-1 oxidation function of mixed function oxidase (MFO), and CS_2 are capable of cross-linking proteins. Pyrrole formation from 2,5-hexanedione is followed by oxidation and reaction with adjacent protein nucleophiles. Dithiocarbamate formation from CS_2 is followed by formation of the protein-bound isothiocyanate and subsequent reaction with adjacent protein nucleophiles.

The elucidation of the pathogenetic mechanism of g-diketone neuropathy has come from an understanding of the biology of the axon and the chemistry of g-diketone reactivity. The g-diketones react with amino groups in all tissues to form pyrroles (Amarnath et al., 1991a). That pyrrole formation is an actual step in the pathogenesis of this axonopathy has been established by two observations. First, 3,3-dimethyl-2,5-hexanedione, which cannot form a pyrrole, is not neurotoxic (Sayre et al., 1986). Second, the d,l-diastereomer of 3,4-dimethyl-2,5-hexanedione (DMHD) both forms pyrroles faster than meso-DMHD and is more neurotoxic than meso-DMHD (Genter et al., 1987).

While all proteins are derivatized by g-diketones, the cytoskeleton of the axon, and especially the neurofilament, are very stable proteins, making it the toxicologically significant target in g-diketone intoxication. The cellular changes are identical in rats and humans: the development of neurofilament aggregates in the distal, subterminal axon, which, as they grow larger, form massive swellings of the axon, often just proximal to nodes of Ranvier. The neurofilament-filled axonal swellings result in marked distortions of nodal anatomy, including the retraction of paranodal myelin. Following labeling of neurofilament proteins with radioactive precursors, the neurofilament transport is impaired in the g-diketone model (Griffin et al., 1984; Pyle et al., 1994). With continued intoxication, swellings are seen more proximally and there is degeneration of the distal axon along with its myelin. Long axons in the CNS also develop neurofilament-filled swellings distally, but axonal degeneration is seen much less often. The attribute of the neurofilament that seemingly determines it as the toxicologically relevant target is its slow rate of transport down the axon (Nixon and Sihag, 1991), predisposing it to progressive derivatization and cross-linking.

Hexane neuropathy is one of the best understood of the toxic neuropathies, and much of this understanding has stemmed from controversy over whether pyrrole formation alone is the injury (an arylation reaction) or whether subsequent oxidation of pyrroles leading to covalent protein cross-linking is a necessary step (Amarnath et al., 1994). The question was apparently resolved in experiments with a novel g-diketone, 3-acetyl-2,5-hexanedione (AcHD) (St. Clair et al., 1988). AcHD results in very rapid pyrrole formation both in vitro and in vivo. However, the electron-withdrawing acetyl group renders the resulting pyrrole essentially inert, so that it does not undergo oxidation. Despite massive pyrrole derivatization, AcHD results in neither clinical nor morphologic evidence of neurotoxicity. Thus, pyrrole derivatization is not sufficient to produce the neurofilamentous swellings; pyrrole oxidation, followed by nucleophilic attack and neurofilament cross-linking, seems to be necessary for neurotoxicity. The extent to which the accumulation is directly responsible for impaired fast axonal transport and axonal degeneration is unclear. Recent observations from transgenic animals lacking axonal neurofilaments suggest that HD impairs fast axonal transport even in the absence of neurofilaments (Stone et al., 1999).

The pathologic processes of neurofilament accumulation and degeneration of the axon are followed by the emergence of a clinical peripheral neuropathy. Experimental animals become progressively weak, beginning in the hind limbs. With continued exposure, the axonopathy may progress, leading to successive weakness in more proximal muscle groups. This is precisely the sequence of events in humans as well, and the initial stocking-and-glove distribution of sensory loss progresses to involve more proximal segments of sensory and motor axons.

Carbon Disulfide The most significant exposures of humans to CS_2 have occurred in the vulcan rubber and viscose rayon industries. Manic psychoses were observed in the former setting and were correlated with very high levels of exposure (Seppaleinen and Haltia, 1980). In recent decades, interest in the human health effects has been focused on the NS and the cardiovascular system, where injury has been documented in workers exposed to much higher levels than those that are allowed today.

What is clearly established is the capacity of CS_2 to cause a distal axonopathy that is identical pathologically to that caused by hexane. There is growing evidence that covalent cross-linking of neurofilaments also underlies CS_2 neuropathy through a series of reactions that parallel the sequence of events in hexane neuropathy. While hexane requires metabolism to 2,5-hexanedione, CS_2 is itself the ultimate toxicant, reacting with protein amino groups to form dithiocarbamate adducts (Lam and DiStefano, 1986). The dithiocarbamate adducts of lysyl amino groups undergo decomposition to isothiocyanate adducts, electrophiles that then react with protein nucleophiles to yield covalent cross-linking (Fig. 16-9). The reaction of the isothiocyanate adducts with cysteinyl sulfhydryls to form *N*,*S*-dialkyldithiocarbamate ester cross-links is reversible, while the reaction with protein amino functions forms thiourea cross-links irreversibly. Over time, the thiourea cross-links predominate and are most likely the most biologically significant (Amarnath et al., 1991b; Valentine et al., 1992, 1995; Graham et al., 1995).

As with hexane neuropathy, it has been postulated that the stability and long transport distance of the neurofilament determine that this protein is the toxicologically relevant target in chronic CS_2 intoxication. Nonetheless, proteins throughout the organism are derivatized and cross-linked as well. Cross-linking has been identified in erythrocyte-associated proteins including spectrin and globin as well as in the putative neurotoxic target neurofilament subunits (Valentine et al., 1993, 1997). Analysis of cross-linking in erythrocyte proteins has verified that cross-linking occurs through thiourea bridges that accumulate with continuing exposure (Erve et al., 1998a,b). Neurofilament cross-linking involves all three subunits and also demonstrates a cumulative dose response and temporal relationship consistent with a contributing event in the development of the axonal neurofilamentous swellings. The correlation of protein cross-linking in erythrocyte proteins and axonal proteins together with the ability to detect covalent modifications on peripheral proteins at subneurotoxic levels and at preneurotoxic time points suggests that modifications on peripheral proteins can be used as biomarkers of effect for CS_2 exposure. These biomarkers together with morphologic changes have been used to establish CS_2 as the ultimate neurotoxic species in the peripheral neuropathy produced by oral administration of *N*,*N*-diethyldithiocarbamate (Johnson, 1998).

The clinical effects of exposure to CS_2 in the chronic setting are very similar to those of hexane exposure, with the development of sensory and motor symptoms occurring initially in a stocking-and-glove distribution. In addition to this chronic axonopathy, CS_2 can also lead to aberrations in mood and signs of diffuse encephalopathic disease. Some of these are transient at first and subsequently become more long-lasting, a feature that is common in vascular insufficiency in the

nervous system. This fact, in combination with the knowledge that CS_2 may accelerate the process of atherosclerosis, suggests that some of the effects of CS_2 on the CNS are vascular in origin.

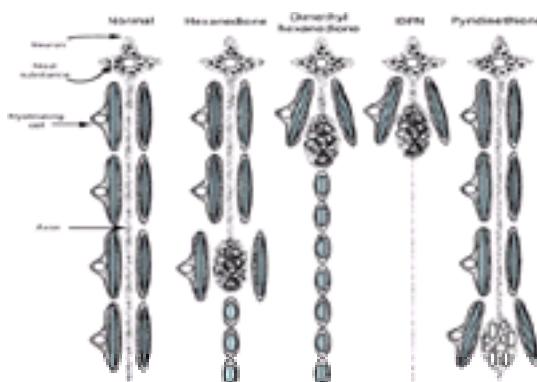
IDPN b,b'-Iminodipropionitrile (IDPN) is a bifunctional nitrile that causes a bizarre "waltzing syndrome," which appears to result from degeneration of the vestibular sensory hair cells (Llorens et al., 1993). In addition, administration of IDPN is followed by massive neurofilament-filled swellings (Griffin and Price, 1980) of the proximal, instead of the distal, axon (Fig. 16-10). The possibility that the nitrile groups undergo bioactivation to generate a bifunctional cross-linking reagent is suggested by the effects of deuterium substitution on the potency and metabolism of IDPN (Denlinger et al., 1992, 1994). The similarity of the neurofilament-filled swellings to those seen with the g-diketones and carbon disulfide is a striking feature of this model neurotoxicant, underscoring this possibility. Axonal swellings do not occur in neurofilament-deficient quails, supporting the notion that the disorder is caused by a selective effect of IDPN on neurofilaments (Mitsuishi et al., 1993).


Figure 16-10. Diagram of axonopathies.

While 2,5-hexanedione results in the accumulation of neurofilaments in the distal regions of the axon, 3,4-dimethyl-2,5-hexanedione results in identical accumulation within the proximal segments. These proximal neurofilamentous swellings are quite similar to those that occur in the toxicity of b,b'-iminodipropionitrile (IDPN), although the distal axon does not degenerate in IDPN axonopathy but becomes atrophic. Pyridinethione results in axonal swellings that are distended with tubulovesicular material, followed by distal axonal degeneration.

Understanding of the similarities between the g-diketones and IDPN was extended when the potency of the g-diketones was increased through molecular modeling. DMHD (3,4-dimethyl-2,5-hexanedione) is an analog of 2,5-hexanedione that accelerates the rates of both pyrrole formation and oxidation of the pyrrole. DMHD is 20 to 30 times more potent as a neurotoxicant and, in addition, the neurofilament-filled swellings occur in the proximal axon (Anthony et al., 1983a), as in IDPN intoxication. In these models of proximal neurofilamentous axonopathies, there is a block of neurofilament transport down the axon; thus, in this situation, the accumulation of neurofilaments results from blockage of the slow component A of axonal transport (Griffin et al., 1978, 1984). Decreasing the rate of intoxication with DMHD changes the location of the swellings to more distal locations, suggesting that the neurofilamentous axonopathies have a common mechanism and that the position of the neurofilamentous swellings along the axon reflects the rate at which this process occurs (Anthony et al., 1983b).

An important difference is seen between the two proximal neurofilamentous axonopathies caused by IDPN and DMHD, however. After DMHD intoxication, animals become progressively paralyzed in all four limbs, corresponding with marked degeneration of the axon distal to the swellings. By contrast, the axon distal to IDPN-induced swellings undergoes atrophy, not degeneration, and the animal does not experience the same muscle weakness or paralysis. This observation suggests not only that axonal degeneration is required before muscle weakness develops but also that the presence of neurofilamentous aggregates in the proximal axon is not incompatible with the survival of the distal axon.

Acrylamide Acrylamide is a vinyl monomer used in the manufacture of paper products, as a flocculant in water treatment, as a soil-stabilizing and waterproofing agent, and for making polyacrylamide gels in the research laboratory. While cautious handling of acrylamide in the laboratory should be encouraged, human poisonings have been largely limited to factory and construction workers exposed to high doses (Kesson et al., 1977; Myers and Macun, 1991; Collins et al., 1989).

The neuropathy induced by acrylamide is a toxic distal axonopathy, beginning with degeneration of the nerve terminal. Continued intoxication results in degeneration of the more proximal axon, a sequence of events that recapitulates what one would expect in "dying back" process. The neuropathy appears identical whether acrylamide is administered in a single dose or in multiple smaller doses (Crofton et al., 1996). The earliest changes are seen in pacinian corpuscles, then in muscle spindles and motor nerve terminals. Within nerve terminals, early events include decreased densities of synaptic vesicles and mitochondria and accumulations of neurofilaments and tubulovesicular profiles (DeGrandechamp et al., 1990), along with evidence for terminal sprouting (DeGrandechamp and Lowndes, 1990). Multifocal accumulations of membranous bodies, mitochondria, and neurofilaments are observed in the distal axon, suggesting abnormal axonal transport. Indeed, retrograde fast transport has been shown to be impaired by acrylamide exposure (Padilla et al., 1993) and appears to occur before any morphologic changes are evident in axons or their terminals. Abnormalities in fast axonal transport have been observed in peripheral nerve axons from transgenic animals lacking neurofilaments when exposed in vitro to acrylamide (Stone et al., 1999).

Studies employing chick or rat embryo neuron cultures have demonstrated that both anterograde and retrograde fast axonal transport are inhibited by acrylamide (Harris et al., 1994). These effects are clearly not the result of ATP depletion. In addition, specific alterations of growth cone structure, including loss of filopodial elements, follow exposure to acrylamide, and these are separable from the effects of ATP depletion and sulfhydryl alkylation (Martenson et al., 1995). Because the growth cone of growing neurites in culture has many similarities to the axon terminal in vivo, it has been suggested that the growth cone alterations are a good model for the initial reactions of acrylamide with its axon terminal target(s).

Organophosphorus Esters Many toxicologists and most physicians who practice in rural areas are aware of the acute cholinergic poisoning induced by certain organophosphorus esters. These compounds, which are used as pesticides and as additives in plastics and petroleum products, inhibit acetylcholinesterase and create a cholinergic excess. However, as tens of thousands of humans could attest, tri-ortho-cresyl phosphate (TOCP) may also cause a severe central peripheral distal axonopathy without inducing cholinergic poisoning. An epidemic of massive proportion occurred during Prohibition in the United States, when a popular drink (Ginger Jake) was contaminated with TOCP. Another outbreak occurred in Morocco when olive oil was adulterated with TOCP. Human cases of paralysis have also occurred after exposure to the herbicides and cotton defoliants EPN (O-ethyl O-4-nitrophenyl phenylphosphonothionate) and leptophos [O-(4-bromo-2,5-dichlorophenyl) O-methyl phenylphosphonothionate] (Abou-Donia and Lapadula, 1990).

The hydrophobic organophosphorus compounds readily enter the NS, where they alkylate or phosphorylate macromolecules and lead to delayed-onset neurotoxicity. There are probably multiple targets for attack by organophosphorus esters, but which targets are critically related to axonal degeneration is not clear. Not all of the organophosphorus esters that inhibit acetylcholinesterase lead to a delayed neurotoxicity. While these "nontoxic" organophosphorus esters inhibit most of the esterase activity of the NS, there is another esterase activity, or *neuropathy target esterase* (NTE), that is inhibited by the neurotoxic organophosphorus esters. Furthermore, there is a good correlation between the potency of a given organophosphorus ester as an axonal toxicant and its potency as an inhibitor of NTE, both in vivo and in culture systems (Funk et al., 1994). Neither the normal function for this enzyme activity nor its relation to axonal degeneration is understood (Lotti et al., 1993). Certain neurotoxic esterase inhibitors—including phosphonates, carbamates, thiocarbamates and sulfonyl fluorides—that do not cause significant neurotoxicity can protect against organophosphate-induced delayed neurotoxicity when given before neurotoxic organophosphates. It has been proposed that these compounds protect through partial inhibition of neurotoxic esterase. In contrast, when these protective neurotoxic esterase inhibitors are administerd up to 12 days following exposure to a neurotoxic organophosphate, the delayed neurotoxicity is enhanced, such that lower initial levels of neurotoxic esterase inhibition are required to produce a delayed neuropathy (Moretto, 2000). Although the promoting agents inhibit neurotoxic esterase, this enzyme is not thought to be the target of promotion. The level of neurotoxic esterase inhibition produced by the promoter is not related to the level of promotion observed, and these promoters appear to exacerbate axonopathies from other etiologic agents as well, such as trauma and 2,5-hexanedione exposure.

The degeneration of axons does not commence immediately after acute organophosphorus ester exposure but is delayed for 7 to 10 days between the acute high-dose exposure and the clinical signs of axonopathy. The axonal lesion in the PNS appears to be readily repaired, and the peripheral nerve becomes refractory to degeneration after repeated doses. By contrast, axonal degeneration in the long tracks of the spinal cord is progressive, resulting in a clinical picture that may

resemble multiple sclerosis.

Pyridinethione Zinc pyridinethione has antibacterial and antifungal properties and is a component of shampoos that are effective in the treatment of seborrhea and dandruff. Because the compound is directly applied to the human scalp, it caused some concern when it was discovered that zinc pyridinethione is neurotoxic in rodents. Rats, rabbits, and guinea pigs all develop a distal axonopathy when zinc pyridinethione is a contaminant of their food (Sahenk and Mendell, 2000). Fortunately, however, zinc pyri-dinethione does not penetrate skin well, and it has not resulted in human injury to date.

Although the zinc ion is an important element of the therapeutic action of the compound, only the pyridinethione moiety is absorbed following ingestion, with the majority of zinc eliminated in the feces. In addition, sodium pyridinethione is also neurotoxic, establishing that it is the pyridinethione that is responsible for the neurotoxicity. Pyridinethione chelates metal ions and, once oxidized to the disulfide, may lead to the formation of mixed disulfides with proteins. However, which of these properties, if either, is the molecular mechanism of its neurotoxicity remains unknown.

Although these molecular issues remain to be resolved, pyridinethione appears to interfere with the fast axonal transport systems. While the fast anterograde system is less affected, pyridinethione impairs the turnaround of rapidly transported vesicles and slows the retrograde transport of vesicles (Sahenk and Mendell, 1980). This aberration of the fast axonal transport systems is the most likely physiologic basis of the accumulation of tubular and vesicular structures in the distal axon (Fig. 16-10). As these materials accumulate in one region of the axon, they distend the axonal diameter, resulting in axonal swellings filled with tubulovesicular profiles. As in many other distal axonopathies, the axon degenerates in its more distal regions beyond the accumulated structures. The earliest signs are diminished grip strength and electrophysiologic changes of the axon terminal, with normal conduction along the proximal axon in the early stages of exposure (Ross and Lawborn, 1990). Ultimately, the functional consequence of the axonal degeneration in this exposure is similar to that of other axonopathies—namely, a peripheral neuropathy.

Microtubule-Associated Neurotoxicity The role of microtubules in axonal transport and in the maintenance of axonal viability is still being elucidated; however, the biochemistry and toxicity of several alkaloids isolated from plants have greatly aided the understanding of these processes. The first of these historically are the vinca alkaloids and colchicine, which bind to tubulin and inhibit the association of this protein subunit to form microtubules. Vincristine, one of the vinca alkaloids, has found clinical use in the treatment of leukemia due to the antimitotic activity of its microtubule-directed action. Colchicine, in contrast, is used primarily in the treatment of gout. Both of these microtubule inhibitors also have been the cause of peripheral neuropathies in patients (Verity, 1997).

Much more recently another plant alkaloid, paclitaxel (Taxol) has been described that has a significantly different interaction with microtubules. Paclitaxel binds to tubules when they are assembled and stabilizes the polymerized form of tubules, so that they remain assembled even in the cold or in the presence of calcium, conditions under which microtubules normally dissociate into tubulin subunits (Schiff and Horwitz, 1981). Paclitaxel has also found its way into clinical usage as a treatment of certain cancers and has resulted in sensorimotor axonopathy—in patients receiving large doses of this compound (Lipton et al., 1989; Sahenk et al., 1994)—or in autonomic neuropathy (Jerian et al., 1993).

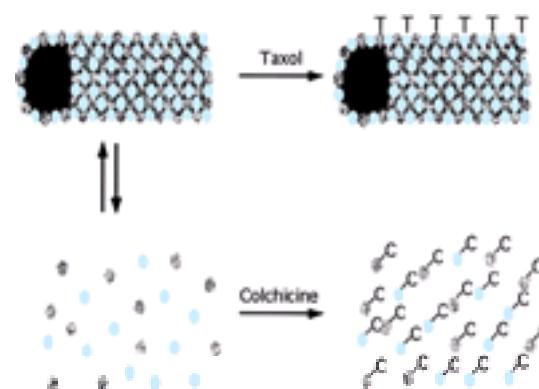
It is fascinating that both the depolymerization of tubules by colchicine and the vinca alkaloids and the stabilization of tubules by paclitaxel lead to an axonopathy. It has been known for some time that microtubules are in a state of dynamic equilibrium in vitro, with tubules existing in equilibrium with dissociated subunits. This process almost certainly occurs in vivo as well, even as tubulin migrates down the axon. Thus, the tubules are constantly associating and dissociating. It is within this dynamic equilibrium that paclitaxel and the vinca alkaloids exert their toxic effects, preventing the interchange of the two pools of tubulin (Fig. 16-11).


Figure 16-11. Neurotoxicants directed toward microtubules.

Colchicine leads to the depolymerization of microtubules by binding to the tubulin monomers and preventing their association into tubules. Paclitaxel stabilizes the microtubules, preventing their dissociation into subunits under conditions in which they would normally dissociate. Both compounds interfere with the normal dynamic equilibrium that exists between tubulin monomers and microtubules, and both are neurotoxic.

The morphology of the axon is, of course, different in the two situations. In the case of colchicine, the axon appears to undergo atrophy and there are fewer microtubules within the axons. In contrast, following exposure to paclitaxel, microtubules are present in great numbers and are aggregated to create arrays of microtubules (Roytta et al., 1984; Roytta and Raine, 1986). Both situations probably interfere with the process of fast axonal transport, although this has not yet been demonstrated definitively with paclitaxel. In both situations, the resultant clinical condition is a peripheral neuropathy.

Myelinopathies

Myelin provides electrical insulation of neuronal processes, and its absence leads to a slowing of conduction and aberrant conduction of impulses between adjacent processes, so-called ephaptic transmission. Toxicants exist that result in the separation of the myelin lamellae, termed *intramyelinic edema,* and in the selective loss of myelin, termed *demyelination* (Fig. 16-4). Intramyelinic edema may be caused by alterations in the transcript levels of myelin basic protein-mRNA (Veronesi et al., 1991) and early in its evolution is reversible. However, the initial stages may progress to demyelination, with loss of myelin from the axon. Demyelination may also result from direct toxicity to the myelinating cell. Remyelination in the CNS occurs to only a limited extent after demyelination. However, Schwann cells in the PNS are capable of remyelinating the axon after a demyelinating injury. Interestingly, remyelination after segmental demyelination in peripheral nerve involves multiple Schwann cells and results, therefore, in internodal lengths (the distances between adjacent nodes of Ranvier) that are much shorter than normal and a permanent record of the demyelinating event.

The compounds in Table 16-3 all lead to a myelinopathy. Some of these compounds have created problems in humans, and many have been used as tools to explore the process of myelination of the NS and the process of remyelination following toxic disruption of myelin. In general, the functional consequences of demyelination depend on the extent of the demyelination and whether it is localized within the CNS or the PNS or is more diffuse in its distribution. Those toxic myelinopathies in which the disruption of myelin is diffuse generate a global neurologic deficit, whereas those that are limited to the PNS produce the symptoms of peripheral neuropathy.

Table 16-3 Compounds Associated with Injury of Myelin (Myelinopathies)

Hexachlorophene Hexachlorophene, or methylene 2,2'-methylenebis(3,4,6-trichlorophenol), resulted in human neurotoxicity when newborn infants, particularly premature infants, were bathed with the compound to avoid staphylococcal skin infections (Mullick, 1973). Following skin absorption of this hydrophobic compound, hexachlorophene enters the NS and results in intramyelinic edema, splitting the intraperiod line of myelin in both the CNS and the PNS. The intramyelinic edema leads to the formation of vacuoles, creating a "spongiosis" of the brain (Purves et al., 1991). Experimental studies with erythrocyte membranes show that hexachlorophene binds tightly to cell membranes, resulting in the loss of ion gradients across the membrane (Flores and Buhler, 1974). It may be that hexachlorophene results in loss of the ability to exclude ions from between the layers of myelin and that, with ion entry, water also separates the myelin layers as "edema." Another, perhaps related effect is the uncoupling of mitochondrial oxidative phosphorylation by hexachlorophene (Cammer and Moore, 1974), because this process is dependent on a proton gradient. Intramyelinic edema is reversible in the early stages, but with increasing exposure, hexachlorophene causes segmental demyelination. Swelling of the brain causes increased intracranial pressure, which may be fatal in and of itself. With high-dose exposure, axonal degeneration is seen, along with degeneration of photoreceptors in the retina. It has been postulated that the pressure from severe intramyelinic edema may also injure the axon, leading to axonal degeneration, and endoneurial pressure measurements support this idea (Myers et al., 1982). The toxicity of hexachlorophene expresses itself functionally in diffuse terms that reflect the diffuse process of myelin injury. Humans exposed acutely to hexachlorophene may have generalized weakness, confusion, and seizures. Progression may occur, to include coma and death.

Tellurium Although human cases have not been reported, neurotoxicity of tellurium has been demonstrated in animals. Young rats exposed to tellurium in their diet develop a severe peripheral neuropathy. Within the first 2 days of beginning a diet containing tellurium, the synthesis of myelin lipids in Schwann cells displays some striking changes (Harry et al., 1989). There is a decreased synthesis of cholesterol and cerebrosides, lipids richly represented in myelin, whereas the synthesis of phosphatidylcholine, a more ubiquitous membrane lipid, is unaffected. Myelin protein mRNA steady-state levels are down-regulated (Morell et al., 1994). The synthesis of free fatty acids and cholesterol esters increases to some degree, and there is a marked elevation of squalene, a precursor of cholesterol. These biochemical findings demonstrate that there are a variety of lipid abnormalities, and the simultaneous increase in squalene and decrease in cholesterol suggest that tellurium or one of its derivatives may interfere with the normal conversion of squalene to cholesterol. Squalene epoxidase, a microsomal monooxygenase that utilizes NAPDH cytochrome P450 reductase, has been strongly implicated as the target of tellurium. It is specifically inhibited by tellurium (Wagner et al., 1995), and its inhibition also occurs with certain organotellurium compounds, with a correlation between the potency of enzyme inhibition and demyelination in vivo (Goodrum, 1998).

At the same time as these biochemical changes are occurring, lipids accumulate in Schwann cells within intracytoplasmic vacuoles; shortly afterwards, these Schwann cells lose their ability to maintain myelin. Axons and the myelin of the CNS are impervious to the effects of tellurium. However, individual Schwann cells in the PNS disassemble their concentric layers of myelin membranes, depriving the adjacent intact axon of its electrically insulated status. Not all Schwann cells are equally affected by the process; rather, those Schwann cells that encompass the greatest distances appear to be the most affected. These cells are associated with the largest-diameter axons, encompass the longest intervals of myelination, and provide the thickest layers of myelin. Thus, it appears that the most vulnerable cells are those with the largest volume of myelin to support (Bouldin et al., 1988).

As the process of remyelination begins, several cells cooperate to reproduce the myelin layers that were previously formed by a single Schwann cell. Perhaps this diminished demand placed upon an individual cell is the reason that remyelination occurs even in the presence of continued exposure to tellurium (Bouldin et al., 1988). The expression of the neurologic impairment is also short in duration, reflecting the transient cellular and biochemical events. The animals initially develop severe weakness in the hind limbs but then recover their strength after 2 weeks on the tellurium-laden diet.

Lead Lead exposure in animals results in a peripheral neuropathy with prominent segmental demyelination, a process that bears a strong resemblance to tellurium toxicity (Dyck et al., 1977). However, the neurotoxicity of lead is much more variable in humans than in rats, and there are also a variety of manifestations of lead toxicity in other organ systems.

The neurotoxicity of lead has been appreciated for centuries. In current times, adults are exposed to lead in occupational settings through lead smelting processes and soldering and in domestic settings through lead pipes or through the consumption of "moonshine" contaminated with lead. In addition, some areas contain higher levels of environmental lead, resulting in higher blood levels in the inhabitants. Children, especially those below 5 years of age, have higher blood levels of lead than adults in the same environment, due to the mouthing of objects and the consumption of substances other than food. The most common acute exposure in children, however, has been through the consumption of paint chips containing lead pigments (Perlstein and Attala, 1966), a finding that has led to public efforts to prevent the use of lead paints in homes with children.

In young children, acute massive exposures to lead result in severe cerebral edema, perhaps from damage to endothelial cells. Children seem to be more susceptible to this lead encephalopathy than adults (Johnston and Goldstein, 1998); however, adults may also develop an acute encephalopathy in the setting of massive lead exposure.

Chronic lead intoxication in adults results in peripheral neuropathy, often accompanied by manifestations outside the NS, such as gastritis, colicky abdominal pain, anemia, and the prominent deposition of lead in particular anatomic sites, creating lead lines in the gums and in the epiphyses of long bones in children. The effects of lead in the peripheral nerve of humans (lead neuropathy) is not entirely understood. Electrophysiologic studies have demonstrated a slowing of nerve conduction. While this observation is consistent with the segmental demyelination that develops in experimental animals, pathologic studies in humans with lead neuropathy typically have demonstrated an axonopathy. Another finding in humans is the predominant involvement of motor axons, creating one of the few clinical situations in which patients present with predominantly motor symptoms. The basis for the effect on the brain (lead encephalopathy) is also unclear, although an effect on the membrane structure of myelin and myelin membrane fluidity has been shown (Dabrowski-Bouta et al., 1999).

Although the manifestations of acute and chronic exposures to lead have been long established, it is only in recent years that the concept has emerged that extremely low levels of exposure to lead in "asymptomatic" children may have an effect on their intelligence. Initial reports noted a relationship between mild elevations of blood lead in children and school performance; more recently, correlations between elevated lead levels in decidual teeth and performance on tests of verbal abilities, attention, and behavior (nonadaptive) have been demonstrated (Needleman and Gatsonis, 1990; Needleman, 1994). Although there is a clear association between lead level and intellectual performance, there has been some discussion as to whether lead is causal. Children with higher blood levels tend to share certain other environmental factors, such as socioeconomic status and parental educational level. However, in spite of these complex social factors, it appears that lead exposure has an adverse effect on the intellectual abilities of children (Needleman, 1994), an association between lead exposure and brain dysfunction that has received experimental support in animal models (Gilbert and Rice, 1987) and has prompted screening for lead in children (Benjamin and Platt, 1999).

Neurotransmission-Associated Neurotoxicity

Many neurotoxicants destroy cellular structures within the NS, providing anatomic footprints of their toxicity. In some instances, however, dysfunction of the NS may occur without evidence of altered cellular structures; rather, the neurotoxicity expresses itself in terms of altered behavior or impaired performance on neurologic tests. In fact, many of the neurotoxic agents that lead to anatomic evidence of cellular injury were first demonstrated to be neurotoxic through the detection of neurologic dysfunction.

Molecular mechanisms are not understood for some of these agents; however, there is a group of such compounds in which the chemical basis of their action is clear. These are the toxicants that impair the process of neurotransmission. A wide variety of naturally occurring toxins as well as synthetic drugs interact with specific mechanisms of intercellular communication. At times, interruption of neurotransmission is beneficial to an individual, and the process may be viewed as neuropharmacology. However, excessive or inappropriate exposure to compounds that alter neurotransmission may be viewed as one of the patterns of neurotoxicology.

This group of compounds may interrupt the transmission of impulses, block or accentuate transsynaptic communication, block reuptake of neurotransmitters, or interfere with second-messenger systems. In general, the acute effects of these compounds are directly related to the immediate concentration of the compound at the active site, which bears a direct relationship to the level of the drug in the blood. The structural similarity of many compounds with similar actions has led to the

recognition of specific categories of drugs and toxins. For example, some mimic the process of neurotransmission of the sympathetic nervous system and are termed the sympathomimetic compounds. As the targets of these drugs are located throughout the body, the responses are not localized; however, the responses are stereotyped in that each member of a class tends to have similar biological effects. In terms of toxicity, most of the side effects of these drugs may be viewed as short-term interactions that are easily reversible with time or that may be counteracted by the use of appropriate antagonists. However, some of the toxicity associated with long-term use is irreversible. For example, phenothiazines, which have been used to treat chronic schizophrenia for long periods of time, may lead to the condition of tardive dyskinesia, in which the patient is left with a permanent disability of prominent facial grimaces (DeVeaugh-Geiss, 1982). Both reversible acute high-dose toxicity and sustained effects following chronic exposure are common features of the agents that interact with the process of neurotransmission. Some compounds which have neurotransmitter-associated toxicity are listed in Table 16-4.

Table 16-4 Compounds Associated with Neurotransmitter-Associated Toxicity

Nicotine Widely available in tobacco products and in certain pesticides, nicotine has diverse pharmacologic actions and may be the source of considerable toxicity. These toxic effects range from acute poisoning to more chronic effects. Nicotine exerts its effects by binding to a subset of cholinergic receptors, the nicotinic receptors. These receptors are located in ganglia, at the neuromuscular junction, and also within the CNS, where the psychoactive and addictive properties most likely reside. Smoking and "pharmacologic" doses of nicotine accelerate heart rate, elevate blood pressure, and constrict blood vessels within the skin. Because the majority of these effects may be prevented by the administration of a- and b-adrenergic blockade, these consequences may be viewed as the result of stimulation of the ganglionic sympathetic nervous system (Benowitz, 1986). At the same time, nicotine leads to a sensation of "relaxation" and is associated with alterations of electroencephalographic (EEG) recordings in humans. These effects are probably related to the binding of nicotine with nicotinic receptors within the CNS, and the EEG changes may be blocked with mecamylamine, an antagonist.

Acute overdose of nicotine has occurred in children who accidentally ingest tobacco products, in tobacco workers exposed to wet tobacco leaves (Gehlbach et al., 1974), and in workers exposed to nicotine-containing pesticides. In each of these settings, the rapid rise in circulating levels of nicotine leads to excessive stimulation of nicotinic receptors, a process that is followed rapidly by ganglionic paralysis. Initial nausea, rapid heart rate, and perspiration are followed shortly by marked slowing of heart rate with a fall in blood pressure. Somnolence and confusion may occur, followed by coma; if death results, it is often the result of paralysis of the muscles of respiration.

Such acute poisoning with nicotine fortunately is uncommon. Exposure to lower levels for longer duration, in contrast, is very common, and the health effects of this exposure are of considerable epidemiologic concern. In humans, however, it has been impossible so far to separate the effects of nicotine from those of other components of cigarette smoke. The complications of smoking include cardiovascular disease, cancers (especially malignancies of the lung and upper airway), chronic pulmonary disease, and attention deficit disorders in children of women who smoke during pregnancy. Nicotine may be a factor in some of these problems. For example, an increased propensity for platelets to aggregate is seen in smokers, and this platelet abnormality correlates with the level of nicotine. Nicotine also places an increased burden on the heart through its acceleration of heart rate and blood pressure, suggesting that nicotine may play a role in the onset of myocardial ischemia (Benowitz, 1986). In addition, nicotine also inhibits apoptosis and may play a direct role in tumor promotion and tobacco-related cancers (Wright et al., 1993).

It seems more clear that chronic exposure to nicotine has effects on the developing fetus. Along with decreased birth weights, attention deficit disorders are more common in children whose mothers smoke cigarettes during pregnancy, and nicotine has been shown to lead to analogous neurobehavioral abnormalities in animals exposed prenatally to nicotine (Lichensteiger et al., 1988). Nicotinic receptors are expressed early in the development of the NS, beginning in the developing brainstem and later expressed in the diencephalon. The role of these nicotinic receptors during development is unclear; however, it appears that prenatal exposure to nicotine alters the development of nicotinic receptors in the CNS (van de Kamp and Collins, 1994)—changes that may be related to subsequent attention and cognitive disorders in animals and children.

Cocaine and Amphetamines Cocaine differs from nicotine in the eyes of the law, a feature of the compound that affects the willingness of users to discuss their patterns of use. Nonetheless, it has been possible to obtain estimates of the number of users. In 1972, approximately 9 million college-age adults were using the drug; in 1982, it was approximately 33 million (Fishburne et al., 1983). In urban settings, from 10 to 45 percent of pregnant women take cocaine (Volpe, 1992), and cocaine metabolites can be detected in as many as 6 percent of babies born at suburban hospitals (Schutzman et al., 1991).

The euphoric and addictive properties of cocaine derive from alterations in catecholaminergic neurotransmission, especially enhanced dopaminergic neurotransmission, by blocking the dopamine reuptake transporter (DAT) (Giros et al., 1996). Acute toxicity due to excessive intake, or overdose, may result in unanticipated deaths. While the tragic accounts of celebrities' overdoses may attract media attention, it is the chronic "recreational" consumption of cocaine that is of greatest epidemiologic concern.

Although cocaine increases maternal blood pressure during acute exposure in pregnant animals, the blood flow to the uterus actually diminishes. Depending on the level of the drug in the mother, the fetus may develop marked hypoxia as a result of the diminished uterine blood flow (Woods et al., 1987). In a study of women who used cocaine during pregnancy, there were more miscarriages and placental hemorrhages (abruptions) than in drug-free women (Chasnoff et al., 1985). Impaired placental function may be the cause for the increase in infarctions and hemorrhages in the newborn infant who has been exposed to cocaine (Volpe, 1992). In addition, the newborn infants of cocaine users were less interactive than normal newborns and exhibited a poor response to stimuli in the environment (Chasnoff et al., 1985). Evidence for other forms of structural damage to brain in newborns exposed to cocaine is mixed (Behnke et al., 1998).

In addition to deleterious effects on fetal growth and development, cocaine abuse is associated with an increased risk of cerebrovascular disease, cerebral perfusion defects, and cerebral atrophy in adults (Filley and Kelly, 1993; Freilich and Byrne, 1992; Kaku and Lowenstein, 1990). While the mechanisms for these effects are not known, imaging studies have demonstrated increased cerebrovascular resistance in cocaine abusers (Herning et al., 1999). Chronic cocaine abuse has been associated with neurodegenerative changes in the striatum, and these changes are thought to underlie some of the neurologic and psychiatric outcomes in chronic cocaine abusers (Wilson et al., 1996b).

Like cocaine, amphetamines exert their effects in the CNS by altering catecholamine neurotransmission; however, unlike cocaine, the actions of amphetamines are not limited to plasma membrane transporters but also appear to involve disruption of vesicular storage of dopamine. Analogous to cocaine, amphetamines have been associated with an increased risk of abnormal fetal growth and development, increased risk of cerebrovascular disease, and increased risk of psychiatric and neurologic problems in chronic abusers that may be related to dopaminergic neurodegeneration (Wilson et al., 1996a).

Excitatory Amino Acids Glutamate and certain other acidic amino acids are excitatory neurotransmitters within the CNS. The discovery that these excitatory amino acids can be neurotoxic at concentrations that can be achieved in the brain has generated a great amount of interest in these "excitotoxins." In vitro systems have established that the toxicity of glutamate can be blocked by certain glutamate antagonists (Rothman and Olney, 1986), and the concept has emerged that the toxicity of excitatory amino acids may be related to such divergent conditions as hypoxia, epilepsy, and neurodegenerative diseases (Meldrum, 1987; Choi, 1988; Lipton and Rosenberg, 1994; Beal, 1992, 1995, 1998).

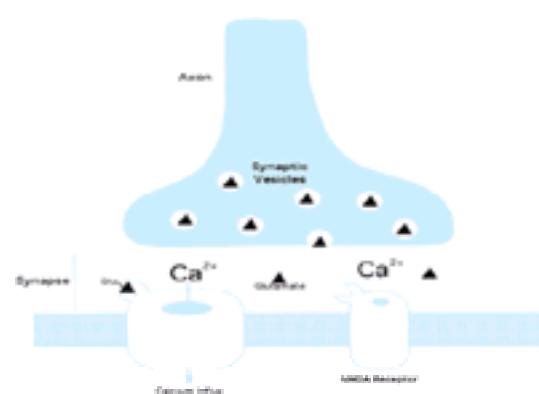
Glutamate is the main excitatory neurotransmitter of the brain and its effects are mediated by several subtypes of receptors (Fig. 16-12) called *excitatory amino acid receptors* (EAARs) (Schoepfer et al., 1994; Hollmann and Heinemann, 1994; Lipton and Rosenberg, 1994). The two major subtypes of glutamate receptors are those that are ligand-gated directly to ion channels (ionotropic) and those that are coupled with G proteins (metabotropic). Ionotropic receptors may be further subdivided by their specificity for binding kainate, quisqualate, and a-amino-3-hydroxy-5-methylis-oxazole-4-propionic acid (AMPA), and N-methyl-D-aspartate (NMDA). The entry of glutamate into the CNS is regulated at the blood-brain barrier and, following an injection of a large dose of glutamate in infant rodents, glutamate exerts its effects in the area of the brain in which the blood-brain barrier is least developed, the circumventricular organ. Within this site of limited access, glutamate injures neurons, apparently by opening glutamate-dependent ion channels, ultimately leading to neuronal swelling and neuronal cell death (Olney, 1978; Coyle, 1987). The toxicity affects the dendrites and neuronal cell bodies but seems to spare axons. The only known related human condition is the "Chinese restaurant syndrome," in which consumption of large amounts of monosodium glutamate as a seasoning may lead to a burning sensation in the face, neck and chest.


Figure 16-12. Schematic diagram of a synapse.

Synaptic vesicles are tranported to the axonal terminus, and released across the synaptic cleft to bind to the postsynaptic receptors. Glutamate, as an excitatory neurotransmitter, binds to its receptor and opens a calcium channel, leading to the excitation of the postsynaptic cell.

The cyclic glutamate analog kainate was initially isolated from a seaweed in Japan as the active component of an herbal treatment of ascariasis. Kainate is extremely potent as an excitotoxin, being a hundredfold more toxic than glutamate and is selective at a molecular level for the kainate receptor (Coyle, 1987). Like glutamate, kainate selectively injures dendrites and neurons and shows no substantial effect on glia or axons. As a result, this compound has found use in neurobiology as a tool. Injected into a region of the brain, kainate can destroy the neurons of that area without disrupting all of the fibers that pass through the same region. Neurobiologists, with the help of this neurotoxic tool, are able to study the role of neurons in a particular area independent of the axonal injuries that occur when similar lesioning experiments are performed by mechanical cutting.

Development of permanent neurologic deficits in individuals accidentally exposed to high doses of an EAAR agonist has underscored the potential importance of EAAs in disease (Perl et al., 1990; Teitelbaum et al., 1990). A total of 107 individuals in the Maritime Provinces of Canada were exposed to domoic acid, an analog of glutamate, and suffered an acute illness that most commonly presented as gastrointestinal disturbance, severe headache, and short-term memory loss. A subset of the more severely afflict-ed patients was subsequently shown to have chronic memory deficits and motor neuropathy. Neuropathologic investigation of patients who died within 4 months of intoxication showed neurodegeneration that was most prominent in the hippocampus and amygdala but also affected regions of the thalamus and cerebral cortex.

Other foci of unusual neurodegenerative diseases also have been evaluated for being caused by dietary exposure to EAARs. Perhaps the best known of these is the complex neurodegenerative disease in the indigenous population of Guam and surrounding islands that shares features of amyotrophic lateral sclerosis, Parkinson's disease, and Alzheimer's disease. Early investigations of this Guamanian neurodegenerative complex suggested that the disorder may be related to an environmental factor, perhaps consumption of seeds of *Cycas circinalis* (Kurland, 1963). Subsequently, a-amino-methylaminopropionic acid (or B- N-methylamino-L-alanine, BMAA) was isolated from the cycad and was shown to be neurotoxic in model systems. The toxicity of BMAA is similar to that of glutamate in vitro and can be blocked by certain EAAR antagonists (Nunn et al., 1987). Studies in vivo, however, have not demonstrated a relationship between BMAA and the Guamanian neurodegenerative complex (Spencer et al., 1987; Hugon et al., 1988; Seawright et al., 1990; Duncan, 1992). Therefore, it remains unresolved what role cycad consumption and environmental factors play in this cluster of atypical neurodegenerative disease.

The expanding field of the excitotoxic amino acids embodies many of the same attributes that characterize the entire discipline of neurotoxicology. Neurotoxicology is generally viewed as the study of compounds that are deleterious to the NS, and the effects of glutamate and kainate may be viewed as examples of this type of deleterious toxicity. Exposure to these excitotoxic amino acids leads to neuronal injury and—when of sufficient degree—may kill neurons. However, the implications of these findings, as with the entire field of neurotoxicology, extend beyond the direct toxicity of the compounds in exposed populations. With kainate, as with many other neurotoxic compounds, has come a tool for neurobiologists who seek to explore the anatomy and function of the NS. Kainate, through its selective action on neuronal cell bodies, has provided a greater understanding of the functions of cells within a specific region of the brain, while previous lesioning techniques addressed only regional functions. Finally, the questions surrounding domoic acid poisoning and the Guamanian neurodegenerative complex serve to remind the student of neurotoxicology that the causes of many neurologic diseases remain unknown. This void in understanding and the epidemiologic evidence that some neurodegenerative diseases may have environmental contributors provide a heightened desire to appreciate more fully the effects of elements of our environment on the NS.

TOXIC RESPONSES OF THE OCULAR AND VISUAL SYSTEM

Donald A. Fox and William K. Boyes

INTRODUCTION TO OCULAR AND VISUAL SYSTEM TOXICOLOGY*

Environmental and occupational exposure to toxic chemicals, gases, and vapors as well as side effects resulting from therapeutic drugs frequently result in structural and functional alterations in the eye and central visual system (Grant, 1986; Anger and Johnson, 1985; Grant and Shuhman, 1993; Otto and Fox, 1993; Jaanus et al., 1995; Fox, 1998). It has been estimated that almost half of all neurotoxic chemicals affect some aspect of sensory function (Crofton and Sheets, 1989). The most frequently reported sensory system alterations occur in the visual system (Anger and Johnson, 1985; Crofton and Sheets, 1989; Fox, 1998). Grant (1986) lists approximately 2800 substances that are reportedly toxic to the eye. In many cases, alterations in visual function are the first symptoms following chemical exposure (Hanninen et al., 1978; Damstra, 1978; Baker et al., 1984; Mergler et al., 1987). Even more relevant is the fact that these alterations often occur in the absence of any clinical signs of toxicity (Baker et al., 1984; Anger and Johnson, 1985). This suggests that sensory systems, and in particular the retina and central visual system, may be especially vulnerable to toxic insult. In fact, alterations in the structure and/or function of the eye or central visual system are among the criteria utilized for setting permissible occupational exposure levels for 33 different chemicals in the United States (Anger, 1984). Moreover, subtle alterations in visual processing of information (e.g., visual perceptual, visual motor) can have profound immediate, long-term, and—in some cases—delayed effects on the mental, social, and physical health and performance of an individual. Finally, ocular and visual system impairments can lead to increased occupational injuries, loss of productive work time, costs for providing medical and social services, lost productivity, and a distinct decrease in the overall quality of life.

The overall goal of this chapter is to review the structural and functional alterations in the mammalian eye and central visual system commonly produced by environmental and workplace chemicals, gases, and vapors and by therapeutic drugs. Except where noted, all these compounds are referred to as chemicals and drugs. The adverse effects of these agents on the different compartments of the eye [i.e., cornea, lens, retina, and retinal pigment epithelium (RPE)], central visual pathway [i.e., optic nerve (ON) and optic tract (OT)], and the central processing areas [i.e., lateral geniculate nucleus (LGN), visual cortex] are addressed (Table 17-1). To further understand the disposition and effects of these chemicals and drugs on the eye and central visual system, the pharmacodynamics and pharmacokinetics of these compartments are briefly reviewed (Table 17-2). Furthermore, the ophthalmologic evaluation of the eye and the testing of visual function are discussed, as the results from these clinical, behavioral, and electrophysiologic studies form the basis of our diagnosis and understanding of adverse visual system effects in patients and animals. Many of the chemicals discussed below initially appear to have a single site and, by inference, mechanism of action, whereas others have several sites and corresponding mechanisms of action. However, a more in-depth examination often reveals that, depending upon dose (concentration), many of these chemicals have multiple sites of action. Two examples illustrate the point. First, as described below in more detail, carbon disulfide produces ON and OT degeneration and also adversely affects the neurons and vasculature of the retina, resulting in photoreceptor and retinal ganglion cell (RGC) structural and functional alterations (Hotta et al., 1971; Raitta et al., 1974; Palacz et al., 1980; Seppalainen et al., 1980; Raitta et al., 1981; De Rouck et al., 1986; Eskin et al., 1988; Merigan et al., 1988; Fox, 1998). Second, inorganic lead clearly affects rod photoreceptors in developing and adult mammals, resulting in rod-mediated (or scotopic) vision deficits; however, structural and functional deficits at the level of the RGCs, visual cortex, and oculomotor system are also observed (Fox and Sillman, 1979; Costa and Fox, 1983; Fox, 1984; Glickman et al., 1984; Lilienthal et al., 1988, 1994; Reuhl et al., 1989; Ruan et al., 1994; Fox et al., 1997; Rice, 1998; Rice and Hayward, 1999; He et al., 2000; and see reviews by Otto and Fox, 1993; Fox, 1998). Finally, some environmental and occupational neurotoxicants (e.g., acrylamide, lead) have been utilized for in vivo and in vitro animal models to examine the pathogenesis of selected retinal, neuronal, or axonal diseases; the basic functions of the retinocortical pathways; and/or the molecular mechanisms of apoptosis (Fox and Sillman, 1979; Vidyasagar, 1981; Lynch et al., 1992; He et al., 2000).

Table 17-1 Ocular and Central Visual System Sites of Action of Selected Xenobiotics following Systemic Exposure

Table 17-2 Distribution of Ocular Xenobiotic-Biotransforming Enzymes

The conceptual approach, format, and overall organization of this entirely new chapter on ocular and visual system toxicology for the 6th edition of Casarett and Doull's *Toxicology: The Basic Science of Poisons* were designed by the authors of this chapter in anticipation that our main audience would be graduate and medical school students, ophthalmologists and occupational physicians, basic and applied science researchers interested in ocular and visual system toxicology, and those interested in having a basic reference source. To write this chapter we synthesized and condensed the information contained in several excellent resources on different aspects of ocular, retinal, and visual system anatomy, biochemistry, cell and molecular biology, histology, pharmacology, physiology, and toxicology (Hogan et al., 1971; Merigan and Weiss, 1980; Fox et al., 1982; Sears, 1984; Dayhaw-Barker et al., 1986; Grant, 1986; Dowling, 1987; Fraunfelder and Meyer, 1989; Ogden and Schachat, 1989; Davson, 1990; Berman, 1991; Boyes, 1992; Chiou, 1992; Hart, 1992; Hockwin et al., 1992; Bartlett and Jaanus, 1995; Herr and Boyes, 1995; Potts, 1996; Fox, 1998; Rodieck, 1998; Ballantyne, 1999). The interested reader should consult these sources for more detail than is provided below. We gratefully acknowledge the use of the information in these sources as well as those cited in the text below.

EXPOSURE TO THE EYE AND VISUAL SYSTEM

Ocular Pharmacodynamics and Pharmacokinetics

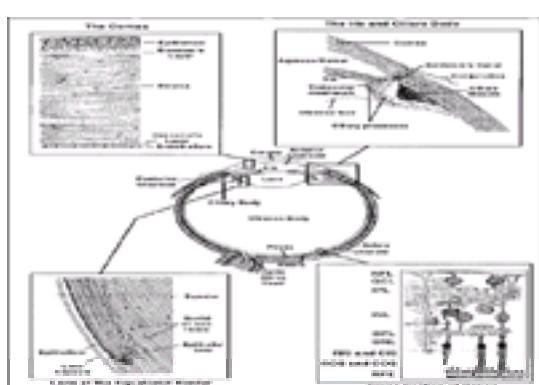
Toxic chemicals and systemic drugs can affect all parts of the eye (Fig. 17-1; Table 17-1). Several factors determine whether a chemical can reach a particular ocular site of action, including the physiochemical properties of the chemical, concentration and duration of exposure, route of exposure, and the movement of the chemical into and across the different ocular compartments and barriers. The cornea and external adnexa of the eye (i.e., conjunctiva and eyelids) are often exposed directly to chemicals (i.e., acids, bases, solvents), gases and particles, and drugs. The first site of action is the tear film—a three-layered structure with both hydrophobic and hydrophilic properties. The outermost tear film layer is a thin (0.1-μm) hydrophobic layer that is secreted by the meibomian (sebaceous) glands. This superficial lipid layer protects the underlying thicker (7-μm) aqueous layer that is produced by the lacrimal glands. The third layer, which has both hydrophobic and hydrophilic properties, is the very thin (0.02 to 0.05 μm) mucoid layer. It is secreted by the goblet cells of the conjunctiva and acts as an interface between the hydrophilic layer of the tears and the hydrophobic layer of the corneal epithelial cells. Thus, water-soluble chemical compounds more readily mix with the tears and gain access to the cornea. However, a large proportion of the compounds that are splashed into the eyes are washed away by the tears and thus are not absorbed.


Figure 17-1. Diagrammatic horizontal cross section of the eye, with medium-power enlargement of details for the cornea, iris and ciliary body, lens, and retina.
The morphologic features, their role in ocular pharmacodynamics, pharmacokinetics, drug metabolism, and the adverse effects of drugs and chemical agents on these sites are discussed in the text.

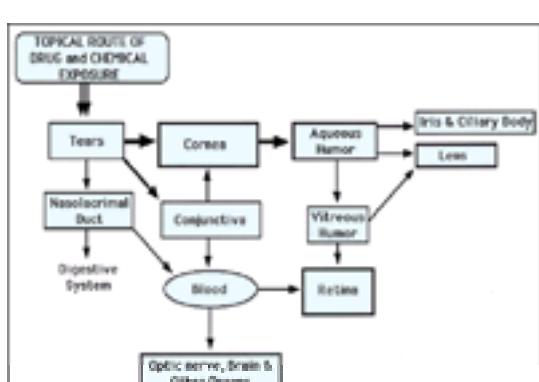
The cornea, an avascular tissue, is considered the external barrier to the internal ocular structures. Once a chemical interacts with the tear film and subsequently contacts the cornea and conjunctiva, the majority of what is absorbed locally enters the anterior segment by passing across the cornea. In contrast, a greater systemic absorption and higher blood concentration occurs through contact with the vascularized conjunctiva (Sears, 1984; Pepose and Ubels, 1992; Fig. 17-2). The human cornea, which is approximately 500 μm thick, has several distinct layers, or barriers, through which a chemical must pass in order to reach the anterior chamber (see discussion on the cornea, below). The first is the corneal epithelium. It is a stratified squamous, nonkeratinized, multicellular hydrophobic layer. These cells have a relatively low ionic conductance through apical cell membranes, and due to the tight junctions (desmosomes), they have a high resistance paracellular pathway. The primary barrier to chemical penetration of the cornea is tight junctions at the superficial layer of the corneal epithelial cells. Thus, the permeability of the corneal epithelium as a whole is low and only lipid soluble chemicals readily pass through this layer. The corneal stroma makes up 90 percent of the corneal thickness and is composed of water, collagen, and glycosaminoglycans. It contains approximately 200 lamellae, each about 1.5 to 2.0 μm thick. Due to the composition and structure of the stroma, hydrophilic chemicals easily dissolve in this thick layer, which can also act as a reservoir for these chemicals. The inner edge of the corneal stroma is bounded by a thin, limiting basement membrane, called Descemet's membrane, which is secreted by the corneal endothelium. The innermost layer of the cornea, the corneal endothelium, is composed of a single layer of large diameter hexagonal cells connected by terminal bars and surrounded by lipid membranes. The endothelial cells have a relatively low ionic conductance through apical cell surface and a high-resistance paracellular pathway. Although the permeability of the corneal endothelial cells to ionized chemicals is relatively low, it is still 100 to 200 times more permeable than the corneal epithelium. The Na^+,K^+-pump is located on the basolateral membrane while the energy-dependent Na^+,HCO_3^--transporter is located on the apical membrane (Sears, 1984; Pepose and Ubels, 1992).


Figure 17-2. Ocular absorption and distribution of drugs and chemicals following the topical route of exposure.
The details for movement of drugs and chemicals between compartments of the eye and subsequently to the optic nerve, brain, and other organs are discussed in the

text. The conceptual idea for this figure was obtained from Lapalus and Garaffo (1992).

There are two separate vascular systems in the eye: (1) the uveal blood vessels, which include the vascular beds of the iris, ciliary body, and choroid, and (2) the retinal vessels (Hogan, 1971; Alm, 1992). In humans, the ocular vessels are derived from the ophthalmic artery, which is a branch of the internal carotid artery. The ophthalmic artery branches into (1) the central retinal artery, which enters the eye and then further branches into four major vessels serving each of the retinal quadrants; (2) two posterior ciliary arteries; and (3) several anterior arteries. In the anterior segment of the eye, there is a blood-aqueous barrier that has relatively tight junctions between the endothelial cells of the iris capillaries and nonpigmented cells of the ciliary epithelium (Hogan, 1971; Alm, 1992). The major function of the ciliary epithelium is the production of aqueous humor from the plasma filtrate present in the stroma of the ciliary processes.

In humans and several widely used experimental animals (e.g., monkeys, pigs, dogs, rats, mice), the retina has a dual circulatory supply: choroidal and retinal. The retinal blood vessels are distributed within the inner or proximal portion of the retina, which consists of the outer plexiform layer (OPL), inner nuclear layer (INL), inner plexiform layer (IPL), and ganglion cell layer (GCL). The endothelial cells of capillaries of the retinal vessels have tight junctions similar to those that form the blood-brain barrier in the cerebral capillaries. These continuous types of capillaries form the blood-retinal barrier and under normal physiologic conditions they are largely impermeable to chemicals such as glucose and amino acids (Alm, 1992). However, at the level of the optic disk the blood-retinal barrier lacks these continuous type of capillaries and thus hydrophilic molecules can enter the optic nerve (ON) head by diffusion from the extravascular space (Alm, 1992) and cause selective damage at this site of action. The outer or distal retina, which consists of the retinal pigment epithelium (RPE), rod, and cone photoreceptor outer segments (ROS, COS) and inner segments (RIS, CIS), and the photoreceptor outer nuclear layer (ONL), are avascular. These areas of the retina are supplied by the choriocapillaris: a dense, one-layered network of fenestrated vessels formed by the short posterior ciliary arteries and located next to the RPE. Consistent with their known structure and function, these capillaries have loose endothelial junctions and abundant fenestrae; they are highly permeable to large proteins. Thus, the extravascular space contains a high concentration of albumin and g-globulin (Sears, 1992).

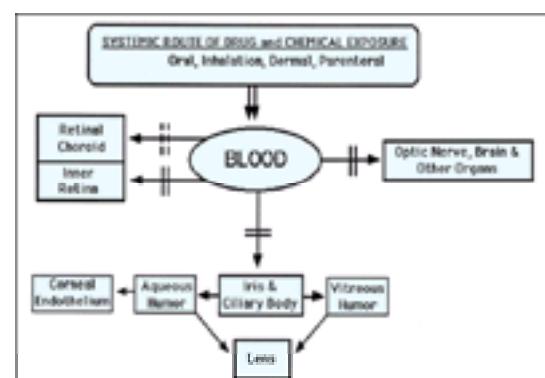
Following systemic exposure to drugs and chemicals by the oral, inhalation, dermal, or parenteral route, these compounds are distributed to all parts of the eye by the blood in the uveal blood vessels and retinal vessels (Fig. 17-3). Most of these drugs and chemicals can rapidly equilibrate with the extravascular space of the choroid where they are separated from the retina and vitreous body by the RPE and endothelial cells of the retinal capillaries, respectively. Hydrophilic molecules with molecular weights less than 200 to 300 Da can cross the ciliary epithelium and iris capillaries and enter the aqueous humor (Sears, 1992). Thus, the corneal endothelium—the cells responsible for maintaining normal hydration and transparency of the corneal stroma—could be exposed to chemical compounds by the aqueous humor and limbal capillaries. Similarly, the anterior surface of the lens also can be exposed as a result of its contact with the aqueous humor. The most likely retinal target sites following systemic drug and chemical exposure appear to be the RPE and photoreceptors in the distal retina because the endothelial cells of the choriocapillaris are permeable to proteins smaller than 50 to 70 kDa. However, the cells of the RPE are joined on their basolateral surface by tight junctions—zonula occludens—that limit the passive penetration of large molecules into the neural retina.


Figure 17-3. Distribution of drugs and chemicals in the anterior and posterior segments of the eye, optic nerve, brain, and other organs following the systemic route of exposure.

The details for movement of drugs and chemicals between compartments of the eye are discussed in the text. The conceptual idea for this part of the figure was obtained from Lapalus and Garaffo (1992). The solid and dotted double lines represent the different blood-tissue barriers present in the anterior segment of the eye, retina, optic nerve, and brain. The solid double lines represent tight endothelial junctions, whereas the dotted double lines represent loose endothelial junctions.

The presence of intraocular melanin plays a special role in ocular toxicology. First, it is found in several different locations in the eye: pigmented cells of the iris, ciliary body, RPE, and uveal tract. Second, it has a high binding affinity for polycyclic aromatic hydrocarbons, electrophiles, calcium, and toxic heavy metals such as aluminum, iron, lead, and mercury (Meier-Ruge, 1972; Potts and Au, 1976; Dräger, 1985; Ulshafer et al., 1990; Eichenbaum and Zheng, 2000). Although this initially may play a protective role, it also results in the excessive accumulation, long-term storage, and slow release of numerous drugs and chemicals from melanin. For example, atropine binds more avidly to pigmented irides and thus its duration of action is prolonged (Bartlett and Jaanus, 1995). In addition, the accumulation of chloroquine in the RPE produces an 80-fold higher concentration of chloroquine in the retina relative to liver (Meier-Rouge, 1972). Similarly, lead accumulates in the human retina such that its concentration is 5 to 750 times that in other ocular tissues (Eichenbaum and Zheng, 2000).

Ocular Drug Metabolism

Metabolism of xenobiotics occurs in all compartments of the eye by well known phase I and II xenobiotic-biotransforming enzymes. Drug metabolizing enzymes such as acetylcholinesterase, carboxylesterase (also known as pseudocholinesterase: see Chap. 6, " Biotransformation of Xenobiotics"), alcohol and aldehyde dehydrogenase, aldehyde and aldose reductase, catalase, monoamine oxidase A and/or B, and Cu $^{2+}$/Zn^{2+} superoxide dismutase as well as several types of proteases are present in the tears, iris-ciliary body, choroid, and retina of many different species (Shanthaverrappa and Bourne, 1964; Waltmann and Sears, 1964; Bausher, 1976; Anderson, 1980; Puro, 1985; Atalla et al., 1998; Berman, 1991; Crouch et al., 1991; Watkins et al., 1991; Gondhowiardjo and van Haeringen, 1993; Downes and Holmes, 1995; Gaudet et al., 1995; Behndig et al., 1998; King et al., 1999; Table 17-2). Compared to other tissues, there is only limited data on the type, number, and activity of cytochrome P450 (CYP) isoforms (phase I metabolism) and phase II conjugating enzymes in ocular tissues (Shichi et al., 1975; Shichi and Nebert, 1982; Sears, 1992; Zhao and Shichi, 1995; Srivastava et al., 1996; Schwartzman, 1997; Singh and Shichi, 1998; Mastyugin et al., 1999). CYP1A1 and CYP1A2—previously known as aryl hydrocarbon hydroxylase activity—are found in all bovine and mouse ocular tissues except the lens and can be induced by 3-methylcholanthrene and b-naphthoflavone (Shichi et al., 1975; Shichi et al., 1982; Zhao and Shichi, 1995). Moreover, a CYP4 family member—CYP4A1 in the mouse and CYP4B1 in the rabbit—is present in corneal epithelium and can be induced by phenobarbital and the peroxisome proliferator clofibrate (Zhao et al., 1996; Mastyugin et al., 1999). This corneal epithelial CYP monooxygenase metabolizes arachidonic acid to two of its major metabolites: 12(R)-HETE [12(R)-hydroxy-5,8,10,14-eicosatrienoic acid] and 12(R)-HETrE [12(R)-hydroxy-5,8,14-eicosatrienoic acid] (Schwartzman, 1987; Asakura et al., 1994; Mastyugin et al., 1999). In the corneal epithelium, 12(R)-HETE is a potent inhibitor of Na $^+$,K$^+$-ATPase, whereas 12(R) HETrE is a potent angiogenic and chemotactic factor (Schwartzman, 1997).

The phase II conjugating enzymes found in bovine, rabbit, and rat ocular tissues include UDP glucuronosyltransferase, glutathione peroxidase, glutathione reductase, glutathione *S*-transferase, and *N*-acetyltransferase (Awasthi et al., 1980; Shichi and Nebert, 1982; Penn et al., 1987; Watkins et al., 1991: Srivastava et al., 1996; Singh and Shichi, 1998; see Table 17-2). The activity of these enzymes varies between species and ocular tissues, however, the whole lens appears to have low biotransformational activity. It was subsequently found that the glutathione *S*-transferase activity was in the lens epithelium and not in the lens cortex or nucleus (Srivastava et al., 1996). Overall, these findings suggest that ocular tissues that contact the external environment or have a blood supply that possess both CYPs and phase II conjugating enzymes, especially those related to glutathione conjugation. The presence and need for a competent glutathione conjugation system is clearly understandable in ocular tissues that directly interact with UV radiation, light, and xenobiotics and that have high rates of metabolism and high lipid content. Finally, further work is needed to determine the presence and activity of other CYP family members in ocular tissue, the various factors (i.e., age, gender, tissue-specific, xenobiotics, etc.) that regulate their expression, and their endogenous and exogenous substrates.

Central Visual System Pharmacokinetics

The penetration of potentially toxic compounds into visual areas of the central nervous system (CNS) is governed, like other parts of the CNS, by the blood-brain barrier (Fig. 17-3). The blood-brain barrier is formed through a combination of tight junctions in brain capillary endothelial cells and foot processes of astrocytic glial cells that surround the brain capillaries. Together these structures serve to limit the penetration of blood-borne compounds into the brain. The concept of an absolute barrier is not correct, however, because the blood-brain barrier is differentially permeable to compounds depending on their size, charge, and lipophilicity. Compounds that are large, highly charged, or otherwise not very lipid soluble tend to be excluded from the brain, whereas smaller, uncharged, and lipid-soluble compounds more readily penetrate into the brain tissue. In addition to entering the CNS through this nonspecific semipermeable diffusion barrier, some specific nutrients including, ions, amino acids, and glucose enter the CNS through selective transport mechanisms. In some cases, toxic compounds may be actively transported into the brain by mimicking the natural substrates of active transport systems. A few areas of the brain lack a blood-brain barrier; consequently blood-borne compounds readily penetrate into the brain tissue in these regions. Interestingly, one such area is the ON near the lamina cribrosa (Alm, 1992), which could cause this part of the central visual system to be vulnerable to exposures that do not affect much of the remainder of the brain.

TESTING VISUAL FUNCTION

Testing for potential toxic effects of compounds on the eye and visual system can be divided into tests of ocular toxicity and tests of visual function. Alternatively, such tests could be grouped according to the professional training of the individual conducting the evaluation. Such a categorization might include tests of contact irritancy or toxicity akin to dermatologic procedures, ophthalmologic evaluations, neurophysiologic studies of the function of the visual system, and behavioral or psychophysical evaluations of visual thresholds and aspects of perception.

Evaluation of Ocular Irritancy and Toxicity

Standard procedures for evaluating ocular irritation have been based on a method originally published by Draize et al. over a half a century ago (Draize et al., 1944). The Draize test, with some additions and revisions, has formed the basis of procedures employed for safety evaluations in data submitted to several government regulatory bodies including the European Economic Community and several federal agencies within the United States. Traditionally, albino rabbits are the subjects evaluated in the Draize test, although the Environmental Protection Agency (EPA) protocol allows different test species to be used if sufficient justification is provided. The standard procedure involves instillation of 0.1 mL of a liquid or 100 mg of a solid into the conjunctival sac of one eye and then gently holding the eye closed for 1 s. The untreated eye serves as a control. Both eyes are evaluated at 1, 24, 48, and 72 h after treatment. If there is evidence of damage in the treated eye at 72 h, the examination time may be extended. The cornea, iris, and conjunctiva are evaluated and scored according to a weighted scale. The cornea is scored for both the degree of opacity and area of involvement, with each measure having a potential range from 0 (none) to 4 (most severe). The iris receives a single score (0 to 2) for irritation, including degree of swelling, congestion, and degree of reaction to light. The conjunctiva is scored for the redness (0 to 3), chemosis (swelling: 0 to 4), and discharge (0 to 3). The individual scores are then multiplied by a weighting factor: 5 for the cornea, 2 for the iris, and 5 for the conjunctiva. The results are summed for a maximum total score of 110. Photographic examples of lesions receiving each score are provided in Datson and Freeberg (1991). In this scale, the cornea accounts for 80 (73 percent) of the total possible points, in accordance with the severity associated with corneal injury.

The Draize test, although a standard for decades, has been criticized on several grounds, including high interlaboratory variability, the subjective nature of the scoring, poor predictive value for human irritants, and—most significantly—for causing undue pain and distress to the tested animals. These criticisms have spawned a concerted effort to develop alternative methods or strategies to evaluate compounds for their potential to cause ocular irritation. These alternatives include modifications of the traditional Draize test to reduce the number of test animals required, reduce the volume of the compound administered, and increase objectivity of scoring (e.g., Kennah et al., 1989; Bruner et al., 1992; Lambert et al., 1993). In addition, several alternative test procedures have been proposed, including the use of skin irritancy tests as substitutes for ocular irritancy and the use of in vitro assays (Datson and Freeberg, 1991; Chamberlain et al., 1997; Kruszewski et al., 1997). Additional research efforts are developing quantitative structure activity relationships to better predict ocular irritancy (Barratt, 1995; Sugai et al., 1990; Kulkarni and Hopfinger, 1999). To date, there is no general consensus as to which of these alternatives, alone or in combination, provides a suitable alternative to the Draize procedure. The Interagency Coordinating Committee on the Validation of Alternative Methods (ICCVAM), a committee with representatives from 14 agencies of the U.S. federal government, however, has established criteria for validating methods to substitute for whole animals tests of ocular corrosiveness or irritancy (NIEHS, 1997). In June of 1999, ICCVAM found that a nonanimal test product developed under the trade name of Corrositex was useful in determining whether compounds have a potential to corrode or burn the skin or eyes (NIEHS, 1999).

The Corrositex assay is an in vitro procedure in which compounds are tested for the ability to penetrate a biological barrier, a hydrated collagen matrix, and cause a color change in an underlying liquid chemical detection system. The chemical detection system is composed of water and pH indicator dyes; it changes color when contact with the test chemical or mixture causes the pH of the solution to become either less than 5 or greater than 8.5. Chemicals that do not cause a color change in the chemical detection system when added directly in the absence of the biological barrier are not eligible for evaluation with this system. The relative corrosivity of test compounds or mixtures is determined by measuring the penetration time. The ICCVAM peer-review panel reported that in comparison with in vivo testing of rabbit skin for corrosivity, the Corrositex assay had an overall sensitivity of 85 percent (76 of 89 compounds tested), a specificity of 70 percent (52 of 74 compounds tested), and an accuracy of 79 percent (128 of 163 compounds tested). The committee concluded that use of Corrositex as a stand alone procedure in some applications, or in a tiered testing approach in other applications, could help to refine, reduce, or replace the use of whole animal testing procedures. Application of the test is limited, however, by the fact that a number of potential test compounds do not cause a change in color when added directly to the fluid chemical detection system and therefore do not qualify for testing. The test also has a rate of false positive results (30 percent) that may be too high for some applications. These limitations emphasize that it is unlikely for any single simple alternative procedure to serve as an adequate substitute for in vivo animal testing, due to the complexity of the living ocular tissue and the number of tissues and processes that must be reproduced (Bruner et al., 1991).

Ophthalmologic Evaluations

There are many ophthalmologic procedures for evaluating the health of the eye. These should be conducted by a trained ophthalmologist or optometrist experienced in evaluating the species of interest. Procedures available range from fairly routine clinical screening evaluations to sophisticated techniques for very targeted purposes, the later of which are beyond the scope of this chapter. A clinical evaluation of the eye addresses the adnexa and both the anterior and posterior structures in the eye. Examination of the adnexa includes evaluating the eyelids, lacrimal apparatus, and palpebral (covering the eyelid) and bulbar (covering the eye) conjunctiva. The anterior structures or anterior segment include the cornea, iris, lens, and anterior chamber. The posterior structures, referred to as the *ocular fundus,* include the retina, retinal vasculature, choroid, ON, and sclera. The adnexa and surface of the cornea can be examined initially with the naked eye and a hand-held light. Closer examination requires a slit-lamp biomicroscope, using a mydriatic drug (causes pupil dilation) if the lens is to be observed. The width of the reflection of a thin beam of light projected from the slitlamp is an indication of the thickness of the cornea and may be used to evaluate corneal edema. Lesions of the cornea can be better visualized with the use of fluorescein dye, which is retained where there is an ulceration of the corneal epithelium. Examination of the fundus requires use of a mydriatic drug. Fundoscopic examination is conducted using a direct or an indirect ophthalmoscope, as described (Gelatt, 1981; Harroff, 1991; Hockwin et al., 1992). Several recently developed techniques are described in Peiffer et al. (2000).

An ophthalmologic examination of the eye may also involve, prior to introducing mydriatics, an examination of the pupillary light reflex. The direct pupillary reflex involves shining a bright light into the eye and observing the reflexive pupil constriction in the same eye. The consensual pupillary reflex is observed in the eye not stimulated. Both the direct and consensual pupillary light reflexes are dependent on function of a reflex arc involving cells in the retina, which travel through the ON, optic chiasm, and optic tract (OT) to project to neurons in the pretectal area. Pretectal neurons travel to both ipsilateral (for the direct reflex) and contralateral (for the consensual reflex) parasympathetic neurons of the midbrain accessory oculomotor (Edinger-Westphal) nucleus. Preganglion neurons from the Edinger-Westphal nucleus project through the oculomotor nerve to the ciliary ganglion. Postganglionic neurons from the ciliary ganglion then innervate the smooth muscle fibers of the iridal pupillary sphincter. The absence of a pupillary reflex is indicative of damage somewhere in the reflex pathway, and differential impairment of the direct or consensual reflexes can indicate the location of the lesion. The presence of a pupillary light reflex, however, is not synonymous with normal visual function. Pupillary reflexes can be maintained even with substantial retinal damage. In addition, lesions in visual areas outside of the reflex pathway, such as in the visual cortex, may also leave the reflex function intact.

Electrophysiologic Techniques

Many electrophysiologic or neurophysiologic procedures are available for testing visual function in a toxicologic context. In a simple sense, most of these procedures involve stimulating the eyes with visual stimuli and electrically recording potentials generated by visually responsive neurons. Different techniques and stimuli are

used to selectively study the function of specific retinal or visual cortical neurons. In the study of the effects of potential toxic substances on visual function, the most commonly used electrophysiologic procedures are the flash-evoked electroretinogram (ERG), visual-evoked potentials (VEPs), and, less often, the electrooculogram (EOG).

ERGs are typically elicited with a brief flash of light and recorded from an electrode placed in contact with the cornea. A typical ERG waveform (see Fox and Farber, 1988) includes an initial negative-going waveform, called the a-wave, that reflects the activation of photoreceptors, and a following positive b-wave that reflects the activity of retinal bipolar cells and associated membrane potential changes in Müller cells, a type of retinal glial cell that buffers extracellular potassium ions and glutamate (Dowling, 1987; Rodieck, 1998). In addition, a series of oscillatory potentials can be observed overriding the b-wave, of which the neural generators are somewhat uncertain, but they presumably reflect various stages of intraretinal signal processing. A standard set of ERG procedures has been recommended and updated for screening assessments of human clinical patients (Marmor et al., 1989; Marmor and Zrenner, 1995). These procedures include the recording of (1) a response reflective of only rod photoreceptor function in the dark-adapted eye, (2) the maximal response in the dark-adapted eye, (3) a response developed by cone photoreceptors, (4) oscillatory potentials, and (5) the response to rapidly flickered light. These recommendations were used to create a protocol for screening the retinal function of dogs in toxicologic studies (Jones et al., 1994). For testing retinal function beyond a screening level evaluation, ERG amplitude and latency versus log stimulus intensity functions are very useful (e.g., Fox and Farber, 1988). Although flash-evoked ERGs do not reflect the function of the RGC layer, ERGs elicited with pattern-reversal stimuli (PERGs) do reflect the activation of RGCs. To date, PERGs have not been used widely in toxicological evaluations.

VEPs are elicited with stimuli similar to those used to evoke ERGs; however, VEPs are recorded from electrodes overlying visual (striate) cortex. Consequently VEPs reflect the activity of the retinogeniculostriate pathway and the activity of cells in the visual cortex. Flash-elicited VEPs have been used in a number of studies of potentially neurotoxic compounds in laboratory animals (Fox et al., 1977, 1982; Dyer et al., 1982; Rebert, 1983; Dyer, 1985; Boyes, 1992; Mattsson et al., 1992; Herr and Boyes, 1995). Pattern-elicited VEPs (PEPs) are more widely used in human clinical evaluations because of their diagnostic value. However, they are infrequently used in laboratory animals because albino rats do not produce usable PEPs (Boyes and Dyer, 1983). Recording PEPs and conducting psychophysic studies with pigmented Long-Evans hooded rats, Fox (1984) found that the PEP spatial frequency functions yielded almost the same visual acuity values (1.4 cycles per degree) as the psychophysically determined spatial resolution limit values (1.8 cycles per degree). These values are in good agreement with those obtained by others using single-cell electrophysiologic and behavioral techniques (Powers and Green, 1978; Birch and Jacobs, 1979; Dean, 1981). Moreover, PEPs and flash-elicited VEPs have exhibited differential sensitivity to some neurotoxic agents (Boyes and Dyer, 1984; Fox, 1984). The U.S. Environmental Protection Agency has published guidelines for conducting visual evoked potential testing in a toxicological context, along with analogous sensory evoked potential procedures for evaluating auditory and somatosensory function (EPA, 1998a).

The EOG is generated by a potential difference between the front and back of the eye, which originates primarily within the RPE (Berson, 1992). Metabolic activity in the RPE generates a light-insensitive potential (the standing potential) and a light-sensitive potential; the difference in amplitude between these two potentials is easily measured as the EOG. The magnitude of the EOG is a function of the level of illumination and health status of the RPE. Electrodes placed on the skin on a line lateral or vertical to the eye measure potential changes correlated with eye movements as the relative position of the ocular dipole changes. Thus, the EOG finds applications in assessing both RPE status and measuring eye movements. The EOG is also used in monitoring eye movements during the recording of other brain potentials, so that eye movement artifacts are not misinterpreted as brain generated electrical activity (Berson, 1992).

As noted in the introduction to this chapter, there is a clear need for testing visual function as a component of the toxicologic evaluation of commercial chemicals. The magnitude of the potential threat posed by visual system toxicity is not known, because sensory function has not been evaluated in a systematic fashion. Currently the EPA screening batteries for neurotoxicologic evaluation of laboratory animals include only minimal evaluations of visual function. Standard screening procedures such as those included in EPA's neurotoxicity screening battery (EPA, 1998b) include a functional observational battery (FOB)—an automated measurement of motor activity and neuropathology. Of the screening procedures, only the FOB evaluates visual function and the extent of these measures is very limited. The entire assessment of visual function includes observing the animal's response to an approaching object such as a pencil and observing the pupil's response to a light. These procedures are limited in not exploring responsiveness over a range of stimulus features such as luminance, color, spatial frequency, and temporal frequency. In addition, they do not evaluate rod or cone sensory thresholds, nor do they isolate potential motor or integrative contributions to task performance. Despite these shortcomings, the FOB has been successful at detecting visual deficits produced by exposure to 3,3'-iminodipropionitrile (Moser and Boyes, 1993) or carbon disulfide (Moser et al., 1998), which illustrates the importance of conducting at least this level of visual function screening in routine testing programs. Some studies include ophthalmologic and/or ocular pathologic evaluations. Comprehensive visual toxicity studies should include ophthalmologic and pathologic evaluation of ocular tissues and assessments of visual function.

Another potentially limiting problem in product safety testing is the routine use of albino animals, whose capacity for visual function is limited at best. The toxicity of many polycyclic aromatic compounds are mediated through interactions with melanin (Potts, 1964, 1996; Meier-Ruge, 1972; see discussion of the retina, below), which is absent in the eyes of albino strains. Furthermore, light-related ocular lesions, including cataracts and retinal degeneration, are often observed in control albino rats and mice used in 2 year product-safety evaluations. It is well known that normal photoreceptor physiology and susceptibility to chemical damage in rats and mice are mediated by light (LaVail, 1976; Williams et al., 1985; Williams, 1986; Penn and Williams, 1986; LaVail et al., 1987; Penn et al., 1987, 1989; Rapp et al., 1990; Backstrom et al., 1993). For example, one study showed that the proportion of Fisher 344 rats in the control group with photoreceptor lesions ranged from less than 10 percent of rats housed on the bottom row of the cage racks to over 55 percent of rats housed on the top row, where the luminance was greater (Rao, 1991). Even under reduced light levels, the incidence of these effects was as high as 15 percent. If albino animals are used as the test subjects, it is important to control the overall level of illumination in the animal colony and also to periodically rotate the animals among the rows of the cage racks. Even under these conditions, it is extremely difficult to interpret pathologic changes in albino rats and mice exposed to test compounds against such high rates of background retinal lesions.

Sensory dysfunction can confound other measures of neurotoxicity. Many behavioral and observational evaluations of neurotoxicity involve presentation of sensory stimuli to human or animal subjects followed by the observation or measurement of a behavioral or motor response. In many cases, the inferences drawn from such measures are stated in terms of the cognitive abilities of the test subject, such as whether learning or memory have been compromised as a function of exposure to the test compound. If the subject was unable to clearly and precisely perceive the test stimuli, which are often complex patterns or contain color, task performance may be affected independently of any effect on cognition. Controlling for visual deficits may alter the interpretation of performance of ostensibly cognitive tasks (Anger et al., 1994; Hudnell et al., 1996; Walkowiak et al., 1998; Cestnick and Coltheart, 1999).

Behavioral and Psychophysical Techniques

Behavioral and psychophysical testing procedures typically vary the parameters of the visual stimulus and then determine whether the subject can discriminate or perceive the stimulus (Woodhouse and Barlow, 1982; Maurissen, 1995). Many facets of visual function in humans and laboratory animals have been studied using these procedures. Often, the goal of these procedures is to resolve the spatial or temporal limits of visual discrimination; however, most visual scenes and targets in our daily life involve discrimination of objects with low to middle spatial and temporal frequencies (Woodhouse and Barlow, 1982). Contrast sensitivity functions are used to assess these parameters. In addition, as discussed below, other visual parameters also have been investigated.

Contrast sensitivity refers to the ability to resolve small differences in luminance contrast, such as the difference between subtle shades of gray. Contrast sensitivity should be measured for a series of visual patterns that differ in pattern size. Typically, such patterns are a series of sine-wave gratings (striped patterns where the luminance changes across the pattern in a sinusoidal profile) where the spatial frequency of the sinusoidal pattern (i.e., the width of the bars in the pattern) varies in log steps. The contrast of the patterns (i.e., the difference between the brightest and darkest parts of the pattern that is adjusted for mean luminance) also varies. The resulting data, when plotted on log/log coordinates, forms a contrast sensitivity function that is representative of the ability to detect visual patterns over the range of visible pattern sizes. Contrast sensitivity functions are dependent primarily on the neural as opposed to the optical properties of the visual system. The contrast sensitivity functions generally form an inverted U-shaped profile with highest sensitivity to contrast at intermediate spatial frequencies. The peak of the function as well as the limits of resolution on both the spatial frequency and contrast axes vary across species. For example, at relatively mesopic (rod- and cone-mediated) luminance levels, the peak of the spatial contrast sensitivity function for the albino rat, hooded rat, cat, and human are 0.1, 0.3, 0.3, and 2 cycles per degree, respectively (Birch and Jacobs, 1979; Fox, 1984).

Some of the visual parameters that have been investigated include (1) the absolute luminance threshold, which is the threshold value for detecting an illuminated target by a dark-adapted subject in a dark-adapted environment; (2) visual acuity, which is the spatial resolution of the visual system [approximately 50 cycles per degree in humans (Woodhouse and Barlow, 1982) and 1.1 to 1.8 cycles per degree in albino and hooded rats (Fox, 1984; Birch and Jacobs, 1979; Dean, 1981)]; (3) color and spectral discriminations (Porkony et al., 1979); (4) critical flicker fusion frequency, which is the threshold value for detecting a flickering light at different luminance intensities; and (5) the peak of the spatial and temporal contrast sensitivity functions at different luminance levels (Woodhouse and Barlow, 1982). Most of these tests are dependent upon the quality of the ocular optics and the ability to obtain a sharply focused visual image on the retina. Thresholds for detecting luminance, contrast, flicker, and color are primarily dependent on retinal and central mechanisms of neural function, although optical impairments (e.g., cataracts)

interfere with these functions. The assessment of visual acuity and contrast sensitivity has been recommended for field studies of humans potentially exposed to neurotoxic substances (ATSDR, 1992).

Color vision deficits are either inherited or acquired. Hereditary red-green color deficits occur in about 8 percent of males (X-linked), while only about 0.5 percent of females show similar congenital deficits (Porkony et al., 1979). Inherited color deficiencies take two common forms: protan, a red-green confusion caused by abnormality or absence of the long-wavelength (red) sensitive cones; and deutan, concomitant confusion of red-green and blue-yellow caused by abnormality or absence of the middle-wavelength (green) sensitive cones. Congenital loss of short-wavelength cones, resulting in a blue-yellow confusion (tritanopia, or type III), is extremely rare. Most acquired color vision deficits, such as those caused by drug and chemical exposure, begin with a reduced ability to perform blue-yellow discriminations (Porkony et al., 1979; Jaanus et al., 1995). With increased or prolonged low-level exposure, the color confusion can progress to the red-green axis as well. Because of the rarity of inherited tritanopia, it is generally assumed that blue-yellow deficits, when observed, are acquired deficits. Köllner's rule of thumb is that disorders of the outer retina produce blue-yellow deficits, whereas disorders of the inner retina and ON produce red-green perceptual deficits (Porkony et al., 1979). Bilateral lesions in the area V4 of visual cortex can also lead to color blindness (prosopagnosia). Several reviews discuss and/or list the effects of drugs and chemicals on color vision (Lyle, 1974; Porkony, 1979; Grant, 1986; Mergler, 1990; Grant and Shuhman, 1993; Jaanus et al., 1995; Lessel, 1998).

Recently, the assessment of color vision by rapid screening procedures has been used to evaluate occupationally and environmentally exposed populations (Mergler, 1990; Geller and Hudnell, 1997; see discussion below of the retina and optic nerve/tract for specific references and details). Color vision may be evaluated using several different testing procedures. Commonly used procedures in human toxicologic evaluations include the Ishihara color plates and chip arrangement tests such as the Farnsworth-Munson 100 Hue (FM-100) test and the simplified 15-chip tests using either the saturated hues of the Farnsworth D-15 or the desaturated hues of the Lanthony Desaturated Panel D-15. The Ishihara plates involve a series of colored spots arranged in patterns that take advantage of perceived difference in shades resulting from either protan or deutan anomalies. Normal observers perceive different sets of embedded numbers than do those with color vision deficits. The Farnsworth-Munson procedure involves arrangement of 85 chips in order of progressively changing color. The relative chromatic value of successive chips induces those with color perception deficits to abnormally arrange the chips. The pattern is indicative of the nature of the color perception anomaly. The FM-100 is considered more diagnostically reliable but takes considerably longer to administer than the similar but more efficient Farnsworth and Lanthony tests. The desaturated hues of the Lanthony D-15 are designed to better identify subtle acquired color vision deficits. For this reason, and because it requires only a few minutes to administer, the Lanthony D-15 was recommended as the procedure for color vision screening of potentially occupationally and environmentally exposed populations (ATSDR, 1992). A critical review of this procedure and its use in toxicologic applications can be found in Geller and Hudnell (1997).

TARGET SITES AND MECHANISMS OF ACTION: CORNEA

The cornea provides the anterior covering of the eye and as such must provide three essential functions. First, it must provide a clear refractive surface. The air-to-fluid/tissue interface at the cornea is the principal refractive surface of the eye, providing approximately 48 diopters of refraction. The curvature of the cornea must be correct for the visual image to be focused at the retina. Second, the cornea provides tensile strength to maintain the appropriate shape of the globe. Third, the cornea protects the eye from external factors, including potentially toxic chemicals. The anatomy is reviewed in the discussion of ocular pharmacodynamics and pharmacokinetics above.

The cornea is transparent to wavelengths of light ranging between 310 (UV) to 2500 nm (IR) in wavelengths. Exposure to UV light below this range can damage the cornea. It is most sensitive to wavelengths of approximately 270 nm. Excessive UV exposure leads to photokeratitus and corneal pathology, the classic example being welder's-arc burns.

The cornea can be damaged by topical or systemic exposure to drugs and chemicals. Reports of such adverse reactions have been catalogued and reviewed by Diamante and Fraunfelder (1998). One summary analysis, of approximately 600 agricultural and industrial chemicals (raw materials, intermediates, formulation components, and sales products), evaluated using the Draize procedure, reported that over half of the materials tested caused no (18 to 31 percent) or minimal (42 to 51 percent) irritation. Depending on the chemical category, between 9 to 17 percent of compounds were graded as slightly irritant, whereas 1 to 6 percent were graded as strong or extreme irritants (Kobel and Gfeller, 1985).

Direct chemical exposure to the eye requires emergency medical attention. Acid and alkali chemicals that come into contact with the cornea can be extremely destructive. Products at pH extremes £2.5 or ³11.5 are considered as extreme ocular irritants (Potts, 1996). They can cause severe ocular damage and permanent loss of vision. Damage that extends to the corneal endothelium is associated with poor repair and recovery. The most important therapy is immediate and adequate irrigation with large amounts of water or saline, whichever is most readily available. The extent of damage to the eye and the ability to achieve a full recovery are dependent upon the nature of the chemical, the concentration and duration of exposure, and the speed and magnitude of the initial irrigation.

Acids

Strong acids with a pH £2.5 can be highly injurious. Among the most significant acidic chemicals in terms of the tendency to cause clinical ocular damage are hydrofluoric acid, sulfurous acid, sulfuric acid, and chromic acid, followed by hydrochloric and nitric acid and finally acetic acid (McCulley, 1998). Injuries may be mild if contact is with weak acids or with dilute solutions of strong acids. Compounds with a pH between 2.5 and 7 produce pain or stinging; but with only brief contact, they will cause no lasting damage (Grant and Shuhman, 1993). Following mild burns, the corneal epithelium may become turbid as the corneal stroma swells (chemosis). Mild burns are typically followed by rapid regeneration of the corneal epithelium and full recovery. In more severe burns, the epithelium of the cornea and conjunctiva become opaque and necrotic and may disintegrate over the course of a few days. In severe burns, there may be no sensation of pain because the corneal nerve endings are destroyed (Grant, 1986; Potts, 1996).

Acid chemical burns of the cornea occur through hydrogen ion–induced denaturing and coagulation of proteins. As epithelial cell proteins coagulate, glycosaminoglycans precipitate and stromal collagen fibers shrink. These events cause the cornea to become cloudy. The protein coagulation and shrinkage of the collagen is protective in that it forms a barrier and reduces further penetration of the acid. The collagen shrinkage, however, contracts the eye and can lead to a dangerous acute increase in intraocular pressure. The pH of the acid is not the only determinant of the severity of injury; however, as equimolar solutions of several chemicals adjusted to the same pH of 2 produce a wide range of outcomes. Both the hydrogen ion and anionic portions of the acid molecules contribute to protein coagulation and precipitation. The tissue proteins also tend to act as buffers (Grant, 1986; Potts, 1996).

Bases or Alkalies

Compounds with a basic pH are potentially even more damaging to the eye than are strong acids. Among the compounds of clinical significance in terms of frequency and severity of injuries are ammonia or ammonium hydroxide, sodium hydroxide (lye), potassium hydroxide (caustic potash), calcium hydroxide (lime), and magnesium hydroxide (McCulley, 1998). One of the reasons that caustic agents are so dangerous is their ability to rapidly penetrate the ocular tissues. This is particularly true for ammonia, which has been measured in the aqueous humor just seconds after application to the cornea. The toxicity of these substances is a function of their pH, being more toxic with increasing pH values. As with acid burns, the concentration of the solution and the duration of contact with the eye are important determinants of the eventual clinical outcome. Rapid and extensive irrigation after exposure and removal of particles, if present, is the immediate therapy of choice (Grant, 1986; Potts, 1996).

A feature of caustic burns that differentiates them from acid burns is that two phases of injury may be observed. There is an acute phase from exposure up to 1 week. Depending on the extent of injury, direct damage from exposure is observed in the cornea, adnexia, and possibly in the iris, ciliary body, and lens. The presence of strong hydroxide ions causes rapid necrosis of the corneal epithelium and, if sufficient amounts are present, penetration through and/or destruction of the successive corneal layers. Strong alkali substances attack membrane lipids, causing necrosis and enhancing penetration of the substance to deeper tissue layers. The cations also react with the carboxyl groups of glycosaminoglycans and collagen, the latter reaction leading to hydration of the collagen matrix and corneal swelling. The cornea may appear clouded or become opaque immediately after exposure as a result of stromal edema and changes to, or precipitation of, proteoglycans. The denaturing of the collagen and loss of protective covering of the glycosoaminoglycans is thought to make the collagen fibrils more susceptible to subsequent enzymatic degradation. Intraocular pressure may increase as a result of initial hydration of the collagen fibrils and later through the blockage of aqueous humor outflow. Conversely, if the alkali burn extends to involve the ciliary body, the intraocular pressure may decrease due to reduced formation of aqueous humor. The acute phase of damage is typically followed by initiation of corneal repair. The repair process may involve corneal neovascularization along with regeneration of the corneal epithelium. Approximately 2 to 3 weeks after alkali burns, however, damaging ulceration of the corneal stroma often occurs. The formation of these lesions is related to the inflammatory infiltration of polymorphonuclear leukocytes and fibroblasts and the release of degratory proteolytic enzymes. Clinically, anti-inflammatory

therapy limits ulcerative damage. Stromal ulceration usually stops when the corneal epithelium is restored (Grant, 1986; Potts, 1996).

Organic Solvents

When organic solvents are splashed into the eye, the result is typically a painful immediate reaction. As in the case of acids and bases, exposure of the eye to solvents should be treated rapidly with abundant water irrigation. Highly lipophilic solvents can damage the corneal epithelium and produce swelling of the corneal stroma. Most organic solvents do not have a strongly acid or basic pH and therefore cause little in the way of chemical burns to the cornea. In most cases, the corneal epithelium will be repaired over the course of a few days and there will be no residual damage. Exposure to solvent vapors may produce small transparent vacuoles in the corneal epithelium, which may be asymptomatic or associated with moderate irritation and tearing (Grant, 1986; Potts, 1996).

Surfactants

These compounds have water-soluble (hydrophilic) properties at one end of the molecule and lipophilic properties at the other end that help to dissolve fatty substances in water and also serve to reduce water surface tension. The widespread use of these agents in soaps, shampoos, detergents, cosmetics, and similar consumer products leads to abundant opportunities for exposure to ocular tissues. Many of these agents may be irritating or injurious to the eye. The hydrophilic portion of these compounds may be anionic, cationic, or neutral. In general the cationic substances tend to be stronger irritants and more injurious that the other types, and anionic compounds more so than neutral ones (Grant, 1986; Potts, 1996). Because these compounds are by design soluble in both aqueous and lipid media, they readily penetrate the sandwiched aqueous and lipid barriers of the cornea (see discussion of ocular pharmacodynamics and pharmacokinetics, above). This property has implications in drug delivery; for example, low concentrations of the preservative benzalkonium chloride to ophthalmic solutions enhances ocular penetration of topically applied medications (Jaanus et al., 1995).

TARGET SITES AND MECHANISMS OF ACTION: LENS

The lens of the eye plays a critical role in focusing the visual image on the retina. While the cornea is the primary refractive surface for bending incoming light rays, the lens is capable of being reshaped to adjust the focal point to adapt for the distance of visual objects. The lens is a biconvex transparent body, encased in an elastic capsule, and located between the pupil and the vitreous humor (Fig. 17-1). The mature lens has a dense inner nuclear region surrounded by the lens cortex. The high transparency of the lens to visible wavelengths of light is a function of its chemical composition, approximately two-thirds water and one-third protein, and the special organizational structure of the lenticular proteins. The water-soluble crystallins are a set of proteins particular to the lens that, through their close intermolecular structure, give the lens both transparency and the proper refractive index. The lens fibers are laid down during development, as the epithelial cells grow and elongate along meridian pathways between the anterior and posterior poles of the lens. As the epithelial cells continue to grow, the nuclei recede and, in the central portions of the lens, disappear, such that the inner lens substance is composed of nonnucleated cells that form long proteinaceous fibers. The lens fibers are arranged within the lens in an onion-like fashion of concentric rings that have a prismatic arrangement in cross section. The regular geometric organization of the lens fibers is essential for the refractive index and transparency of the lens. At birth, the lens has no blood supply and no innervation. Nutrients are provided from the aqueous and vitreous fluids and are transported into the lens substance through a system of intercellular gap-type junctions. The lens is a metabolically active tissue that maintains careful electrolyte and ionic balance. The lens continues to grow throughout life, with new cells added to the epithelial margin of the lens as the older cells condense into a central nuclear region. The dramatic growth of the lens is illustrated by increasing its weight, from approximately 150 mg at 20 years of age to approximately 250 mg at 80 years of age (Patterson and Delamere, 1992).

Cataracts are decreases in the optical transparency of the lens that ultimately can lead to functional visual disturbances. They are the leading cause of blindness worldwide, affecting an estimated 30 to 45 million people. In the United States, approximately 400,000 people develop cataracts each year, which accounts for about 35 percent of existing visual impairments (Patterson and Delamere, 1992). Cataracts can occur at any age; they can also be congenital (Rogers and Chernoff, 1988). However, they are much more frequent with advancing age. Senile cataracts develop most frequently in the cortical or nuclear regions of the lens and less frequently in the posterior subcapsular region of the lens. Senile cataracts in the cortical region of the lens are associated with disruptions of water and electrolyte homeostasis, while nuclear cataracts are characterized by an increase in the water-insoluble fraction of lens proteins (Patterson and Delamere, 1992).

Recent studies indicate that both genetic and environmental factors contribute to age-related and environmentally mediated cataracts and that these involve several different mechanisms of action (Hammond et al., 2000; Ottonello et al., 2000; Spector, 2000). Risk factors for the development of cataracts include aging, diabetes, low antioxidant levels, and exposure to a variety of environmental factors. Environmental factors include exposure to UV radiation and visible light, trauma, smoking, and exposure to a large variety of topical and systemic drugs and chemicals (e.g., Grant, 1986; Leske et al., 1991; Taylor and Nowell, 1997; Spector, 2000). Several different mechanisms of action have been hypothesized to account for the development of cataracts. These include the disruption of lens energy metabolism, hydration and/or electrolyte balance, the occurrence of oxidative stress due to the generation of free radicals and reactive oxygen species, and the occurrence of oxidative stress due a decrease in antioxidant defense mechanisms (Giblin, 2000; Ottonello et al., 2000; Spector, 2000). The antioxidants include glutathione, superoxide dismutase, catalase, ascorbic acid, and vitamin E. The generation of reactive oxygen species leads to oxidation of lens membrane proteins and lipids. A critical pathway in the development of high-molecular-weight aggregates involves the oxidation of protein thiol groups, particularly in methionine or cysteine amino acids, that leads to the formation of polypeptide links through disulfide bonds, and in turn, high-molecular-weight protein aggregates (Patterson and Delamere, 1992; Ottonello et al., 2000; Spector, 2000). These large aggregations of proteins can attain a size sufficient to scatter light, thus reducing lens transparency. Oxidation of membrane lipids and proteins may also impair membrane transport and permeability.

Corticosteroids

Topical or systemic treatment with corticosteroids causes cataracts (Urban and Cotlier, 1986). Observable opacities begin in the posterior subcapsular region of the lens and progress into the cortical region as the size of the lesion increases. Development of cataracts in individuals varies as a function of total dose of the drug, age, and the nature of the individual's underlying disease. Recently it was estimated that 22 percent of patients receiving corticosteroid immunosuppressive therapy for renal transplants experienced cataracts as a side effect of therapy (Veenstra et al., 1999). The use of inhaled corticosteroids—commonly prescribed asthma therapy—was once thought to be without this risk, but recent epidemiologic evidence documents a significant association between inhaled steroidal therapy and development of nuclear and posterior subcapsular cataracts (Cumming et al., 1997; Cumming and Mitchell, 1999). There are two proposed mechanisms through which corticosteroids might cause cataracts. One proposal involves disruption of the lens epithelium electrolyte balance through inhibition of Na^+,K^+-ATPase. The regular hexagonal array structure of normal lens epithelial cells is disrupted and appears reticulated, while gaps appear between the lateral epithelial cell borders in lenses of humans with steroid-induced cataracts (Karim et al., 1989). Another theory is that corticosteroid molecules react with lens crystallin proteins through Schiff base reactions between the carbonyl group of the steroid and protein amino groups, with subsequent rearrangement into stable products (Urban and Cotlier, 1986). The resulting covalent corticosteroid-crystallin adducts would be high-molecular-weight light-scattering complexes. Whichever mechanism is responsible, these results illustrate the importance of routine ophthalmologic screening of patients receiving chronic corticosteroid therapy.

Light

The most important oxidizing agents are visible light and UV radiation, particularly UV-A (320 to 400 nm) and UV-B (290 to 320 nm), and other forms of electromagnetic radiation. Light- and UV-induced photooxidation leads to generation of reactive oxygen species, and oxidative damage that can accumulate over time. Higher-energy UV-C (100 to 290 nm) is even more damaging. At sea level, the atmosphere filters out virtually all UV-C and all but a small fraction of UV-B derived from solar radiance (AMA Report, 1989). The cornea absorbs about 45 percent of light with wavelengths below 280 nm, but only about 12 percent between 320 and 400 nm. The lens absorbs much of the light between 300 and 400 nm and transmits 400 nm and above to the retina (Patterson and Delamere, 1992). Absorption of light energy in the lens triggers a variety of photoreactions, including the generation of fluorophores and pigments that lead to the yellow-brown coloration of the lens. Sufficient exposure to infrared radiation, as occurs to glassblowers, or microwave radiation will also produce cataracts through direct heating of the ocular tissues.

Naphthalene

Accidental exposure to naphthalene results in cortical cataracts and retinal degeneration (Grant, 1986; Potts, 1996). Naphthalene itself is not cataractogenic; instead, the metabolite 1,2-dihydro-1,2-dihydroxynaphthalene (naphthalene dihydrodiol) is the cataract-inducing agent (van Heyningen and Pirie, 1967). Subsequent studies using biochemical and pharmacologic techniques, in vitro assays, and transgenic mice showed that aldose reductase in the rat lens is a major protein associated with naphthalene dihydrodiol dehydrogenase activity and that lens aldose reductase is the enzyme responsible for the formation of naphthalene dihydrodiol (Sato, 1993; Lee and Chung, 1998; Sato et al., 1999). In addition, in vivo and in vitro studies have shown that aldose reductase inhibitors prevent naphthalene-induced cataracts

(Lou et al., 1993; Sato et al., 1999). Finally, there is a difference in naphthalene-induced cataract formation between albino and pigmented rats, with the latter showing a faster onset and more uniform cataract (Murano et al., 1993).

Phenothiazines

It has been known since the 1950s that schizophrenics receiving phenothiazine drugs as anti-psychotic medication develop pigmented deposits in their eyes and skin (Grant, 1986; Potts, 1996). The pigmentation begins as tiny deposits on the anterior surface of the lens and progresses, with increasing dose, to involve the cornea as well. The phenothiazines combine with melanin to form a photosensitive product that reacts with sunlight, causing formation of the deposits. The amount of pigmentation is related to the dose of the drug, with the annual yearly dose being the most predictive dose metric (Thaler et al., 1985). More recent epidemiologic evidence demonstrates a dose-related increase in the risk of cataracts from use of phenothiazine-like drugs, including both antipsychotic drugs such as chlorpromazine and nonantipsychotic phenothiazines (Issac et al., 1991).

TARGET SITES AND MECHANISMS OF ACTION: RETINA

The adult mammalian retina is a highly differentiated tissue containing nine distinct layers plus the RPE, ten major types of neurons, and three cells with glial functions (Fig. 17-1). The nine layers of the neural retina, which originate from the cells of the inner layer of the embryonic optic cup, are the nerve fiber layer (NFL), ganglion cell layer (GCL), inner plexiform layer (IPL), inner nuclear layer (INL), outer plexiform layer (OPL), outer nuclear layer (ONL), rod and cone photoreceptor inner segment layer (RIS; CIS), and the rod and cone photoreceptor outer segment layer (ROS; COS). The RPE, which originates from the cells of the outer layer of the embryonic optic cup, is a single layer of cuboidal epithelial cells that lies on Bruch's membrane adjacent to the vascular choroid. Between the RPE and photoreceptor outer segments lies the subretinal space, which is similar to the brain ventricles. The ten major types of neurons are the rod (R) and cone (C) photoreceptors, ON-rod and ON-cone bipolar cells (BC), OFF-cone bipolar cells, horizontal cells (HC), numerous subtypes of amacrine cells (AC), an interplexiform cell (IPC), and ON-RGCs and OFF-RGCs. The three cells with glial functions are the Müller cells (MC), fibrous astrocytes, and microglia. The somas of the MCs are in the INL. The end feet of the MCs in the proximal or inner retina along with a basal lamina form the internal limiting membrane (ILM) of the retina, which is similar to the pial surface of the brain. In the distal retinal, the MC end feet join with the photoreceptors and zonula adherens to form the external limiting membrane (ELM), which is located between the ONL and RIS/CIS. The interested reader is referred to the excellent references in the Introduction as well as to numerous outstanding websites devoted exclusively to the retina (e.g., http://webvision.umh.es/webvision/ intro.html; http://cvs.anu.edu.au/; http://retina.anatomy.upenn.edu/~lance/retina/retina.html) for basic information on the anatomic, biochemical, cell and molecular biological, and physiologic aspects of retinal structure and function.

The mammalian retina is highly vulnerable to toxicant-induced structural and/or functional damage due to (1) the presence of a highly fenestrated choriocapillaris that supplies the distal or outer retina as well as a portion of the inner retina; (2) the very high rate of oxidative mitochondrial metabolism, especially that in the photoreceptors (Linsenmeier, 1986; Ahmed et al., 1993; Medrano and Fox, 1994, 1995; Braun et al., 1995; Winkler, 1995; Shulman and Fox, 1996); (3) high daily turnover of rod and cone outer segments (LaVail, 1976; Rodieck, 1998); (4) high susceptibility of the rod and cones to degeneration due to inherited retinal dystrophies as well as associated syndromes and metabolic disorders (Ogden and Schachat, 1989; Hart, 1992; von Soest et al., 1999); (5) presence of specialized ribbon synapses and synaptic contact sites (Dowling, 1987; Ogden and Schachat, 1989; Cohen, 1992; Rodieck, 1998); (6) presence of numerous neurotransmitter and neuromodulatory systems, including extensive glutamatergic, GABAergic and glycinergic systems (Rauen et al., 1996; Brandstätter et al., 1998; Rodieck, 1998; Kalloniatis and Tomisich, 1999; Winkler et al., 1999); (7) presence of numerous and highly specialized gap junctions used in the information signaling process (Cohen, 1992; Cook and Becker, 1995; Rodieck, 1998); (8) presence of melanin in the choroid and RPE and also in the iris and pupil (Meier-Rouge, 1972; Potts, 1996); (9) a very high choroidal blood flow rate, as high as ten times that of the gray matter of the brain (Alm, 1992; Cohen, 1992); and (10) the additive or synergistic toxic action of certain chemicals with ultraviolet and visible light (Dayhaw-Barker et al., 1986; Backstrom et al., 1993).

The retina is also an excellent model system for studying the effects of chemicals on the developing and mature CNS. Its structure-function relations are well established. The neurogenetic steps of development of the neurons and glial components are well characterized. The development of the CNS and most retinal cells occurs early during gestation in humans (Hendrickson, 1992; Hendrickson and Drucker, 1992) and continues for an additional 7 to 14 days postnatally in the rat (Dobbing and Sands, 1979; Raedler and Sievers, 1975). Therefore, the rodent retina has relevance for chemical exposure during the early gestation period in humans as well as during early postnatal development. The retina contains a wide diversity of synaptic transmitters and second messengers whose developmental patterns are well described. Moreover, the rodent retina is easily accessible, it has most of the same anatomical and functional features found in the developing and mature human retina, and the rat rod pathway is similar to that in other mammals (Dowling, 1987; Finlay and Sengelbaub, 1989; Berman, 1991; Chun et al., 1993). Finally, rat rods have similar dimensions, photochemistry, and photocurrents as human and monkey rods (Baylor et al., 1984; Schnapf et al., 1988). These general and specific features underscore the relevance and applicability of using the rodent retina to investigate the effects of chemicals on this target site as well as a model to investigate the neurotoxic effects of chemicals during development.

Each of the retinal layers can undergo specific as well as general toxic effects. These alterations and deficits include but are not limited to visual field deficits, scotopic vision deficits such as night blindness and increases in the threshold for dark adaptation, cone-mediated (photopic) deficits such as decreased color perception, decreased visual acuity, macular and general retina edema, retinal hemorrhages and vasoconstriction, and pigmentary changes. The list of chemicals and drugs that cause retinal alterations is extensive, as evidenced by an examination of Grant's *Toxicology of the Eye* (Grant, 1986) and Dr. Potts' chapter entitled "Toxic Responses of the Eye" in an earlier edition of the present work (1996). In addition, the review chapter by Jaanus et al. (1995) discusses the adverse retinal effects of therapeutic systemic drugs. The main aim of this section is to discuss in detail several chemicals and drugs (1) that are currently used pharmacological agents or environmentally relevant neurotoxicants; (2) whose behavioral, physiologic, and/or pathologic effects on retina are known; and (3) whose retinal site(s) and/or mechanism of action are well characterized. In addition, the effects of organic solvents and organophosphates on retinal function and vision are discussed, as these are emerging areas of concern.

The chemical- and drug-induced alterations in retinal structure and function are grouped into two major categories. The first category focuses on retinotoxicity of systemically administered therapeutic drugs. Four major drugs are discussed in detail: chloroquine/hydroxychloroquine, digoxin/digitoxin, indomethacin, and tamoxifen. The second category focuses on well-known neurotoxicants that produce retinotoxicity: inorganic lead, methanol, selected organic solvents, and organophosphates. See Chap. 16, "Toxic Responses of the Nervous System," and Chap. 23, "Toxic Effects of Metals," for information on the effects of lead on the brain and other target organs. See Chap. 16 and Chap. 24, "Toxic Effects of Solvents and Vapors," for additional information on methanol and the organic solvents discussed below.

Retinotoxicity of Systemically Administered Therapeutic Drugs

Chloroquine and Hydroxychloroquine Two of the most extensively studied retinotoxic drugs are chloroquine (Aralen) and hydroxychloroquine (Plaquenil). The first cases of chloroquine-induced retinopathy were reported more than 40 years ago (Jaanus et al., 1995; Potts, 1996). These 4-aminoquinoline derivatives are used as antimalarial and anti-inflammatory drugs. The low-dose therapy used for malaria is essentially free from toxic side effects; however, the chronic, high-dose therapy used for rheumatoid arthritis, and discoid and systemic lupus erythematosus (initially 400 to 600 mg/day for 4 to 12 weeks and then 200 to 400 mg day; Ellsworth et al., 1999) can cause irreversible loss of retinal function. Chloroquine, its major metabolite desethylchloroquine, and hydroxychloroquine have high affinity for melanin, which results in very high concentrations of these drugs accumulating in the choroid and RPE, ciliary body, and iris during and following drug administration (Rosenthal et al., 1978; Potts, 1996). Prolonged exposure of the retina to these drugs, especially chloroquine, may lead to an irreversible retinopathy. In fact, small amounts of chloroquine and its metabolites were excreted in the urine years after cessation of drug treatment (Bernstein, 1967). Approximately 20 to 30 percent of patients who received high doses of chloroquine exhibited some type of retinal abnormality, while 5 to 10 percent showed severe changes in retinal function (Burns, 1966; Potts, 1996; Shearer and Dubois, 1967; Sassaman et al., 1970; Krill et al., 1971). Hydroxychloroquine is now the drug of choice for treatment of rheumatic diseases because it has fewer side effects and less ocular toxicity. Doses less than 400 mg per day appear to produce little or no retinopathy even after prolonged therapy (Johnson and Vine, 1987).

The clinical findings accompanying chloroquine retinopathy can be divided into early and late stages. The early changes include (1) the pathognomonic "bull's-eye retina" visualized as a dark, central pigmented area involving the macula, surrounded by a pale ring of depigmentation, which, in turn, is surrounded by another ring of pigmentation; (2) a diminished EOG; (3) possible granular pigmentation in the peripheral retina; and (4) visual complaints such as blurred vision and problems discerning letters or words. Late-stage findings, which can occur during or even following cessation of drug exposure, include (1) a progressive scotoma, (2) constriction of the peripheral fields commencing in the upper temporal quadrant, (3) narrowing of the retinal artery, (4) color and night blindness, (5) absence of a typical retinal pigment pattern, and (6) very abnormal EOGs and ERGs. These late-stage symptoms are irreversible. Interestingly, dark adaptation is relatively normal even during the late stages of chloroquine retinopathy, which helps distinguish the peripheral retinal changes from those observed in patients with retinitis pigmentosa (Bernstein, 1967).

In humans and monkeys, long-term chloroquine administration results in sequential degeneration of the RGCs, photoreceptors, and RPE and the eventual migration of RPE pigment into the ONL and OPL. In addition, in the RPE there is a thickening of the RPE layer, an increase in the mucopolysaccharide and sulfhydryl group content, and a decrease in activity of several enzymes (Potts, 1996; Ramsey and Fine, 1972; Rosenthal et al., 1978). Although the molecular mechanism of action is unknown, it has been suggested that the primary biochemical mechanism is inhibition of protein synthesis (Bernstein, 1967).

Digoxin and Digitoxin The cardiac glycosides digoxin (Lanoxin) and digitoxin (Crystodigin) are digitalis derivatives used in the treatment of congestive heart disease and in certain cardiac arrhythmias. As part of the extract of the plant foxglove, digitalis was recommended for heart failure (dropsy) over 200 years ago. Digitalis-induced visual system abnormalities such as decreased vision, flickering scotomas, and altered color vision were documented during that time (Withering, 1785). Approximately 20 to 60 percent of patients with cardiac glycoside serum levels in the therapeutic range and 50 to 80 percent of the patients with cardiac glycoside serum levels in the toxic range complain of visual system disturbances within 2 weeks after the onset of therapy (Robertson et al., 1966a; Aronson and Ford, 1980; Rietbrock and Alken, 1980; Haustein et al., 1982; Piltz et al., 1993; Duncker et al., 1994). Digoxin produces more toxicity than digitoxin due to its greater volume of distribution and plasma protein binding (Haustein and Schmidt, 1988). The most frequent visual complaints are color vision impairments and hazy or snowy vision, although complaints of flickering light, colored spots surrounded by bright halos, blurred vision, and glare sensitivity also are reported. The color vision disturbances have been confirmed with the Farnsworth-Munsell 100 Hue Test (Aronson and Ford, 1980; Rietbrock and Alken, 1980; Haustein et al., 1982; Haustein and Schmidt, 1988; Duncker and Krastel, 1990). Clinical examinations show that these patients have decreased visual acuity and central scotomas but no funduscopic changes. ERG analysis revealed a depressed critical flicker fusion frequency function, reduced rod and cone amplitudes, increased rod and cone implicit times, and elevated rod and cone thresholds (Robertson et al., 1966a; Robertson et al., 1966b; Alken and Belz, 1984; Duncker and Krastel, 1990; Madreperla et al., 1994). Taken together, these ophthalmologic, behavioral, and electrophysiologic findings demonstrate that the photoreceptors are a primary target site of the cardiac glycosides digoxin and digitoxin.

The above results suggest that cone photoreceptors are more susceptible to the effects of cardiac glycosides than rod photoreceptors. To directly test this hypothesis, Madreperla et al. (1994) conducted electrophysiologic (suction electrode) experiments with isolated tiger salamander (*Ambystoma tigrinum*) rods and cones exposed to different physiologically and toxicologically relevant concentrations of digoxin in the bathing solution. Following a single light flash of saturating intensity, rods and cones exhibited concentration-dependent decreases in the peak light (current) response. The cones, however, were about 50 times more sensitive to digoxin and were impaired to a greater degree at the same digoxin concentration than the rods. Neither the rods or cones recovered to their dark-adapted baseline following the short-duration saturating light flash. The rods, however, appeared to recover faster and more completely than the cones. Moreover, following a return to control Ringer's solution, the photoreceptors still did not recover to their dark-adapted baseline response level. This latter finding correlates with the slow recovery of the ERG seen in patients following termination of digoxin exposure (Robertson et al., 1966b; Duncker and Krastel, 1990; Madreperla et al., 1994) and is most likely due to the high affinity and slow off-rate of digoxin binding to the cardiac glycoside site located on the extracellular side of the catalytic a-subunit of the Na$^+$,K$^+$-ATPase enzyme (Sweadner, 1989).

Digitalis glycosides, like ouabain, are potent inhibitors of retinal Na$^+$,K$^+$-ATPase (Winkler and Riley, 1977; Fox et al., 1991b; Ottlecz et al., 1993; Shulman and Fox, 1996). Digoxin binding studies show that the retina has the highest number of Na$^+$,K$^+$-ATPase sites of any ocular tissue, even higher than those of brain (Lissner et al., 1971; Lufkin et al., 1967). There are three different isoforms of the a subunit of Na$^+$,K$^+$-ATPase (i.e., a1, a2, and a3), and they differ most significantly in their sensitivity to cardiac glycoside inhibition (Sweadner, 1989). In the rat retina, the a1-low and a3-high ouabain affinity isoforms of the enzyme account for ³97 percent of the Na$^+$,K$^+$-ATPase mRNA. The a3 isoform is localized to rat photoreceptors, horizontal cells, and bipolar cells. Photoreceptors predominantly express the a3 mRNA (~85 percent), a small amount of a1 mRNA (~15 percent), and almost no detectable a2 mRNA. Electron microscopic immunocytochemistry studies reveal that the a3 isoform is localized exclusively to the plasma membrane of the rat photoreceptor inner segments (McGrail and Sweadner, 1989; Schneider and Kraig, 1990; Schneider et al., 1990). The a3 isozyme accounts for most of the rod Na$^+$,K$^+$-ATPase activity (Shulman and Fox, 1996). The rat rod photoreceptor Na$^+$,K$^+$-ATPase–specific activity is approximately threefold higher than whole retinal (Fox et al., 1991b; Shulman and Fox, 1996) or whole brain values (Marks and Seeds, 1978). This is also reflected in the two- to threefold greater ouabain-sensitive oxygen consumption in the dark-adapted outer retina relative to the whole or inner retina, respectively (Medrano and Fox, 1995; Shulman and Fox, 1996). The rod Na$^+$,K$^+$-pump maintains the dark current responsible for the light response and operates near V_{max} in the dark-adapted or depolarized state, due to the high flux of Na$^+$ ions into the rod outer segments through the cGMP gated nonselective cation channels. In addition, light adaptation in mammalian rods is critically dependent upon Na$^+$,K$^+$-ATPase activity (Demontis et al., 1995). During constant illumination, the rod Na$^+$,K$^+$-pump is slowed in response to a decrease in intracellular Na$^+$ (Demontis et al., 1995) and a dopamine-mediated inhibition that is independent of the intracellular Na$^+$ concentration (Shulman and Fox, 1996). Presently there is no such information on the role of Na$^+$,K$^+$-ATPase in cones or on cone Na$^+$,K$^+$-ATPase–specific activity.

Indomethacin Indomethacin is a nonsteroidal anti-inflammatory drug with analgesic and antipyretic properties that is frequently used for the management of arthritis, gout, and musculoskeletal discomfort. It inhibits prostaglandin synthesis by inhibiting cyclooxygenase. The first cases of indomethacin-induced retinopathy were reported approximately 30 years ago (Jaanus et al., 1995; Potts, 1996). Chronic administration of 50 to 200 mg per day of indomethacin for 1 to 2 years has been reported to produce corneal opacities, discrete pigment scattering of the RPE perifoveally, paramacular depigmentation, decreases in visual acuity, altered visual fields, increases in the threshold for dark adaptation, blue-yellow color deficits, and decreases in ERG and EOG amplitudes (Burns, 1966; Burns, 1968; Henkes et al., 1972; Koliopoulos and Palimeris, 1972; Palimeris et al., 1972). Decreases in the ERG a- and b-wave amplitudes, with larger changes observed under scotopic dark-adapted than light-adapted conditions, have been reported. Upon cessation of drug treatment, the ERG waveforms and color vision changes return to near normal, although the pigmentary changes are irreversible (Burns, 1968; Henkes et al., 1972; Palimeris et al., 1972). The mechanism of retinotoxicity is unknown; however, it appears likely that the RPE is a primary target site.

Tamoxifen Tamoxifen (Nolvadex, Tamoplex), a triphenylethylene derivative, is a nonsteroidal antiestrogenic drug that competes with estrogen for its receptor sites. It is a highly effective antitumor agent used for the treatment of metastatic breast carcinoma in postmenopausal women. Tamoxifen-induced retinopathy following chronic high-dose therapy (180 to 240 mg per day for ~2 years) was first reported 20 years ago (Kaiser-Kupfer et al., 1981). At this dose, there is widespread axonal degeneration in the macular and perimacular area, as evidenced by the presence of different sized yellow-white refractile opacities in the IPL and NFL observed during fundus examination. Macular edema may or may not be present. Clinical symptoms include a permanent decrease in visual acuity and abnormal visual fields, as the axonal degeneration is irreversible (reviewed by Jaanus et al., 1995; Potts, 1996; Ah-Song and Sasco, 1997). Several prospective studies, with sample sizes ranging from 63 to 303 women with breast cancer, have shown that chronic low-dose tamoxifen (20 mg per day) can result in a small but significant increase in the incidence (£10 percent) of keratopathy (Pavlividis et al., 1992; Gorin et al., 1998; Lazzaroni et al., 1998; Noureddin et al., 1999). In addition, these studies showed that retinopathy is much less frequently observed than with high-dose therapy and, except for a few reports of altered color vision and decreased visual acuity, there were no significant alterations in visual function. Following cessation of low-dose tamoxifen therapy, most of the keratopathy and retinal alterations except the corneal opacities and retinopathy were reversible (Pavlividis et al., 1992; Gorin et al., 1998; Noureddin et al., 1999).

Retinotoxicity of Known Neurotoxicants

Inorganic Lead Inorganic lead is probably the oldest known and most studied environmental toxicant. For almost 100 years, it has been known that overt lead poisoning [mean blood lead (BPb) ³80 µg/dL] in humans produces visual system pathology and overt visual symptoms (Grant, 1986; Otto and Fox, 1993; Fox, 1998). Clinical symptoms include amblyopia, blindness, optic neuritis or atrophy, peripheral and central scotomas, paralysis of eye muscles, and decreased visual function. More recently, it has been shown that low-(BPb from 10 to 20 µg/dL) to moderate-(BPb from 21 to 60 µg/dL) level lead exposure produces scotopic and temporal visual system deficits in occupationally exposed factory workers and developmentally lead-exposed monkeys and rats (Bushnell et al., 1977; Guguchkova, 1972; Cavelleri et al., 1982; Betta et al., 1983; Signorino et al., 1983; Campara et al., 1984; Jeyaratnam et al., 1986; Fox and Farber, 1988; Lilienthal et al., 1988; Fox et al., 1991a; Fox and Katz, 1992; Otto and Fox, 1993; Lilienthal et al., 1994; Fox, 1998; Rice, 1998). Interestingly, relatively little effort has been made to understand the impact of lead-induced alterations in the visual system of children, although recent preliminary studies suggest that scotopic deficits are present (Rothenberg et al., 1999). Moreover, relatively little effort has been made to understand the impact of lead-induced alterations on retinal and central visual information processing on learning and memory in children, although these types of visual deficits can adversely affect learning and memory as well as experimental procedures used to assess these cognitive parameters (Anger et al., 1994; Hudnell et al., 1996; Walkowiak et al., 1998; Cestnick and Coltheart, 1999).

Studies in Occupationally Exposed Workers Clinical and electrophysiologic studies in lead-exposed factory workers have assessed both the site of action and extent of injury. Several cases of retrobulbar neuritis and ON atrophy have been observed following chronic moderate-level or acute high-level lead exposure (Sherer, 1935; Baghdassarian, 1968; Baloh et al., 1979; Karai et al., 1979). Most of these cases presented with fundus lesions, peripheral or paracentral scotomas while the most severe cases also had a central scotoma. Generally, the scotomas were not observed until approximately 5 years of continuous lead exposure. Interestingly, the earliest observable scotomas were not detected under standard photopic viewing conditions but became evident only under scotopic or mesopic (rod- and cone-mediated) viewing conditions. These ophthalmologic findings correlate directly with the ERG data observed in similarly exposed lead workers. No alterations in

the critical flicker fusion threshold (i.e., temporal resolution) were observed when the test was conducted under photopic conditions or when using red lights but consistent decreases in temporal resolution were observed when the test was conducted under scotopic conditions or when green lights were used (Cavelleri et al., 1982; Betta et al., 1983; Signorino et al., 1983; Campara et al., 1984; Jeyaratnam et al., 1986). Moreover, in occupationally lead-exposed workers with or without visual acuity deficits or no observable alterations following ophthalmologic examination, the sensitivity and amplitude of the a-wave and/or b-wave of the dark-adapted ERG were decreased (Guguchkova, 1972; Scholl and Zrenner, 2000). In other lead-exposed workers, one funduscopic study noted the presence of a grayish lead pigmentary deposit in the area peripheral to the optic disk margins (Sonkin, 1963).

In addition to the retinal deficits, occulomotor deficits occur in chronically lead-exposed workers who have no observable ophthalmologic abnormalities. Results from three independent studies, including a follow-up, show that the mean accuracy of saccadic eye movements is lower in lead-exposed workers and the number of overshoots are increased (Baloh et al., 1979; Spivey et al., 1980; Specchio et al., 1981; Glickman et al., 1984). In addition, these studies also revealed that the saccade maximum velocity was decreased. Moreover, one study also observed abnormal smooth pursuit eye movements in lead-exposed workers (Specchio et al., 1981). Although the site and mechanism of action underlying these alterations are unknown, they most likely result from CNS-mediated deficits.

In summary, these results suggest that occupational lead exposure produces concentration- and time-dependent alterations in the retina such that higher levels of lead directly and adversely affect both the retina and ON, whereas lower levels of lead appear to primarily affect the rod photoreceptors and the rod pathway. Interestingly, these latter clinical findings showing preferential lead-induced rod-selective deficits in sensitivity and temporal resolution are observed in both in vivo and in vitro animal studies (see below). Furthermore, these retinal and oculomotor alterations were, in most cases, correlated with the blood lead levels and occurred in the absence of observable ophthalmologic changes, CNS symptoms, and abnormal performance test scores. Thus, these measures of temporal visual function may be among the most sensitive for the early detection of the neurotoxic effects of inorganic lead.

In Vivo and in Vitro Animal Studies Lead exposure to adult and developing animals produces retinal damage and functional deficits. The degree and extent of these alterations depends upon the dose, age, and duration of lead exposure. High-level lead exposure to adult rabbits for 60 to 300 days (Hass et al., 1964; Brown, 1974; Hughes and Coogan, 1974) and to newborn rats for 60 days (Santos-Anderson et al., 1984) resulted in focal necrosis of the rod inner and outer segments, necrosis in the inner nuclear layer and Müller cells, and lysosomal inclusions in the RPE. In addition, high-level lead exposure to mice and rats from birth to weaning resulted in hypomyelination of the ON and a reduction in its diameter; but, interestingly, there were no changes in the sciatic nerve (Tennekoon et al., 1979; Toews et al., 1980). Newborn monkeys exposed to high levels of lead for 6 years had no changes in ON diameter or myelination, although visual cortex neuronal volume and branching were decreased (Reuhl et al., 1989). Rhesus monkeys exposed prenatally and postnatally to moderate or high levels of lead for 9 years, followed by almost 2 years of no lead exposure, had decreased tyrosine hydroxylase immunoreactivity in the large dopaminergic amacrine cells and a complete loss of tyrosine hydroxylase immunoreactivity in small subset of amacrine cells (Kohler et al., 1997). These results suggest that long-term lead exposure produces a decrease in tyrosine hydroxylase synthesis, a finding consistent with other studies (Lasley and Lane, 1988; Jadhav and Ramesh, 1997), and/or a loss of a subset of tyrosine hydroxylase–positive amacrine cells, a finding consistent with recent in vitro work (Scortegagna and Hanbauer, 1997). In contrast to these studies, 6 weeks of moderate-level lead exposure to adult rats (Fox et al., 1997) and 3 weeks of low- or moderate-level lead exposure to neonatal rats from birth to weaning produces rod- and bipolar cell–selective apoptotic cell death (Fox and Chu, 1988; Fox et al., 1997). Moreover, recent results reveal that brief (15-min) exposure of isolated adult rat retinas to nanomolar to micromolar Pb^{2+}, concentrations regarded as pathophysiologically relevant (Cavalleri et al., 1984; Al-Modhefer et al., 1991), resulted in rod-selective apoptosis (He et al., 2000). By extension, these results suggest that the triggering event (initiating phase) and the execution phase of rod and bipolar cell death share common underlying biochemical mechanisms.

Results from several studies suggest that an elevated level of rod photoreceptor Ca^{2+} and/or Pb^{2+} plays a key role in the process of apoptotic rod cell death in humans and animals during inherited retinal degenerations, retinal diseases and injuries, chemical exposure, and lead exposure. These include patients with retinitis pigmentosa and cancer-associated retinopathy (Thirkill et al., 1987; van Soest et al., 1999), retinal degeneration (*rd*) mice (Chang et al., 1993; Fox et al., 1999), rats injected with antirecoverin monoclonal antibodies (Adamus et al., 1998), rats with hypoxic-ischemic injury (Crosson et al., 1990), rats with light-induced damage (Edward et al., 1991), and lead-exposed rats (Fox and Chu, 1988; Fox et al., 1997, 1999). In addition, moderate-level Pb^{2+} exposure produces apoptotic neuronal cell death in primary cultured cells (Oberto et al., 1996; Scortegagna et al., 1997). In vivo and in vitro data suggest that Pb^{2+} produces a dose (concentration)-dependent inhibition of rod cGMP phosphodiesterase (PDE), a resultant elevation of rod cGMP (Fox and Farber, 1988; Fox et al., 1991a; Srivastava et al., 1995a; Srivastava et al., 1995b; Fox et al., 1997), which gates the nonselective cation channel of the rod photoreceptor outer segments (Yau and Baylor, 1989), and an elevation of the rod Ca^{2+} concentration (Fox and Katz, 1992; Medrano and Fox, 1994; He et al., 2000). Detailed kinetic analysis revealed that picomolar Pb^{2+} competitively and directly inhibits rod cGMP PDE relative to millimolar concentrations of Mg^{2+} (Srivastava et al., 1995a, 1995b). In addition, nanomolar Pb^{2+} can elevate the rod Ca^{2+} (and Pb^{2+}) concentration via its competitive inhibition of retinal Na$^+$,K$^+$-ATPase relative to MgATP (Fox et al., 1991b). Once inside the rod, both Ca^{2+} and Pb^{2+} enter the mitochondria via the ruthenium red-sensitive Ca^{2+} uniporter and induce mitochondrial depolarization [as measured by the mitochondrial membrane potential sensitive dye JC-1 (5,5',6,6',-tetrachloro- 1,1',3,3',-tetraethylbenzimidazolycarbocyanine iodide)], swelling, and cytochrome *c* release (He et al., 2000). The effects of Ca^{2+} and Pb^{2+} were additive and blocked completely by the mitochondrial permeability transition pore inhibitor cyclosporin A, whereas the calcineurin inhibitor FK506 had no effect. Following cytochrome *c* release, caspase-9 and caspase-3 are sequentially activated. The caspase-9 inhibitor LEHD-fmk (carbobenzoxy-Leu-Glu-His-Asp-CH$_2$F) and caspase-3 inhibitor DEVD-fmk (carbobenzoxy-Asp-Glu-Val-Asp-CH$_2$F)—but not the caspase-8 inhibitor IETD-fmk (carbobenzoxy-Ile-Glu-Thr-Asp-CH$_2$F)—blocked the postmitochondrial events. There was no evidence of oxidative stress or lipid peroxidation in this model, as the levels of reduced and oxidized glutathione and pyridine nucleotides as well as several lipid parameters in rods were unchanged. These results demonstrate that rod mitochondria are the target site for Ca^{2+} and Pb^{2+}. This is consistent with numerous studies from different tissues demonstrating that lead is preferentially associated with mitochondria and particularly with the inner membrane and matrix fractions (Barltrop et al., 1971; Bull, 1980; Pounds, 1984). Taken together, the results suggest that Ca^{2+} and Pb^{2+} bind to the internal divalent metal binding site of the mitochondrial permeability transition pore (Szabo et al., 1992) and subsequently open it, which initiates the cytochrome *c*–caspase cascade of apoptosis in rods (He et al., 2000).

In vitro extracellular and intracellular electrophysiologic recordings in isolated whole retinas or photoreceptors reveal that nanomolar to micromolar concentrations of lead chloride selectively depress the amplitude and absolute sensitivity of the rod but not cone photoreceptor potential (Fox and Sillman, 1979; Sillman et al., 1982; Tessier-Lavigne et al., 1985; Frumkes and Eysteinsson, 1988). These electrophysiologic results are similar to the ERG alterations observed in occupationally lead-exposed workers (Cavelleri et al., 1982; Betta et al., 1983; Signorino et al., 1983; Campara et al., 1984; Jeyaratnam et al., 1986) and in adult rats exposed to low and moderate levels of lead only during development (Fox and Farber, 1988; Fox and Rubinstein, 1989; Fox et al., 1991a; Fox and Katz, 1992). In addition, these developmentally lead-exposed rats exhibit rod-mediated increases in dark and light adaptation time, decreases in critical flicker fusion frequency (i.e., temporal resolution), decreases in relative sensitivity, and increases in a- and b-wave latencies (Fox and Farber, 1988; Fox and Rubinstein, 1989; Fox et al., 1991a; Fox and Katz, 1992) and decreases in the temporal response properties of both sustained (X-type) and transient (Y-type) RGCs, such as decreased optimal temporal frequency and temporal resolution (Ruan et al., 1994). By extension, these results suggest that there is a common underlying biochemical mechanism responsible for these rod-mediated deficits. In vivo and in vitro data suggest that lead-induced inhibition of cGMP PDE and resultant elevation of rod Ca^{2+} underlies the ERG deficits (Fox and Katz, 1992; Medrano and Fox, 1994; Fox et al., 1997; He et al., 2000). Finally, rod-mediated alterations in dark adaptation and b-wave amplitude are also observed in adult rats and monkeys with prenatal and lifetime moderate- and high-level lead exposure (Hennekes et al., 1987; Lilienthal et al., 1988; Lilienthal et al., 1994. In the lead-exposed monkeys, the amplitude of the scotopic b-wave was increased—an effect hypothesized to result from the loss of dopaminergic amacrine cells or their processes (Lilienthal et al., 1994; Kohler et al., 1997). If rods and blue-sensitive cones in humans exhibit the same sensitivity to a lead-induced inhibition of cGMP-PDE as they do to the drug-induced inhibition of cGMP-PDE (Zrenner and Gouras, 1979; Zrenner et al., 1982). Fox and Farber (1998) predicted that blue-cone color vision deficits as well as scotopic deficits may be found in adults and children exposed to lead. Recently, S- (or blue-) cone deficits were observed in an occupationally lead-exposed worker (Scholl and Zrenner, 2000).

Methanol Methanol is a low-molecular-weight (32), colorless and volatile liquid that is widely used as an industrial solvent; a chemical intermediate; a fuel source for picnic stoves, racing cars, and soldering torches; an antifreeze agent; and an octane booster for gasoline. The basic toxicology and references can be found in two thorough reviews (Tephly and McMartin, 1984; Eells, 1992). Briefly, methanol is readily and rapidly absorbed from all routes of exposure (dermal, inhalation, and oral), easily crosses all membranes, and thus is uniformly distributed to organs and tissues in direct relation to their water content. Following different routes of exposures, the highest concentrations of methanol are found in the blood, aqueous and vitreous humor, and bile as well as the brain, kidneys, lungs, and spleen. In the liver, methanol is oxidized sequentially to formaldehyde by alcohol dehydrogenase in human and nonhuman primates or by catalase in rodents and then to formic acid. It is excreted as formic acid in the urine or oxidized further to carbon dioxide and then excreted by the lungs. Formic acid is the toxic metabolite that mediates the metabolic acidosis as well as the retinal and ON toxicity observed in humans, monkeys, and rats with a decreased capacity for folate metabolism (Tephly and McMartin, 1984; Murray et al., 1991; Eells, 1992; Lee et al., 1994a; Lee et al., 1994b; Garner et al., 1995a; Garner et al., 1995b; Eells et al., 1996; Seme et al., 1999).

Human and nonhuman primates are highly sensitive to methanol-induced neurotoxicity due to their limited capacity to oxidize formic acid. The toxicity occurs in several stages. It first occurs as a mild CNS depression, followed by an asymptomatic 12- to 24-h latent period, followed by a syndrome consisting of formic acidemia, uncompensated metabolic acidosis, ocular and visual toxicity, coma, and possibly death (Tephly and McMartin, 1984; Eells, 1992). The treatment of methanol

poisoning involves both combating acidosis and preventing methanol oxidation, but it is not discussed further here. Experimental rats have been made as sensitive to acute methanol exposure as primates by using two different, but related, procedures that effectively reduce the levels of hepatic tetrahydrofolate. One study used a brief (4 h) conditioning and then continuous exposure (60 h) to subanesthetic concentrations of nitrous oxide to inhibit methionine synthase and reduce the level of hepatic tetrahydrofolate (Murray et al., 1991; Eells et al., 1996; Seme et al., 1999). The other fed rats a folate-deficient diet for 18 weeks (Lee et al., 1994a; Lee et al., 1994b). Administration of methanol to these rats with a decreased capacity for folate metabolism resulted in toxic blood formate concentrations of 8 to 16 mM (Murray et al., 1991; Lee et al., 1994a; Lee et al., 1994b; Garner et al., 1995a; Garner et al., 1995b; Eells et al., 1996; Seme et al., 1999). Permanent visual damage occurs in humans and monkeys when the blood folate levels exceed 7 mM (Tephly and McMartin, 1984; Eells, 1992).

Acute methanol poisoning in humans, monkeys, and experimental rats results in profound and permanent structural alterations in the retina and ON and visual impairments ranging from blurred vision to decreased visual acuity and sensitivity to blindness. Ophthalmologic studies of exposed humans and monkeys reveal varying degrees of edema of the papillomacular bundle, ON head, and entire optic disk (Benton and Calhoun, 1952; Potts, 1955; Baumbach et al., 1977; Hayreh et al., 1980). Histopathologic and ultrastructural investigations in methanol-exposed monkeys and folate-modified rats show retinal edema, swollen and degenerated photoreceptors, degenerated RGCs, swollen retinal pigment epithelial cells, axonal (ON) swelling, and mitochondrial swelling and disintegration in each of these cells but especially in the photoreceptors and ON (Baumbach et al., 1977; Hayreh et al., 1980; Murray et al., 1991; Seme et al., 1999). Considering the differences in species, methanol exposures, time course of analysis, and procedures utilized, the overall data for the acute effects of methanol on the ERG are remarkably consistent. Following methanol exposure, the ERG b-wave amplitude in humans, monkeys, and folate-modified rats starts to decrease significantly when the blood formate concentration exceeded 7 mM (Potts, 1955; Ruedeman, 1961; Ingemansson, 1983; Murray et al., 1991; Lee et al., 1994b). These ERG b-wave alterations, as well as flicker-evoked ERG alterations (Seme et al., 1999), occur at lower formate concentrations than those associated with structural changes in the retina and ON, as discussed above. Decreases in the a-wave amplitude are delayed, relative to the b-wave and occur when blood formate concentrations further increase (Ruedeman, 1961; Ingemansson, 1983; Murray et al., 1991; Eells et al., 1996). In addition, it has been shown that intraretinal metabolism of methanol is necessary for the formate-mediated alterations in the ERG (Garner et al., 1995a), although intravenous infusion of formate in monkeys does induce ON edema (Martin-Amat et al., 1978). Finally, in the folate-modified rats, it appears that photoreceptors that respond to a 15-Hz flicker/510-nm wavelength mesopic-photopic stimulus [i.e., rods and middle wavelength–sensitive (M) cones] are more sensitive to methanol than the ultraviolet-sensitive (UV) cones (Seme et al., 1999).

The retinal sources of the ERG a-wave and b-wave are discussed in the beginning of this chapter. Thus, the data from the ERG b-wave methanol studies suggests that the initial effect of formate is directly on the depolarizing (ON-type) rod bipolar cells, Müller glial cells, and/or synaptic transmission between the photoreceptors and bipolar cells. A well-designed series of pharmacologic, ERG, and potassium-induced Müller cell depolarization studies using several controls and folate-modified rats revealed a direct toxic effect of formate on Müller glial cell function (Garner et al., 1995a; Garner et al., 1995b). These studies also provided evidence that formate does not directly affect depolarizing rod bipolar cells or synaptic transmission between the photoreceptors and bipolar cells. Formate also appears to directly and adversely affect the rod and cone photoreceptors as evidenced by the markedly decreased ERG a-wave and flicker response data (Ruedeman, 1961; Ingemansson, 1983; Murray et al., 1991; Eells et al., 1996; Seme et al., 1999).

Although there are no direct data on the underlying molecular mechanism responsible for the toxic effects of formate on Müller glial cells and photoreceptors, several findings suggest that the mechanism involves a disruption in oxidative energy metabolism. First, the whole retinal ATP concentration is decreased in folate-deficient rats 48 h following methanol exposure, the time point when the b-wave was lost (Garner et al., 1995b). Second, both formate-(10 to 200 mM) and formaldehyde-(0.5 to 5 mM)inhibited oxygen consumption in isolated ox retina, and formaldehdye was considerably more potent (Kini and Cooper, 1962). Third, similar concentrations of formaldehyde inhibited oxidative phosphorylation of isolated ox retinal mitochondria, with greater effects observed using FAD-linked than NADH-linked substrates (Kini and Cooper, 1962). Unfortunately the effects of formate were not examined. Fourth, and consistent with the above results, formate inhibits succinate-cytochrome *c* reductase and cytochrome oxidase activity (Ki = 5 to 30 mM), but not NADH-cytochrome *c* reductase activity in isolated beef heart mitochondria and/or submitochondrial particles (Nicholls, 1976). Fifth, ultrastructural studies reveal swollen mitochondria in rat photoreceptor inner segment and ON 48 to 72 h after nitrous oxide/methanol exposure (Murray et al., 1991; Seme et al., 1999). To date, there are no such studies conducted on the Müller glial cells. Taken together, these results suggest formate is a mitochondrial poison that inhibits oxidative phosphorylation of photoreceptors, Müller glial cells, and ON. The evidence for this hypothesis and establishment of subsequent steps resulting in retinal and ON cell injury and death remain to be elucidated.

Organic Solvents *Trichloroethylene, Xylene, Toluene, n-Hexane and Mixtures* The neurotoxicity of organic solvents is well established; however, there are not many reports concerning the adverse effects of organic solvents on the retina and visual system despite findings of structural alterations in rods and cones as well as functional alterations such as color vision deficits, decreased contrast sensitivity, and altered visual-motor performance (Raitta et al., 1978; Odkvist et al., 1983; Baker and Fine, 1986; Larsby et al., 1986; Mergler, 1990; Arlien-Söborg, 1992; Backstrom and Collins, 1992; Backstrom et al., 1993; Broadwell et al., 1995; Fox, 1998; also see Chap. 24, "Toxic Effects of Solvents and Vapors").

Dose-response color vision loss (acquired dyschromatopsia) and decreases in the contrast sensitivity function occur in workers exposed to organic solvents such as trichlorethylene, alcohols, xylene, toluene, *r*-hexane, mixtures of these and others. Adverse effects usually occur only at concentrations above the occupational exposure limits (Raitta et al., 1978; Baird et al., 1994; Mergler et al., 1987, 1988, 1991; Nakatsuka et al., 1992). A large percentage of workers in microelectronic plants, print shops, and paint manufacturing facilities, who were exposed to concentrations of solvents that exceeded the threshold limit values, had acquired dyschromatopsia as assessed by the Lanthony D-15 desaturated color arrangement panel (Mergler et al., 1987, 1988, 1991). These workers had no observable clinical abnormalities as assessed by biomicroscopy, funduscopy, and peripheral visual field tests. The color vision losses were mainly blue-yellow losses, although more severe red-green losses were reported. As a rule, acquired blue-yellow losses generally result from lens opacification or outer retinal alterations, whereas red-green losses are associated with inner retinal, retrobular, or central visual pathway alterations (Porkony et al., 1979). Moreover, these occupationally exposed workers also exhibited intermediate spatial frequency losses in their contrast sensitivity function, which reflect alterations in neural function (Mergler et al., 1991). The data from the Mergler et al. (1987, 1988, 1991) studies appear to show gender differences in these adverse visual effects. For example, one recent comprehensive color vision study on male workers exposed to only toluene shows that even high concentration of this solvent had no effect on color vision (Muttray et al., 1995). However, one study on female workers, where the Lanthony D-15 desaturated test was used to assess color vision, showed a trend toward increased prevalence of color vision impairment following exposure to low to moderate concentrations of toluene (Zavalic et al., 1996). Similar blue-yellow deficits as well as macular changes were observed in workers exposed to *n*-hexane for 5 to 21 years (Raitta et al., 1978). These findings correlate with the rod and cone degeneration observed in rats exposed to 2,5-hexanedione (Backstrom and Collins, 1992; Backstrom et al., 1993). Clearly more detailed, well-designed, and well-executed studies are needed to determine (1) which solvent(s) cause alterations in color vision, (2) are spatial and temporal contrast sensitivity affected, (3) the dose(concentration)-response relations between exposure and effects, (4) possible gender differences, and (5) whether these deficits are reversible.

Styrene Five independent studies report that workers exposed to mean atmospheric concentrations of styrene ranging from 20 to 70 ppm exhibit concentration-dependent alterations in color vision (Gobba et al., 1992; Fallas et al., 1992; Chia et al., 1994; Eguchi et al., 1995; Campagna et al., 1995). A combined data analysis from two of the above studies (Gobba et al., 1991; Campagna et al., 1995) suggests that the threshold for color visual impairments is £4 ppm styrene (Campagna et al., 1996). This is well below the threshold limit value–time weighted average (TLV-TWA) value for any country: range 20 to 50 ppm. The findings of similar blue-yellow color vision deficits by five different groups of investigators in different countries argues convincingly for the reproducibility and validity of these styrene-induced color vision deficits. The reversibility of these impairments is unknown, however, in one study no recovery was found after a 1-month period of no exposure (Gobba et al., 1991). The findings reveal the sensitivity of the visual system and especially the photoreceptors to toxicant exposure. Moreover, the results demonstrate that the Lanthony D-15 desaturated test can be a sensitive and reliable test for detecting color vision abnormalities in solvent-exposed workers. In summary, the evidence indicates that organic solvents can produce color vision deficits in occupationally exposed workers.

Organophosphates The neurotoxicity of organophosphates is well established (see Chap. 16, " Toxic Responses of the Nervous System"); however, the link between organophosphate exposure and retinotoxicity is presently unresolved. Clinical studies conducted in Japan, reports on ocular toxicity from laboratory animals exposed to organophosphates, and reports to the EPA by pesticide manufacturers suggest that various organophosphates produce retinotoxicity and chronic ocular damage (Ishikawa, 1973; Plestina and Piukovic-Plestina, 1978; Dementi, 1994). However, many of the early clinical reports were poorly designed and remain unconfirmed. The evidence for organophosphate-induced retinal toxicity is strongest for fenthion (dimethyl 3-methyl-4-methylthiophenyl phosphorothionate) (Imai et al., 1983; Misra et al., 1985; Boyes et al., 1994; Tandon et al., 1994). A recent epidemiologic study of licensed pesticide applicators in two states, North Carolina and Iowa, did not find a statistically increased risk of retinal degeneration from use of organophosphate insecticides as a class, but risks were increased for some individual members of the chemical class (Kamel et al., 2000). Interestingly this study did identify an increased risk of retinal degeneration in workers using fungicides. One unexplained report in the Japanese studies was a high incidence of myopia in children exposed to organophosphates. A recent report found that visual control of ocular growth was impaired in the eyes of chicks exposed to the organophosphate insecticide chlorpyrifos (Geller et al., 1998). Until further detailed, well-designed, and replicated clinical and basic science studies are conducted, an adequate discussion of the sites and mechanisms of action of organophosphates must be delayed. In the interim, the references noted above will provide the interested reader with a synopsis of the current status in this area.

TARGET SITES AND MECHANISMS OF ACTION: OPTIC NERVE AND TRACT

The ON consists primarily of RGC axons carrying visual information from the retina to several distinct anatomic destinations in the CNS. Both myelinated and nonmyelinated axons are present and grouped into bundles of axons that maintain a topographic distribution with respect to the site of origin in the retina. At the optic chiasm, the fibers split, so that, in humans and other primates, those fibers originating from the temporal retina continue in the OT toward the ipsilateral side of the brain, while those fibers originating in the nasal half of the retina cross the midline and project to the contralateral side of the brain. In species with sideward-facing eyes such as the rat, a larger proportion of the ON fibers (up to 90 percent) cross the midline. Fibers from the ON terminate in the dorsal LGN, the superior colliculus, and pretectal areas. Information passing through the LGN to visual cortex gives rise to conscious visual perception. Information traveling to the superior colliculus is used to generate eye movements. Pathways leading to the pretectal areas subserve the pupil response. The LGN of primates contains six histologic layers that are alternately innervated by cells from the contralateral and ipsilateral eyes. The cells projecting to and from the ventral two layers of the LGN have large cell bodies and consequently this pathway is referred to as the magnocellular system. Retinal ganglion cells projecting to the magnocellular layers of the LGN are referred to as either M-type or Pa cells. Magnocellular neurons are sensitive to fast moving stimuli and to low levels of luminance contrast, but are insensitive to differences in color. The cells from the magnocellular pathway are involved in motion perception. On the dorsal side of the LGN, the cells are smaller and form the parvocellular pathway. Retinal ganglion cells projecting to the parvocellular layers of the LGN are referred to as P-type or Pb cells. Parvocellular neuron are sensitive to color and to fine detailed patterns, have slower conduction velocities, and are involved in perception of color and form (Horton, 1992; Rodieck, 1998).

Disorders of the ON may be termed *optic neuritis, optic neuropathy,* or *ON atrophy,* referring to inflammation, damage or degeneration, respectively, of the ON. *Retrobulbar neuritis* refers to inflammation or involvement of the orbital portion of the ON posterior to the globe. Among the symptoms of ON disease are reduced visual acuity, contrast sensitivity, and color vision. Toxic effects observed in the ON may originate from damage to the ON fibers themselves or to the RGC somas that provide axons to the ON. A number of toxic and nutritional disorders can adversely affect the ON. Deficiency of thiamine, vitamin B_{12}, or zinc results in degenerative changes in ON fibers. Occasional toxic and nutritional and toxic factors interact to produce ON damage. A condition referred to as *alcohol-tobacco amblyopia* or simply as *toxic amblyopia* is observed in habitually heavy users of these substances and is associated nutritional deficiency. Dietary supplementation with vitamin B_{12} is therapeutically helpful, even when patients continue to consume large amounts of alcohol and tobacco (Grant, 1986; Anderson and Quigley, 1992; Potts, 1996).

Acrylamide

Acrylamide monomer is used in a variety of industrial and laboratory applications, where it serves as the basis for the production of polyacrylamide gels and other polyacrylamide products. Exposure to acrylamide produces a distal axonopathy in large-diameter axons of the peripheral nerves and spinal cord that is well documented in humans and laboratory animals (Spencer and Schaumburg, 1974a, 1974b). Visual effects of acrylamide exposure occur at dose levels sufficient to cause substantial peripheral neuropathy, but the selective nature of the visual deficits and associated neuropathology is very instructive. While the large-diameter and long axons are most vulnerable to acrylamide in the peripheral nerve and spinal cord, this is not the case in the OT. The middle diameter axons of the Pb-type RGCs that project to the parvocellular layers of the LGN of New- and Old-World primates degenerate after prolonged treatment with acrylamide (Eskin and Merigan, 1986; Lynch et al., 1989). The larger-diameter Pa-type RGCs that project to the magnocellular layers of the LGN are apparently spared. Visual function testing in these primates, without a functional parvocellular system, revealed selective perceptual deficits in detecting visual stimuli with high spatial-frequency components (i.e., fine visual patterns) and low temporal-frequency components (i.e., slowly modulating sine waves) (Merigan and Eskin, 1986). On the other hand, the monkeys' perception of larger visual patterns, modulated at higher temporal rates, was not impaired. These toxicologic experiments helped elucidate the functional differentiation of primate parvocellular and magnocellular visual systems. Why the axons of the ON and OT show a different size-based pattern of vulnerability than do axons of the peripheral nerve and spinal cord is not currently understood.

Carbon Disulfide

Carbon disulfide (CS_2) is used in industry to manufacture viscose rayon, carbon tetrachloride, and cellophane. The neurotoxicity of CS_2 is well known and involves damage to the peripheral and central nervous systems as well as profound effects on vision (Beauchamp et al., 1983). The peripheral neuropathy results from a distal axonal degeneration of the large-caliber and long axons of the peripheral nerves and spinal cord, probably through the reactions with the sulfhydryl groups of axonal neurofilament proteins, yielding covalent cross linkages that lead to filamentous tangles and axonal swellings (Graham and Valantine, 2000). The mechanism of action through which inhalation of high concentrations of CS_2 vapors leads to psychotic mania is not currently established but may result from alterations in catecholamine synthesis or neuronal degeneration in several brain areas (Beauchamp et al., 1983). In the visual system, workers exposed to CS_2 experience loss of visual function accompanied by observable lesions in the retinal vasculature. Among the changes in visual function reported in viscose rayon workers are central scotoma, depressed visual sensitivity in the peripheral visual field, optic atrophy, pupillary disturbances, blurred vision, and disorders of color perception. A recent workplace study of 123 Belgian viscose rayon workers found a statistical association between a weighted cumulative CS_2 exposure score, deficits in color vision measured using the Farnsworth-Munsell 100-HUE test, and observations of excess microaneurysms observed ophthalmoscopically and in fundus photographs (Vanhoorne et al., 1996). This association was not observed in the 42 workers who were never exposed to levels above the TLV value of 31 mg/m^3. The coexistence of retinal microaneurysms with functional loss has led to the presumption that the visual deficits were a secondary consequence of vascular disease and perhaps of retinal hemorrhages. This association was addressed in carbon disulfide–exposed macaque monkeys used in visual psychophysical, fluorescein angiography, and fundus photography studies as well as postmortem neuropathologic evaluations (Merigan et al., 1988; Eskin et al., 1988). They observed markedly decreased contrast sensitivity functions, decreased visual acuity, and degeneration of the RGCs, all of which occurred in the absence of retinal microaneurysms or hemorrhages. There was little evidence of effects on the other retinal neurons. These findings indicate that the retinal and ON pathology produced by CS_2 are likely a direct neuropathologic action and not the indirect result of vasculopathy. Interestingly, and importantly, after cessation of exposure, the visual acuity measures recovered temporarily in two of the CS_2-treated monkeys; however, the contrast sensitivity measures did not recover. This demonstrates the independence of these two measures and the utility and importance of independent evaluations of contrast sensitivity and visual acuity.

Cuban Epidemic of Optic Neuropathy

During 1992 and 1993, an epidemic occurred in Cuba in which over 50,000 people suffered from optic neuropathy, sensory and autonomic peripheral neuropathy, high-frequency neural hearing loss, and myelopathy. This is thought to be the largest epidemic of neurologic disease in the twentieth century (Roman, 1998). The affected individuals were characterized as having bilateral low visual acuity, impaired color perception, impaired visual contrast sensitivity, central scotoma, optic disk pallor, and, in particular, loss of nerve fibers from the papillomacular bundle (Sadun et al., 1994a; Hedges et al., 1997). Individuals with neurologic findings demonstrated stocking-glove sensory deficits, leg cramps, sensory ataxia, altered reflexes, and complaints of memory loss (Mojon et al., 1997). Various authors noticed similarities between the Cuban cases and nutritional or alcohol-tobacco amblyopia, Leber's hereditary optic neuropathy, and Strachan's disease (Hedges et al., 1994; Hirano et al; 1994; Espinosa et al., 1994; Sadun et al., 1994b; Mojon et al., 1997). The optic neuropathy resembled methanol poisoning (Roman, 1998; Sadun, 1998). The outbreak of the epidemic was linked to nutritional deficiencies from food shortages after a combination of reduced aid from the former Soviet Union and continued economic sanctions that included shipments of food and medicines imposed by the United States (Hedges et al., 1997; Mojon et al., 1997; Roman, 1998). Aggressive supplementation of the diet with B vitamins and folic acid led to a significant clinical improvement in most identified cases (Mojon et al., 1997). Nutritional deficiencies were a primary contributor to the epidemic; however, it was not clear whether they were solely responsible or whether dietary insufficiency served to make individuals more susceptible to other factors. Genetic susceptibility factors and viral exposures have been considered (Johns et al., 1994; Johns and Sadun, 1994; Newman et al., 1994; Mas et al., 1997; Hedges et al., 1997). One likely contributing factor was coexposure to low levels of neurotoxic compounds that would otherwise have been tolerated (Sadun, 1998). In addition to low food intake, risk factors for the development of optic neuropathy included use of tobacco, in particular the frequent smoking of cigars, and high cassava consumption (Roman, 1998). The mitochondrial toxicant cyanide may be a contaminant of both cassava and tobacco products. Moderate to severe folic acid deficiency was observed in more than half of the cases (Roman, 1998). Samples of local home-brewed rum showed approximately 1 percent contamination with methanol, a level that would not produce ON toxicity in normal healthy individuals (Sadun et al., 1994). However, one-quarter of the Cuban patients showed elevated serum formate concentrations, probably a result of folic acid deficiency. The maximum serum formate concentrations observed (approximately 4 mM) were equivalent to levels that produce retinal and ON toxicity in a rodent model of methanol toxicity (Eells et al., 1996). Sadun (1998) postulated that mitochondrial impairment, created by the combination of low nutritional status and toxic exposures, was responsible for the neurologic impairments. The nutritional deficiency would lead to ATP depletion. Exposure to either cyanide or formic acid, the toxic metabolite of methanol, causes inhibition of cytochrome oxidase, which further depletes ATP levels (Nicholls, 1976; also see retinal section for additional references and details). Because axoplasmic transport of new mitochondria from nerve cell bodies to distal axonal segments is energy-dependent (Vale et al., 1992), the lowered ATP levels would be expected to impair mitochondrial transport and start a vicious cycle of further ATP depletion and reduced mitochondrial transport to the nerve terminal regions. Sadun proposed that the nerve fibers most sensitive to this type of damage would be the long peripheral nerve axons, which have high transport demands, and the small caliber fibers of the ON, in particular at the papillomacular bundle, which have physical constrictions to transporting mitochondria. Exposure to toxicants could not be documented in most of the people identified late in the epidemic, suggesting nutritional deficit as the principal cause. However, coexposure to low levels of mitochondrial toxicants or other

factors may have pushed individuals over a threshold for causing nerve damage.

Ethambutol

The dextro isomer of ethambutol is widely used as an antimycobacterial agent for the treatment of tuberculosis. It is well known that ethambutol produces dose-related alterations in the visual system, such as blue-yellow and red-green dyschromatopsias, decreased contrast sensitivity, reduced visual acuity, and visual field loss. The earliest visual symptoms appear to be a decrease in contrast sensitivity and color vision, although impaired red-green color vision is the most frequently observed and reported complaint. However, the loss of contrast sensitivity may explain why some patients with normal visual acuity and color perception still complain of visual disturbance. These visual system alterations can occur with a few weeks of doses equal to or greater than 20 mg/kg body weight; however, they usually become manifest after several months of treatment (Koliopoulos and Palimeris, 1972; Polak et al., 1985; Salmon et al., 1987; Jaanus et al., 1995). The symptoms are primarily associated with one of two forms of retrobulbar neuritis (i.e., optic neuropathy). The most common form, seen in almost all cases, involves the central ON fibers and typically results in a central or paracentral scotoma in the visual field and is associated with impaired red-green color vision and decreased visual acuity, whereas the second form involves the peripheral ON fibers and typically results in a peripheral scotoma and visual field loss (Jaanus et al., 1995; Lessell, 1998).

In experimental animals, ethambutol causes RGC and ON degeneration, discoloration of the tapetum lucidum (in dogs), retinal detachment (in cats), and possibly amacrine and bipolar cell alterations (van Dijk and Spekreijse, 1983; Grant and Shuhman, 1995; Sjoerdsma et al., 1999). Although the mechanism responsible for producing the RGC and ON degeneration is unknown, recent in vivo studies in rats and in vitro rat RGC cell culture experiments suggest that ethambutol causes RGC death secondary to glutamate-induced excitotoxicity (Heng et al., 1999). Pharmacologic studies, using the in vivo and in vitro models, show that although ethambutol is not a direct NMDA-receptor agonist, it makes RGCs more sensitive to endogenous levels of glutamate. Using the fluorescent Ca^{2+} dyes calcium green 1-AM and rhod-2, Heng et al. (1999) showed that following application of ethambutol in the presence, but not absence, of glutamate to isolated RGCs, there was a decrease in cytosolic Ca^{2+} and a subsequent increase in mitochondrial Ca^{2+}. Interestingly, the increase in mitochondrial Ca^{2+} resulted in an increase in the mitochondrial membrane potential as measured by the mitochondrial membrane potential sensitive dye JC-1. The authors (Heng et al., 1999) postulate that this latter phenomenon occurs as a result of an ethambutol-mediated chelation of Zn^{2+} from the mitochondrial ATPase inhibitor protein IF1 (Rouslin et al., 1993) that subsequently results in the inhibition of mitochondrial ATP synthesis and elevation of mitochondrial membrane potential. These intriguing ideas have merit; however, many additional experiments will be needed to prove this hypothesis. In addition, the authors suggest that some glutamate antagonists may be useful in decreasing the side effects of ethambutol—a practical suggestion that appears worthy of clinical investigation.

TARGET SITES AND MECHANISMS OF ACTION: THE CENTRAL VISUAL SYSTEM

Many areas of the cerebral cortex are involved in the perception of visual information. The primary visual cortex—called V1, Brodmann's area 17, or striate cortex—receives the primary projections of visual information from the LGN and also from the superior colliculus. Neurons from the LGN project to visual cortex maintaining a topographic representation of the receptive field origin in the retina. The receptive fields in the left and right sides of area 17 reflect the contralateral visual world and representations of the upper and lower regions of the visual field are separated below and above, respectively, the calcarine fissure. Cells in the posterior aspects of the calcarine fissure have receptive fields located in the central part of the retina. Cortical cells progressively deeper in the calcarine fissure have retinal receptive fields that are located more and more peripherally in the retina. The central part of the fovea has tightly packed photoreceptors for resolution of fine detailed images, and the cortical representation of the central fovea is proportionately larger than the peripheral retina in order to accommodate a proportionately larger need for neural image processing. The magnocellular and parvocellular pathways project differently to the histologically defined layers of primary striate visual cortex and then to extrastriate visual areas. The receptive fields of neurons in visual cortex are more complex than the circular center-surround arrangement found in the retina and LGN. Cortical cells respond better to lines of a particular orientation than to simple spots. The receptive fields of cortical cells are thought to represent computational summaries of a number of simpler input signals. As the visual information proceeds from area V1 to extrastriate visual cortical areas, the representation of the visual world reflected in the receptive fields of individual neurons becomes progressively more complex (Horton, 1992).

Lead

In addition to the well-documented retinal effects of lead (see above), lead exposure during adulthood or perinatal development produces structural, biochemical, and functional deficits in the visual cortex of humans, nonhuman primates, and rats (Fox et al., 1977; Winneke, 1979; Costa and Fox, 1983; Sborgia et al., 1983; Fox, 1984; Otto et al., 1985; Lilienthal et al., 1988; Reuhl et al., 1989; Otto, 1990; Murata et al., 1993; Otto and Fox, 1993; Altmann et al., 1994, 1998; Winneke et al., 1994). Quantitative morphometric studies in monkeys exposed to either high levels of lead from birth or infancy to 6 years of age revealed a decrease in visual cortex (areas V1 and V2), cell volume density, and a decrease in the number of initial arborizations among pyramidal neurons (Reuhl et al., 1989). The former results may be due to an absolute decrease in total cell numbers, possibly resulting from lead-induced apoptosis as observed in the retina (Fox et al., 1997; He et al. 2000). This may also account for the decreased density of cholinergic muscarinic receptors found in the visual cortex of adult rats following moderate level developmental lead exposure (Costa and Fox, 1983). The morphometric results on neuronal branching are reminiscent of earlier findings in the neocortex of rats following high level developmental lead exposure (Petit and LeBoutillier, 1979), and recent findings in the somatosensory cortex of rats following low or moderate level developmental lead exposure (Wilson et al., 2000). These alterations could partially contribute to the decreases in contrast sensitivity observed in lead-exposed rats and monkeys (Fox, 1984; Rice, 1998), the alterations in the amplitude and latency measures of the flash and pattern-reversal evoked potentials in lead-exposed children, workers, monkeys, and rats (Fox et al., 1977; Winneke, 1979; Sborgia et al., 1983; Otto et al., 1985; Lilienthal et al., 1988; Otto, 1990; Murata et al., 1993; Altmann et al., 1994, 1998; Winneke et al., 1994), and the alterations in tasks assessing visual function in lead-exposed children (Winneke et al., 1983; Hansen et al., 1989; Muñoz et al., 1993).

Methyl Mercury

Methyl mercury became notorious in two episodes of mass poisoning (see Chap. 16, "Toxic Responses of the Nervous System"). In the 1950s industrial discharges of mercury into Minamata Bay in Japan became biomethylated to form methyl mercury, which then accumulated in the food chain and reached toxic concentrations in the fish and shellfish consumed in the surrounding communities. Hundreds of people were poisoned, showing a combination of sensory, motor, and cognitive deficits. A more widespread episode of methyl mercury poisoning affected thousands of Iraqi citizens who mistakenly ground wheat grain into flour that had been treated with methyl mercury as a fungicide and that was intended for planting and not for direct human consumption.

Visual deficits are a prominent feature of methyl mercury intoxication in adult humans, along with several other neurologic manifestations such as difficulties with sensation, gait, memory, and cognition. Methyl mercury poisoned individuals experienced a striking and progressive constriction of the visual field (peripheral scotoma) as patients became progressively less able to see objects in the visual periphery (Iwata, 1977). The narrowing of the visual world gives impression of looking through a long tunnel, hence the term *tunnel vision.* Visual field constrictions also have been observed in methyl mercury–poisoned monkeys (Merigan, 1979). On autopsy of some of the Minamata patients, focal neurologic degeneration was observed in several brain regions including motor cortex, cerebellum, and calcarine fissure of visual cortex (Takeuchi and Eto, 1977). The histopathologic feature was a destruction of the cortical neural and glial cells, with sparing of the subcortical white matter, optic radiations, and LGN. Monkeys and dogs that were treated experimentally with methyl mercury showed greater damage in the calcarine fissure, associated with higher regional concentrations of protein-bound mercury, than in other brain regions (Yoshino et al., 1966; Berlin et al., 1975). In the Minamata patients there was a regional distribution of damage observed within striate cortex, such that the most extensive damage occurred deep in the calcarine fissure and was progressively less in the more posterior portions. Thus, the damage was most severe in the regions of primary visual cortex that subserved the peripheral visual field, with relative sparing of the cortical areas representing the central vision. This regional distribution of damage corresponded with the progressive loss of peripheral vision while central vision was relatively preserved. Methyl mercury–poisoned individuals also experienced poor night vision (i.e., scotopic vision deficits), also attributable to peripheral visual field losses. Similar changes were observed in adult monkeys exposed to methyl mercury (Berlin et al., 1975). Interestingly, mercury also accumulates in the retina of animals exposed to methyl mercury (DuVal et al., 1987) and produces rod-selective electrophysiologic and morphologic alterations (Fox and Sillman, 1979; Braekevelt, 1982). The neurologic damage in adult cases of Minamata disease was focally localized in the calcarine cortex and other areas but was more globally distributed throughout the brain in those developmentally exposed.

The levels of methyl mercury exposure experienced by people in Minamata Bay were undoubtedly high. Studies of visual function in nonhuman primates exposed to methyl mercury during perinatal development demonstrate a decrease in visual contrast sensitivity, visual acuity, and temporal flicker resolution at dose levels lower than those associated with constriction of the visual fields (Rice and Gilbert, 1982; Rice and Gilbert, 1990; Rice, 1996). Monkeys exposed to methyl mercury from birth onward or in utero plus postnatally exhibited spatial vision deficits under both high and low luminance conditions, although the deficits were greater under scotopic illumination (Rice and Gilbert, 1982; Rice, 1990). The effects on temporal vision were different. That is, monkeys exposed from birth displayed superior low-luminance temporal vision, while high-luminance temporal vision was not impaired. In contrast, monkeys exposed to methyl mercury in utero plus postnatally exhibited deficits in low-frequency high-luminance temporal vision, while low-luminance temporal vision was superior to that of control monkeys (Rice, 1990). These data indicate that the spatial and temporal vision deficits produced by developmental exposure to methyl mercury are different from those produced during adulthood.

The underlying mechanisms have yet to be determined.

TOXIC RESPONSES OF THE HEART AND VASCULAR SYSTEMS

Kenneth S. Ramos, Russell B. Melchert, Enrique Chacon, and Daniel Acosta, Jr.

INTRODUCTION

The cardiovascular system has two major components: the myocardium and a diverse network of vascular vessels consisting of arteries, capillaries, and veins. Both units of the cardiovascular system have important functions in supplying the tissues and cells of the body with appropriate nutrients, respiratory gases, hormones, and metabolites and removing the waste products of tissue and cellular metabolism as well as foreign matter such as invading microorganisms. In addition, the cardiovascular system, through its circulation of blood and fluids to every tissue in the body, is responsible for maintaining the optimal internal homeostasis of the body as well as for critical regulation of body temperature and maintenance of tissue and cellular pH. Thus, the cardiovascular system plays a critical role in the well-being and survival of the other major organs of the body, especially highly vascularized organs that are dependent on nutrients and oxygen carried by the blood. If the cardiovascular system is injured by disease or toxic chemicals, this damage has a far-reaching impact on the survival of the organism.

The discipline of cardiovascular toxicology is concerned with the adverse effects of drugs, chemicals, and xenobiotics on the heart and circulatory system of a living organism. The introduction of drugs or xenobiotics into the body eventually leads to their absorption into the bloodstream and transport to the heart; toxic interactions with the cardiovascular system usually are determined by the concentration of a xenobiotic in contact with the myocardium or vasculature and by the duration of exposure. A wide spectrum of xenobiotics—including drugs, natural products, industrial chemicals, and environmentally introduced agents—may interact directly with the cardiovascular system to cause structural and/or functional changes. There may also be indirect actions secondary to changes in other organ systems, especially the central and autonomic nervous systems and selective actions of the endocrine system. Functional alterations that affect the rhythmicity of the heart, if severe enough, may lead to lethal arrhythmias without major evidence of structural damage to the myocardium. Structural alterations such as degenerative necrosis and inflammatory reactions are often caused by direct effects of chemicals on the myocardium.

This chapter presents a major review on general mechanisms of cardiotoxicity and injury to the vasculature and provides a systematic examination of major categories of cardiovascular toxicants. Specifically, the authors have highlighted the roles of ion homeostasis, altered blood flow, oxidative stress, organelle dysfunction, and apoptosis and oncosis in the production of injury to the heart by prototypic myocardial toxicants. The discussion of injury to the vascular system focuses on mechanisms that involve vascular reactivity, bioactivation and erratic detoxification, and molecular genetic alterations. Several major classes of cardiovascular toxicants are described: (1) pharmaceutical agents, such as antineoplastics, antibiotics, autonomic and centrally acting drugs, antihistamines, immunosuppressants, cardiovascular-acting pharmacologic drugs, local anesthetics, and other miscellaneous drugs; (2) natural products, such as steroids, cytokines, vitamins, and animal/plant toxins; and (3) industrial chemicals, such as solvents, alcohols, heavy metals, gases, alkylamines, halogenated amines, and other miscellaneous agents. In order to provide a clearer picture of the toxic responses of the heart and vascular systems, an overview of the physiology of the myocardium and vasculature is also presented.

OVERVIEW OF CARDIAC PHYSIOLOGY

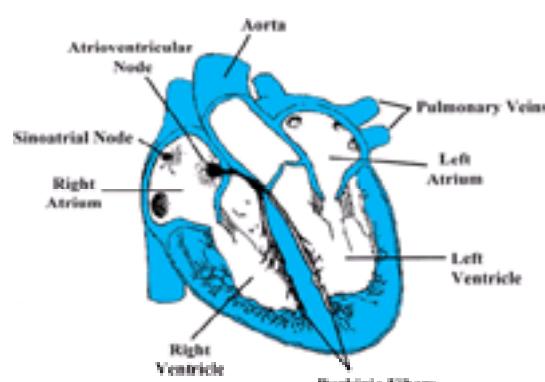
A clear grasp of the normal anatomy and physiology of the heart provides the basis for understanding the effects of xenobiotics on cardiac function. Figure 18-1 illustrates the basic anatomy of the heart. The main purpose of the heart is to pump blood to the lungs and the systemic arteries so as to provide oxygen and nutrients to all the tissues of the body. The heart consists of four pumping chambers: the right and left atria and the right and left ventricles. Venous blood from the systemic circulation enters the right atrium and right ventricle, from which it is then pumped into the lungs to become oxygenated. The left atrium and ventricle then receive the oxygenated blood via the pulmonary veins and pump it to the systemic arteries via the aorta. In addition, the heart receives oxygenated blood flow from the right and left coronary arteries, which begin at the root of the aorta. Each contraction cycle consists of an orchestrated series of events that result in the blood-pumping action of the heart.


Figure 18-1. Diagram illustrating the basic anatomy of the heart.

Review of Cardiac Structure

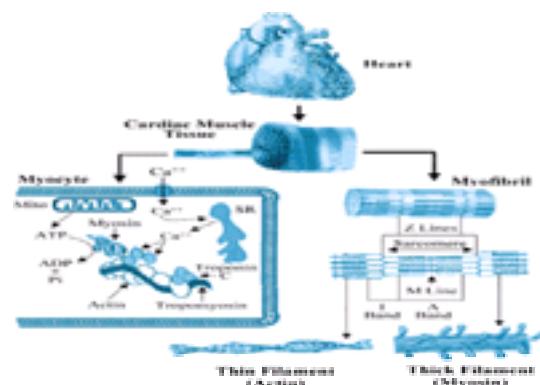
The structural organization of myocardial tissue is shown in Fig. 18-2. The primary contractile unit within the heart is the cardiac muscle cell, or cardiac myocyte. Cardiac myocytes are composed of several major structural features and organelles. A primary component is the contractile elements known as the myofibril. Each myofibril consists of a number of smaller filaments (the thick and thin myofilaments). The thick filaments are special assemblies of the protein myosin, whereas the thin filaments are made up primarily of the protein actin. Cardiac myosin is a hexamer composed of one pair of myosin heavy chains (MHC) and two pairs of myosin light chains (MLC). Two isoforms of MHC, a and b, are expressed in cardiac muscle; the expression of these is under developmental control and may be altered by a variety of physiologic, pathologic, and pharmacologic stimuli (Martin et al., 1996; Metzger et al., 1999). Furthermore, the predominant isoform expressed in normal adult cardiac tissue also depends upon the species examined. Similarly, two isoforms of actin are expressed in the heart (cardiac and skeletal a-actin), and, as with MHC, actin isoform expression is influenced by developmental, physiologic, pathologic, and pharmacologic stimuli. Again, the primary isoform of actin found in normal adult cardiac muscle also depends upon the species examined.


Figure 18-2. Structural organization of cardiac muscle tissue.

Under electron microscopy, these essential structural components of myocardial contractile proteins display alternating dark bands (A bands, predominantly composed of myosin) and light bands (I bands, predominantly composed of actin). Visible in the middle of the I band is a dense vertical Z line. The area between two Z lines is called a sarcomere, the fundamental unit of muscle contraction. Although cardiac and skeletal muscle share many similarities, a major difference lies in the organization of cardiac myocytes into a functional syncytium where cardiac myocytes are joined end-to-end by dense structures known as intercalated disks. Within these, there are tight gap junctions that facilitate action potential propagation and intercellular communication. About 50 percent of each cardiac myocyte is composed of myofibrils. The rest of the intracellular space contains the remaining major components of the cell: mitochondria (33 percent), one or more nuclei (5 percent), the sarcoplasmic reticulum (2 percent), lysosomes (very low), glycogen granules, a Golgi network, and cytosol (12 percent) (Opie, 1986a).

Cellular Phenotypes within the Heart

The major cellular phenotype in the heart is the cardiac myocyte, which is the largest cell in the heart and contributes to the majority of cardiac mass. However, cardiac myocytes make up only about one-quarter of all the cells in the heart. Cardiac fibroblasts, vascular cells, Purkinje cells, and other connective tissue cells make up the majority of cell number in the heart. Cardiac fibroblasts make up approximately 90 percent of these "nonmuscle" cells. Cardiac myocytes are generally considered to be terminally differentiated. That is, although these cells may be multinucleated, they normally do not divide after birth. The heart undergoes a significant increase in size and mass throughout growth of the organism, but the increase in heart size and mass is produced by enlargement (or hypertrophy) of pre-existing cardiac myocytes (Li et al., 1996). With regard to this developmental period, cardiac hypertrophy is considered to be a normal physiologic process. Although cardiac myocyte division has been debated for some time, the clear lack of significant regeneration of cardiac tissue and subsequent hypertrophy of remaining myocytes following myocardial infarction suggests, at best, a very limited proliferative capacity of mature cardiac myocytes. Moreover, hypertrophy of remaining cardiac myocytes is a hallmark of cardiac remodeling following myocardial infarction. In contrast, cardiac fibroblasts may continue to proliferate after birth, particularly in response to injury. Cardiac fibroblasts also contribute to cardiac remodeling following myocardial infarction and are believed to promote fibrosis and scarring of injured cardiac tissue. Thus, from a toxicological perspective, the heart is vulnerable to injury because of limited proliferative capacity of cardiac myocytes, and promotion of cardiac fibroblast proliferation and cardiac remodeling following injury.

Cardiac Electrophysiology

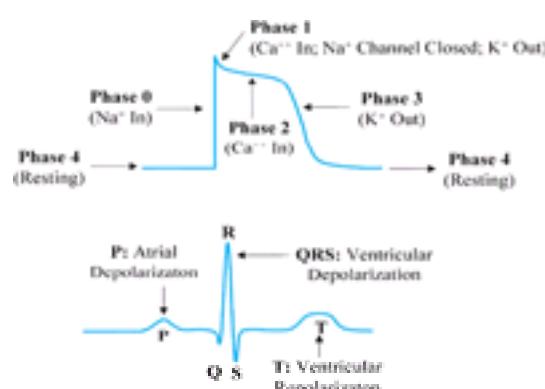
Review of the Action Potential The ionic basis of membrane activity is reflected by and dependent upon changes in the transmembrane potential. At any given time, the electrical potential across the cardiac myocyte cytoplasmic membrane (sarcolemma) is a reflection of the ion concentration gradients across the membrane. The characteristic appearance of the cardiac action potential demonstrates how ion currents result in changes in membrane potential (Fig. 18-3). In a resting cell, the density of the electrical charge on both sides of the sarcolemma is referred to as phase 4, or diastolic membrane potential, which is normally around –90 mV (inside negative with respect to the outside of the cell). When an action potential is initiated, voltage-gated sodium (Na $^+$) channels open, and there is a rapid influx of Na$^+$, which depolarizes the cell from approximately –90 mV (nonpacemaker cardiac cells) to greater than 0 mV, thus giving rise to the Na $^+$ current (I_{Na}) and the upstroke of the action potential (phase 0). The initial, brief, and rapid depolarization that occurs following phase 0 is produced by closure of voltage-gated Na $^+$ channels and activation of voltage-gated transient outward potassium (K $^+$) channels (phase 1). During the rapid influx of Na $^+$ and resulting membrane depolarization, voltage-gated calcium (Ca^{2+}) channels open and Ca^{2+} begins a slower but prolonged inward flux at approximately –30 to –40 mV, giving rise to Ca $^{2+}$ current (I_{Ca}). As the Na$^+$ current dissipates, Ca^{2+} continues to enter the cell, giving rise to the characteristic plateau appearance of phase 2. Final repolarization (phase 3) of the cell results from closure of voltage-gated Ca^{2+} channels and K$^+$ efflux through two major types of K$^+$ channels: a channel responsible for inward rectifier current (I_{K1}) and a channel responsible for delayed rectifier current (I_K). Thus the normal resting potential is restored, but the cell must continue to normalize the Na $^+$ and K$^+$ concentration gradients through activity of the Na$^+$,K$^+$-ATPase that actively extrudes intracellular Na $^+$ in exchange for extracellular K$^+$. For further detailed information regarding ion channels and currents in the heart, refer to the review article by Boyett and colleagues (1996).


Figure 18-3. Characteristic cardiac action potential and electrocardiogram (ECG).

Electrical Conduction in the Heart The cardiac cycle begins in pacemaker cells that spontaneously depolarize and pass a depolarizing electrical current to

neighboring cells. Pacemaker cells do not contract but are responsible for initiating and conducting action potentials to the cardiac myocytes. Spontaneous depolarization is different from nerve and muscle excitation in that pacemaker cells do not remain at a constant resting potential. Instead, a pacemaker cell's membrane potential slowly depolarizes toward threshold as a result of a decreased K^+ efflux that is superimposed on a slow inward leak of Na^+ and Ca^{2+}. Overall, there is a gradual accumulation of positive ions inside the cells, causing the intracellular space to become less negative relative to the extracellular space. This gradual depolarization toward threshold eventually gives rise to an action potential. Once threshold is reached, Na^+ channels open and then Ca^{2+} channels open, leading to a rapid influx of Ca^{2+} and production of the characteristic action potential, as discussed above (Fig. 18-3).

Spontaneous depolarization can be found in various regions throughout the heart: the sinoatrial (SA) node, the atrioventricular (AV) node, the bundle of His (atrioventricular bundle), and Purkinje fibers. Under physiologic conditions, SA nodal cells exhibit the fastest rate of action potential discharge and thus set the pace of the heart (hence the term *pacemaker*). If the SA node is damaged or inhibited, the next fastest depolarizing cells (AV node) assume the pacemaking activity. AV nodal cells spontaneously depolarize at a slower rate than SA nodal cells, and the bundle of His and Purkinje fibers spontaneously fire at yet a slower rate. The non-SA nodal pacemaker cells are referred to as latent pacemakers and can take over to set the cardiac pace if the normal pacemaker cells fail. However, because of decreased rates of firing in the latent pacemaker cells, normal cardiac function is compromised as a result of slower spontaneous depolarization rates.

Normally, the cardiac cycle begins with spontaneous depolarization of cells in the SA node. The electrical impulse propagates through the atrial muscle and converges on the AV node. The dense fibrous tissue of the AV node causes the electrical impulse to slow down owing to the slower Ca^{2+}-dependent upstroke. This delayed transfer of current between the atria and the ventricles allows the atria to complete contraction before depolarization of the ventricles. The AV node impulse is then sent down the bundle of His, the bundle branches, and the Purkinje network, causing depolarization and contraction of muscle cells in the ventricles.

Electrical cardiac activity is regulated by the autonomic ner- vous system (ANS). The ANS influences heart rate and contractility in accordance with the body's demand. The efferent ANS consists of sympathetic and parasympathetic fibers. The chemical transmitter of the sympathetic system is norepinephrine (nor-adrenaline), and the chemical transmitter of the parasympathetic system is acetylcholine (ACh). Sympathetic activation alters SA and AV nodal function as well as atrial and ventricular contractility. Parasympathetic fibers (vagal fibers) are found in the SA and AV nodes as well as in atrial muscle. Thus, norepinephrine and similar sympathomimetics stimulate the rate of depolarization and the rate of impulse transmission, resulting in an increase in cardiac rate and contractility of the myocardium. The major effect of parasympathomimetics is to enhance the vagal tone of the SA and AV nodes and the atrial muscle and thus decrease the rate of depolarization with only a slight decrease in ventricular contractility.

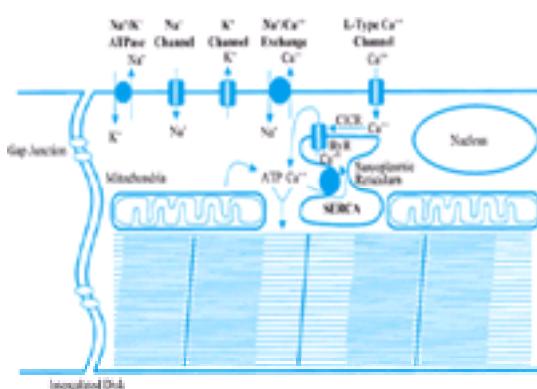
Excitation-Contraction Coupling The key to conversion of electrical activity to mechanical work in the heart lies in the coupling of cardiac myocyte excitation (depolarization) to mechanical contraction. An overview of the process of excitation-contraction coupling is presented in Fig. 18-4. For contraction to occur, both energy (in the form of ATP) and Ca^{2+} must be readily available. Energy for contraction is obtained from the splitting of adenosine triphosphate (ATP) by hydrolysis via an ATPase site on myosin. Each mole of ATP hydrolyzed liberates about 30 kilojoules (kJ) of energy. The ATP necessary for contraction is derived from three major sources: oxidative phosphorylation in the mitochondria, substrate-level phosphorylation in glycolysis and the citric acid cycle, and ADP phosphorylation by creatine phosphokinase. However, oxidative phosphorylation is the most significant source of ATP in the heart, accounting for more than 90 percent of total ATP production (Vary et al., 1981). The heart contains about 3 mg of ATP per gram of wet weight (5 μmol/g) and a pool of creatine phosphate that is approximately three times larger; this accounts for a minimal reserve sufficient to last only about 50 to 75 beats (Opie, 1986b). Since the majority of ATP for contraction is provided by the mitochondria, it is not surprising that mitochondria occupy a large portion of each cardiac myocyte and maintain integrity to support myocardial function.


Figure 18-4. Overview of excitation-contraction coupling in cardiac myocytes.

Upon rapid depolarization (rapid influx of Na^+ through fast channels; phase 0 of the action potential), L-type Ca^{2+} channels are opened allowing a slower but sustained influx of Ca^{2+} down the electrochemical gradient (phase 2 of the action potential). During the process of Ca^{2+}-induced Ca^{2+} release (CICR), slight elevation in intracellular free Ca^{2+} stimulates Ca^{2+} release from the sarcoplasmic reticulum (SR) through ryanodine receptors (RyR). The SR provides the majority of Ca^{2+} required for contraction. The mitochondria provide energy for contraction in the form of ATP. Repolarization of the cell occurs largely by activation of K^+ channels and efflux of K^+ (phase 3 of the action potential). For relaxation, the SR Ca^{2+} ATPase (SERCA) actively pumps Ca^{2+} back into the SR, although some Ca^{2+} may be removed by the Na^+/Ca^{2+} exchanger or by sarcolemmal Ca^{2+} pumps.

The Ca^{2+} necessary for contraction comes largely from two sources: extracellular Ca^{2+} and intracellular Ca^{2+} stores. Beginning in phase 0 (rapid depolarization) and persisting in the plateau of the action potential (phase 2), voltage-gated Ca^{2+} channels (L type) are open, allowing influx of extracellular Ca^{2+} down the electrochemical gradient. Furthermore, some extracellular Ca^{2+}, albeit likely a small amount, enters the cell through the Na^+/Ca^{2+} exchanger (in reverse mode) during depolarization, whereby intracellular Na^+ is exchanged for extracellular Ca^{2+}. Although uptake of external Ca^{2+} during this process is necessary and contributes to contraction and in some cases may be sufficient for contraction, the majority of Ca^{2+} required for contraction comes from the sarcoplasmic reticulum (SR). Ryanodine receptors (RyRs), closely related to inositol trisphosphate (IP$_3$) receptors, reside on the surface of the SR, and serve as Ca^{2+} release channels. Although IP$_3$ receptors may release some of the Ca^{2+} required for contraction, RyRs are thought to contribute the majority of Ca^{2+} release from the SR. When intracellular free Ca^{2+} rises subsequent to opening of L-type Ca^{2+} channels, RyRs are activated to release Ca^{2+} from the SR. This process is known as Ca^{2+}-induced Ca^{2+} release (CICR), and CICR contributes the majority of Ca^{2+} necessary for contraction. Following CICR, a transient increase in intracellular free Ca^{2+} concentration (Ca^{2+} transient) occurs allowing contraction to proceed. Mechanical contraction of cardiac myocytes occurs when Ca^{2+} binds to the protein troponin C (located on a complex with tropomysin), which under resting conditions inhibits the interaction of myosin and actin. Following a Ca^{2+}-induced conformational change in troponin C and tropomysin, the ATPase catalytic site and myosin binding site on actin are exposed. Then, ATP is hydrolyzed, inducing a conformational change in myosin and subsequently allowing myosin to bind actin, thus producing "cross-bridge cycling" and contraction.

Relaxation of cardiac myocytes requires reductions in cytoplasmic free Ca^{2+} and consequently reductions in the free Ca^{2+} pool available for interaction with troponin C. Several ion pumps and exchangers facilitate removal or sequestration of Ca^{2+}. The sarcolemmal Na^+/Ca^{2+} exchange (in forward mode) may extrude Ca^{2+} from the cell by exchanging intracellular Ca^{2+} for extracellular Na^+. In addition, a uniporter exists on the mitochondrial membrane, which acts to sequester Ca^{2+} into the mitochondria. Furthermore, a sarcolemmal Ca^{2+} ATPase can actively extrude Ca^{2+} from the cell. However, the majority of Ca^{2+} available for interaction with troponin C is removed by the active ion pump SR Ca^{2+} ATPase (SERCA), which actively pumps Ca^{2+} back into the SR, whereas the other ion pumps and exchangers make significantly less contributions to Ca^{2+} reduction (Bers, 1997). The SERCA requires energy in the form of ATP; therefore, ATP is required for both contraction and relaxation. As SERCA reduces cytoplasmic free Ca^{2+}, and consequently Ca^{2+} available for interaction with troponin C, the actin-myosin interaction ceases and the cell relaxes.

Cardiac Function

Electrocardiogram Electrical currents generated during depolarization and repolarization spread throughout the heart, body fluids, and body surface. Therefore electrical activity of the heart is monitored by recording electrodes placed on the skin surface, resulting in the characteristic electrocardiogram (ECG). Examination of ECG patterns is useful for diagnosing abnormal heart rates, arrhythmias, and damage to heart muscle. On the ECG shown in Fig. 18-3, deflections (or waves) are

recorded that correspond to atrial depolarization (P wave), ventricular depolarization (QRS complex), and ventricular repolarization (T wave); however, atrial repolarization is not normally observed on the ECG because it is obscured by the large QRS complex. Several useful intervals are noted on the ECG, such as the PR interval, corresponding primarily to conduction through the AV node; QRS duration, corresponding to ventricular depolarization; the ST interval, corresponding to ventricular repolarization; and the QT interval, corresponding to ventricular depolarization and repolarization. Prolongations of the PR interval may indicate disturbances of AV nodal conduction; whereas prolongations of QRS duration may indicate blocks in conduction pathways through the ventricles (bundles of His). Any significant deviations of the ST interval from the isoelectric line may indicate ischemic damage to the heart. The QT interval varies with heart rate and is often corrected for heart rate (QTc) when possibly abnormal ECGs are being considered. Prolongation of the QTc interval is frequently observed with agents that prolong action potential duration within the heart. Therefore the ECG records useful information that may indicate possible mechanisms by which xenobiotics adversely affect cardiac function.

Cardiac Output The primary indicator of cardiac function is cardiac output (i.e. the volume of blood pumped by the ventricles per minute). Cardiac output is dependent on heart rate and stroke volume (the amount of blood ejected by the ventricles during systole). If stroke volume were easily and noninvasively measured, then the monitoring of cardiac output would be routine because heart rate is readily acquired, and cardiac output would be equivalent to heart rate (beats per minute) times stroke volume (milliliters per beat). However, stroke volume is not routinely obtained, and accurate measurement of cardiac output requires either echocardiography with Doppler techniques or indicator-dilution techniques. Normal cardiac output at rest is approximately 5 L/min in an average adult human (Sherwood, 1993), and this value may increase three- to four-fold during strenuous exercise. Measurement of cardiac output in animals is useful for determining potential adverse effects of xenobiotics on cardiac function, because the primary concern regarding cardiotoxicity is how an agent affects the pumping action of the heart. Reflecting the ability of the heart to meet the demands of the body (e.g., exercise), numerous factors affect cardiac output either by altering heart rate or stroke volume: autonomic regulation of heart rate or contractility, preload (muscle stretch from ventricular filling), afterload (arterial pressure and peripheral vascular resistance), and left ventricular size. Therefore toxicants may alter cardiac output though numerous mechanisms and effects on the heart, vasculature, and/or nervous system.

DISTURBANCES IN CARDIAC FUNCTION

Abnormal Heart Rhythm

Typical chemically induced disturbances in cardiac function consist of effects on heart rate (chronotropic), contractility (inotropic), conductivity (dromotropic), and/or excitability (bathmotropic). The normal human heart rate at rest is approximately 70 beats per minute. A rapid resting heart rate (i.e., above 100 beats per minute) is known as tachycardia (Greek *tachys,* meaning "rapid"), whereas a slow heart rate (i.e., below 60 beats per minute) is known as bradycardia (Greek *bradys,* meaning "slow"). Any variation from normal rhythm is termed an arrhythmia, and arrhythmias are often complications secondary to other on-going disturbances in cardiac function, such as ischemic heart disease or cardiac hypertrophy (as described below). Arrhythmias are classified on the basis of their origin (supraventricular or ventricular).

Supraventricular arrhythmias (atrial in origin) are further divided into two categories: (1) supraventricular tachycardia based on defects in AV nodal reentry circuits or anatomic bypass tracts and (2) atrial fibrillation, where there is some form of atrial muscle injury. Although often symptomatic, atrial arrhythmias are seldom fatal, largely because the ventricles will fill even in the absence of atrial contraction. *Atrial flutter* is characterized by rapid and regular atrial depolarizations between 200 and 380 beats per minute. However, because of the longer refractory period of the AV node and ventricles, the ventricles typically are unable to synchronize their depolarization with the rapidly firing atria. During atrial flutter, only one of every two to three atrial depolarizations passes through the AV node to depolarize the ventricles. *Atrial fibrillation* is characterized by rapid, randomized, and uncoordinated depolarizations of the atria. This erratic depolarization results in regularly shaped QRS complexes without a definite P wave (atrial repolarization). Atrial contractions are unsynchronized, and AV conduction is also irregular. The AV irregularity causes irregular ventricular rhythm and subsequent inefficiency in ventricular filling. Less ventricular filling time results in diminished blood pumping to the extent that the pulse rate may be depressed. Under normal circumstances, pulse rate coincides with heart rate.

In contrast to atrial arrhythmias, ventricular arrhythmias are almost always symptomatic and will lead to loss of consciousness within a few seconds and even to death if they are unresolved or untreated. Therefore most ventricular arrhythmias are considered at least potentially life-threatening. Frequently, ventricular arrhythmias arise from muscle injury secondary to ischemia, infarction, and subsequent scarring and fibrosis or by ventricular hypertrophy. Such arrhythmias may begin as *ventricular tachycardia* and progress to more severe complications such as ventricular fibrillation. *Ventricular fibrillation* is characterized by repetitive, rapid, and randomized excitation of the ventricles, usually as a result of ectopic foci in the ventricles. Impulses travel chaotically around the ventricles. Hence, the ventricles become inefficient as pumps and death is inevitable unless normal rhythm is reestablished through the use of electrical defibrillation or cardiac compression.

Heart block is due to impairments in the cardiac conducting system. Typically, the atria maintain regular beating rates, but the ventricles occasionally fail to depolarize. For example, only every second or third atrial impulse may pass to depolarize the ventricles. Heart blocks are classified on the basis of their degree of depression of the conduction system. Complete heart block is characterized by complete block of conduction between the atria and ventricles. Under complete heart block, the atria beat regularly but the ventricles begin their own pacemaker activity at a much slower rate. Thus, the P wave (atrial depolarization) exhibits normal rhythm, while the QRS and T waves exhibit a slower rhythm that is independent of the P wave rhythm.

Xenobiotics may alter normal heart rate or rhythm. Those that are particularly prone to produce arrhythmias are compounds that interfere with ion channel function, alter action potential, or disturb conductance through the heart. As extensions of the mechanisms of action or lack of specificity, many antiarrhythmic drugs carry the risk of promoting arrhythmias. Examples of these drugs are included later in the chapter. Far too frequently, however, drugs used to treat non-cardiac-related illness are later found to alter ion homeostasis and/or flux in cardiac myocytes. Examples of such compounds include some antibacterial agents and antihistamines, as discussed later in the chapter. Therefore monitoring of heart rhythm with ECG is important in testing the cardiotoxic potential of drugs or chemicals.

Ischemic Heart Disease

Ischemic heart disease (IHD) is a major leading cause of death for men and women in the United States and other industrialized nations. IHD may be produced by a variety of pathologic conditions and/or xenobiotics that disturb the balance of myocardial perfusion and myocardial oxygen and nutrient demand. Pathologic conditions and/or compounds that reduce myocardial perfusion may induce ischemia and subsequent oxygen and nutrient deficiency as well as inadequate removal of metabolic products. A major cause of IHD is coronary artery atherosclerosis and resulting arterial obstruction. Several major syndromes comprise the clinical manifestations of IHD, including myocardial infarction, angina pectoris (pain radiating to the chest, left shoulder and/or arm, or neck) and its three variants (stable angina, unstable angina and Prinzmetal angina), and chronic ischemia with heart failure. Many of these syndromes may end in sudden cardiac death, but the severity of symptoms and progression of disease vary dramatically between affected individuals. Unfortunately, an alarming number of cases of myocardial infarction and/or sudden cardiac death fail to present symptoms and are assumed to be "silent" or asymptomatic ischemia. IHD may be produced by pathologic conditions other than atherosclerosis. For example, cardiac hypertrophy (discussed below) may contribute to IHD through increased myocardial oxygen demand, decreased perfusion of the hypertrophic wall, and increased risk of arrhythmias. In some cases, coronary vasospasm not associated with atherosclerotic plaques may contribute to IHD. Xenobiotics that have been associated with ischemic heart disease include cocaine, sympathomimetics, and anabolic-androgenic steroids (as reviewed later in the chapter).

Whatever the cause of IHD and its clinical syndromes, the end results when left unresolved or untreated share some common effects on cardiac myocyte function and viability. Because the myocardium derives the majority of the ATP required for contraction from the aerobic metabolism of glucose, pathologic conditions or xenobiotics that reduce myocardial perfusion, and thus oxygen and nutrient delivery, will force the cardiac myocytes to derive ATP from creatine phosphate and anaerobic glycolysis until stores are depleted. Therefore, ATP depletion begins almost immediately in ischemic cardiac myocytes, and within 20 to 40 min, ATP is significantly depleted and irreversible injury begins. Undoubtedly, large numbers of cardiac myocytes within the ischemic or infarcted zone will undergo nonapoptotic (oncocytic necrosis, or *oncosis*) cell death (discussed below). However, more recent research has demonstrated that significant numbers of myocytes will undergo programmed cell death, or *apoptosis* (discussed below), following ischemia or infarction (Haunstetter and Izumo, 1998). Interestingly, the apoptotic regions of myocyte death following ischemia appear to be near the border zone, perhaps extending into adjacent perfused myocardium, which suggests the release of local factors (e.g., cytokines) in necrotic regions that alter viability of surrounding regions. The size of the ischemic or infarcted zone will depend on a number of factors including the duration and severity of ischemia, position of obstruction or size of the myocardial bed at risk, and collateral blood flow capabilities (Buja, 1998). Following myocyte death, cytosolic contents may eventually enter the systemic circulation, where they may be detected as markers of IHD. For example, serum levels of cardiac-specific isoforms of lactate dehydrogenase (LDH), creatine kinase (CK), and troponin are elevated several hours following acute myocardial infarction (AMI). Eventually, permanently damaged zones are replaced with scar tissue contributed by connective tissue cells such as cardiac fibroblasts. Furthermore, surviving cardiac myocytes compensate for increased workload by increasing in size (hypertrophy). The *cardiac remodeling* process thus includes initial myocyte loss and subsequent connective tissue cell activation and scar production, hypertrophy of remaining myocytes, altered cardiac geometry, and microcirculatory changes within the heart.

Cardiac Hypertrophy and Heart Failure

As mentioned above, cardiac hypertrophy is an important component to cardiac remodeling following IHD. However, cardiac hypertrophy is a growth response during development of the organism and is often a compensatory response of the heart to increased workload. For example, prolonged hypertension contributes to load-induced left ventricular hypertrophy. Therefore, cardiac hypertrophy in and of itself does not necessarily result in a disturbance in cardiac function. With regard to cardiac remodeling following injury, hypertrophy of surviving myocytes may be necessary to sustain cardiac output for life support. At some point in the progression of IHD, however, the hypertrophic myocardium may "decompensate," resulting in failure. During failure, ventricular contractility and/or compliance are reduced, such that cardiac output is diminished. Failure may present as left- or right-sided failure or both. When left-sided failure is the primary pathology, blood pools in the lungs and pulmonary edema develops. When right-sided failure is the primary pathology, blood pools in the extremities and pitting edema is found in the lower legs.

Unfortunately, the mechanisms responsible for the transition from cardiac hypertrophy to failure are not understood. Likely possibilities include ischemia (resulting from larger myocytes, increased oxygen demand, and limited capillary density), synthesis of defective contractile proteins or Ca^{2+} handling proteins, and/or increased deposition of collagen with resulting fibrosis. Thus, scientists are challenged with attempting to determine the point at which hypertrophy becomes pathologic and the mechanisms responsible for the conversion of hypertrophy to overt failure. To this end, significant advancements have occurred in the understanding of stimuli for and signaling pathways of cardiac myocyte hypertrophy (discussed below) and death (discussed under "General Mechanisms of Cardiotoxicity," further on). For toxicologists, these findings may have considerable impact on the understanding of xenobiotic-induced cardiotoxicity. Chronic exposure to some xenobiotics may promote hypertrophic growth of cardiac myocytes by serving as direct stimuli or by altering signaling pathways associated with hypertrophic growth.

Hypertrophic Stimuli Sustained hypertension may induce compensatory left ventricular hypertrophy. Similarly, when neonatal rat cardiac myocytes are grown in culture and subjected to stretch, a hypertrophic growth response is observed where cell size and/or protein synthesis is stimulated while DNA content remains unchanged. Thus, mechanical load or stretch serves as a hypertrophic stimulus, perhaps through secretion of autocrine or paracrine growth factors such as angiotensin II. Furthermore, several other growth factors, hormones, and pharmacologic agents will stimulate hypertrophic growth of cardiac myocytes in vitro (Hefti et al., 1997). These hypertrophic stimuli include alpha $_1$ adrenergic agonists (epinephrine, norepinephrine, phenylphrine), growth factors (endothelin-1 and transforming growth factor beta), cytokines (leukemia inhibitor factor, interleukin-1b, and cardiotrophin-1), prostaglandins (prostaglandin F $_{2a}$), and hormones (thyroid hormone and testosterone). Many of these stimuli may promote growth of cardiac myocytes in vivo, providing necessary stimulation for cardiac hypertrophy during development or compensatory hypertrophy during cardiac remodeling.

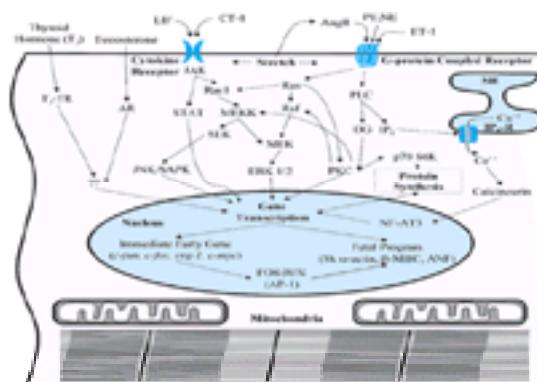
Hypertrophic Signal Transduction Following interactions of hypertrophic stimuli with receptors, a multitude of enzyme systems and second messengers are activated: phospholipases A $_2$, C, and D (PLA$_2$, PLC, PLD), protein kinase C (PKC), three subfamilies of mitogen-activated protein kinases (MAPKs) [extracellular signal-regulated kinases (ERK 1/2), c-jun NH$_2$-terminal kinase/stress-activated protein kinases (JNK/SAPK), and p38 reactivating kinase (p38 RK)], receptor tyrosine kinases (RTKs), S6 kinases, and increases in intracellular free Ca $^{2+}$ and subsequent activation of the calcineurin pathway (Sugden, 1999). Importantly, considerable cross-talk between these general pathways exists. For example, increases in PLC and PLD activity stimulate increases in PKC activity and Ca $^{2+}$ through increased formation of diacylglycerol (DG) and inositol trisphosphate (IP $_3$). Receptor tyrosine kinases may activate PLC, PKC, and MAPKs. In addition, PKC activates MAPKs and may activate JNK/SAPK in cardiac myocyte cultures exposed to mechanical stretch. The common downstream effectors in these cross-talk schemes seem to be PKC, ERK 1/2, JNK/SAPK, and calcineurin; and in cardiomyocyte cultures, various hypertrophic stimuli are coupled to these enzyme systems. Figure 18-5 summarizes the various signaling pathways known to be involved in hypertrophic growth of cardiac myocytes. Many of these signaling enzymes serve as potential targets for pharmacologic intervention in hypertrophic growth and may also serve as target enzymes whereby xenobiotics may alter cardiac myocyte function. Importantly, variations in these signaling pathways should be expected depending upon species and developmental stage of the cardiac tissue or cells used.


Figure 18-5. Signal transduction pathways involved in hypertrophic growth of cardiac myocytes.

The figure represents a simplistic view of the signaling pathways involved in hypertrophic growth of cardiac myocytes. Significant "cross-talk" between various pathways is present, and opposing pathways are not shown. Arrows represent activation or increases in second messengers. Question marks represent additional steps leading to the response have not been identified. *Abbreviations for stimuli:* AngII, angiotensin II; ANP, atrial natriuretic peptide; CT-1, cardiotrophin 1; ET-1, endothelin-1; LIF, leukemia inhibitor factor; NE, norepinephrine; PE, phenylephrine; T $_3$, thyroid hormone, triiodothyronine. *Abbreviations for growth pathways:* AR, androgen receptor; Ca^{2+}, intracellular free calcium; DG, diacylglycerol; ERK ½, extracellular signal–regulated kinases 1 and 2; IP $_3$, inositol-1,4,5-trisphosphate; JAK, Janus kinase; JNK/SAPK, c-Jun N-terminal kinase/stress-activated protein kinase; MEK, mitogen-activated protein kinase effector kinase; MEKK, MEK kinase; p70 S6K, ribosomal S6 kinase; PKC, protein kinase C; PLC, phospholipase C; Rac, a member of the Ras superfamily; Raf, a mitogen-activated protein kinase kinase kinase; Ras, a GTPase; SEK, SAPK effector kinase; STAT, signal transducer and activator of transcription; TR, thyroid hormone receptor. *Abbreviations for nuclear components:* ANF, atrial natriuretic factor; AP-1, heterodimeric transcription factor consisting of FOS and JUN; b-MHC, b-myosin heavy chain; JUN, protein product of *c-jun;* FOS, protein product of *c-fos;* NF-AT3, nuclear factor and activator of T-cells 3; Sk a-actin, skeletal a-actin.

Cardiomyopathies

The term *cardiomyopathy* essentially refers to any disease state that alters myocardial function. Therefore, causes of cardiomyopathy include IHD (ischemic cardiomyopathy), cardiac hypertrophy, infectious diseases (e.g., viral cardiomyopathy), drug- or chemical-induced cardiomyopathy, and unknown causes (idiopathic cardiomyopathy). Regardless of exact cause, the cardiomyopathies can be divided into two major categories: dilated cardiomyopathy and hypertrophic cardiomyopathy. *Dilated cardiomyopathy* is produced by progressive cardiac hypertrophy, decompensation, ventricular dilation, and eventual systolic dysfunction or impaired contractility. Some drugs or chemicals may produce dilated cardiomyopathy, including chronic alcohol consumption (alcoholic cardiomyopathy) and doxorubicin (discussed later in the chapter). *Hypertrophic cardiomyopathy* is produced by progressive cardiac hypertrophy, with diastolic dysfunction including impaired compliance of the ventricular walls and reduced diastolic ventricular filling. Many cases of hypertrophic cardiomyopathy are due to inherited diseases with mutations in contractile proteins such as b-myosin heavy chain, troponin, or tropomysin, while other cases are idiopathic.

GENERAL MECHANISMS OF CARDIOTOXICITY

Interference with Ion Homeostasis

As discussed above, the cardiac action potential and excitation-contraction coupling are dependent upon tight regulation of ion channel activity and ion homeostasis. Therefore any xenobiotic that disrupts ion movement or homeostasis may induce a cardiotoxic reaction composed principally of disturbances in heart rhythm. The most notorious agents that disrupt ion channel activity and promote arrhythmia are, ironically, the drugs used to treat arrhythmias and other cardiac diseases.

Inhibition of Na$^+$,K$^+$-ATPase

Because Na$^+$,K$^+$-ATPase is responsible for reducing intracellular Na $^+$ in exchange for extracellular K$^+$, agents that inhibit cardiac Na$^+$,K$^+$-ATPase will increase resting

intracellular Na$^+$ concentrations. This, in turn, will increase intracellular Ca^{2+} concentrations through Na$^+$/Ca^{2+} exchange in reverse mode, and the elevated intracellular Ca^{2+} and Ca^{2+} stores thus contribute to the inotropic actions of these agents. These properties in part lead to the clinical usefulness of the cardiac glycosides (digoxin and digitoxin) in the treatment of heart failure. These drugs are also useful for slowing conduction velocity in the treatment of atrial fibrillation. However, excessive inhibition by high doses of cardiac glycosides can lead to Ca^{2+} overload (sustained elevated intracellular free Ca^{2+} concentration) through Na$^+$/Ca^{2+} exhange in reverse mode. Perhaps related to elevated intracellular Ca^{2+}, cardiac glycosides will increase the incidence and magnitude of afterdepolarizations thus contributing ectopic arrhythmias.

Na$^+$ Channel Blockade Agents that bind to and inhibit Na$^+$ channels in cardiac cells will alter cardiac excitability by requiring greater membrane depolarization for opening of Na$^+$ channels. Effects of Na$^+$ channel blockade include reduction of conduction velocity, prolonged QRS duration, decreased automaticity, and inhibition of triggered activity from delayed or early afterdepolarizations (Roden, 1996). These properties lead to the clinical usefulness of the class I antiarrhythmic agents disopyramide, flecainide, lidocaine, mexiletine, moricizine, phenytoin, procainamide, propafenone, quinidine, and tocainide (as discussed later in the chapter). However, excessively slowed conduction may facilitate reentry arrhythmias, thus providing a proarrhythmic effect, particularly when the drugs are used in the setting of AMI or previous history of AMI (Nattel, 1998). An example of how slowed conduction velocity may induce proarrhythmic effects is supraventricular tachycardia arising from atrial flutter. In atrial flutter, atrial depolarizations may rise as high as 200 and 380 beats per minute, yet only one of every two to three atrial depolarizations passes through the AV node to depolarize the ventricles. Use of a Na$^+$ channel blocker would slow conduction velocity and reduce atrial depolarization rate but may actually increase the rate of depolarizations reaching the ventricles, resulting in ventricular tachycardia (Roden, 1996). As discussed later in the chapter, Na$^+$ channel blockade also contributes to the cardiotoxic effects of local anesthetics such as cocaine.

K$^+$ Channel Blockade Many different K$^+$ channels are expressed in the human heart, and these may be blocked by a variety of compounds (Boyett et al., 1996). A prototypical K$^+$ channel blocker used experimentally is 4-aminopyridine. Blockade of K$^+$ channels increases action potential duration and increases refractoriness (the cell is undergoing repolarization and is refractory to depolarization). These properties in part contribute to the clinical usefulness of the antiarrhythmic agents amiodarone, bretylium, dofetilide, ibutilide, quinidine, and sotalol. Prolonged action potential duration contributes to the development of early afterdepolarizations and promotion of ventricular tachycardia. An unusual tachycardia frequently develops with excessive K$^+$ channel blockade. On the ECG, the arrhythmia presents as a polymorphic ventricular tachycardia known as torsades de pointes or twisting around the isoelectric points. Most of the clinically available agents that block K$^+$ channels do so nonspecifically with the exception, perhaps, of dofetilide, the newest agent, which may be a more specific K$^+$ channel blocker. Amiodarone and quinidine, for example, also block Na$^+$ channels, while sotalol inhibits beta-adrenergic receptors in the heart. Consequently, these agents may be considered potentially arrhythmogenic from effects not related to K$^+$ channels. Moreover, unexpected blockade of K$^+$ channels has lead to the removal of several "noncardiac" drugs from the U.S. market (e.g., astemizole, cisapride, grepafloxacin, and terfenadine, as described later in the chapter). Blockade of K$^+$ channels is also implicated in the mechanism of cardiotoxicity of tricyclic antidepressants (as discussed later in the chapter). Toxicities stemming from inhibition of K$^+$ channels likely result from disproportionate prolongation of action potential duration during slow heart rates, thus predisposing the myocardium to early afterdepolarizations and triggered activity (Roden, 1996) and subsequent "quinidine syncope" (Jackman et al., 1988).

Ca^{2+} Channel Blockade The primary Ca^{2+} channel expressed in the human heart is the L-type voltage-gated Ca^{2+} channel, although T-type Ca^{2+} channels are also expressed. As described previously, the L-type Ca^{2+} channels contribute to excitation-contraction coupling; whereas, the T-type Ca^{2+} channels contribute to pacemaker potential in the SA node (Boyett et al., 1996). L-type Ca^{2+} channels are also expressed in vascular smooth muscle. A variety of agents inhibit these channels. Bepridil, verapamil, and diltiazem inhibit L-type Ca^{2+} channels throughout the vasculature and in the heart. Although the dihydropyridines may also block Ca^{2+} channels in the heart, they exert more profound effects on the vasculature and are often referred to as "vascular selective." Therefore both groups of Ca^{2+} blockers receive significant use for the treatment of hypertension. Verapamil and diltiazem are also used for the treatment of angina and cardiac arrhythmias. Blockade of Ca^{2+} channels in the heart produces a negative inotropic effect due to reductions in Ca^{2+}-induced Ca^{2+} release. Furthermore, verapamil and diltiazem decrease the rate of the SA-nodal pacemaker cell depolarizations and slow AV conduction; they are useful for the treatment of supraventricular tachycardia. As a consequence of these effects, verapamil and diltiazem exert a negative chronotropic effect and may produce bradycardia. Interestingly, the dihydropyridine Ca^{2+} channel blockers typically induce a reflex tachycardia subsequent to peripheral vascular dilation and baroreceptor reflex leading to increased sympathetic outflow from the medulla.

Altered Coronary Blood Flow

Coronary Vasoconstriction Xenobiotic-induced constriction of the coronary vasculature will induce symptoms consistent with IHD (described previously). Coronary vasospasm is thought to participate in the mechanisms of toxicity of several agents. Catecholamines such as epinephrine normally enhance coronary blood flow through increased release of metabolic vasodilators (e.g., adenosine) and through a relative increase in diastolic duration at higher heart rates where epinephrine stimulation of beta-adrenergic receptors increases heart rate, contractility, and myocardial oxygen consumption. Thus, catecholamine-induced increases in coronary blood flow largely stem from indirect actions of these agents—effects that largely override direct actions of the agents. In constrast, the direct effect of sympathomimetics on the coronary vasculature includes coronary vasospasm through activation of alpha-adrenergic receptors. When beta-adrenergic receptors are blocked or during underlying pathophysiologic conditions of the heart, the direct actions of sympathomimetics may predominate leading to coronary vasoconstriction. In dogs, for example, coronary artery stenosis produced a coronary vasoconstrictive response mediated by sympathetic nerve stimulation and blocked by alpha-adrenergic receptor antagonists (Heusch and Duessen, 1983). In addition, release of autocoids during underlying pathophysiologic conditions may enhance coronary vasoconstriction. For example, histamine, thromboxane A$_2$, and some leukotrienes may exert direct coronary vasoconstriction. Finally, some cardiotoxic agents may induce coronary vasoconstriction and subsequent myocardial ischemia as a part of a multicomponent mechanism of toxicity. For example, coronary vasoconstriction has been implicated in cocaine-induced cardiotoxicity (discussed later in the chapter).

Ischemia-Reperfusion Injury As described previously, IHD is a leading cause of morbidity and mortality in the United States and other industrialized nations. Relief of the offending cause of ischemia (e.g., thrombolytic therapy following acute myocardial infarction) provides reperfusion of the myocardium. However, depending on the duration of ischemia, a reversible contractile dysfunction remains for one to several days following reperfusion—a condition referred to as myocardial stunning. Thus, reperfusion of the myocardium leads to subsequent tissue damage that may be reversible or permanent, and this phenomenon is known as ischemia-reperfusion (I/R) injury.

Intracellular acidosis, inhibition of oxidative phosphorylation, and ATP depletion are consequences of myocardial ischemia. Reperfusion of ischemic tissue results in cell death. Several mechanisms have been proposed to account for the reperfusion injury, including the generation of toxic oxygen radicals (O$_2$ paradox), Ca^{2+} overload (Ca^{2+} paradox), uncoupling of mitochondrial oxidative phosphorylation, and physical damage to the sarcolemma. However, none of these mechanisms adequately explains the cell injury associated with I/R.

A more recent hypothesis to explain the mechanism of cell death associated with I/R injury is the pH paradox (Lemasters et al., 1995). Following reperfusion of the myocardium, reoxygenation, Ca^{2+} loading, and a return to physiologic pH occur. These changes correspond with the onset of cell death. Inhibition of Na$^+$/H$^+$ exchange across the sarcolemma during reperfusion maintains intracellular acidosis and prevents cell killing despite reoxygenation or Ca^{2+} overload. The pH paradox suggests that the acidosis of ischemia is generally protective and that a return to physiologic pH precipitates cell injury. Thus, rescue of ischemic myocardium may be possible to a much greater extent than is generally assumed, provided that the tissue is reperfused at acidic pH, followed by a gradual return of pH to normal levels.

Ischemic Preconditioning An interesting phenonomen related to I/R injury is the paradoxical protection from long-term ischemic injury provided by single or multiple brief periods of ischemia and/or hypoxia (preconditioning). Ischemic preconditioning prior to a longer-term ischemic insult will reduce infarct size, risk of I/R related arrhythmias, and severity of myocardial stunning. Although cardiac myocyte death may be delayed by ischemic preconditioning, cell death is not necessarily prevented. The mechanisms responsible for the paradoxical protection provided by preconditioning are not fully understood, but several likely mechanisms have been proposed. Adenosine may be a major mediator of preconditioning. Acting through its G protein–coupled receptors, adenosine utilizes a wide variety of signaling pathways including phospholipase C, protein kinase C, tyrosine kinases, and MAPK. Subsequently, at least one of the downstream effectors of adenosine receptor activation is the ATP-sensitive K$^+$ channel, which is phosphorylated after adenosine exposure. Opening of ATP-sensitive K$^+$ channels residing on the sarcolemmal membrane and/or in the mitochondrial membrane may provide the subsequent protection from I/R injury. At the sarcolemmal membrane level, opening ATP-sensitive K$^+$ channels would shorten phase 3 of the action potential, hyperpolarize the membrane, reduce Ca^{2+} entry and overload, and spare ATP (Gross and Fryer, 1999). At the mitochondrial membrane level, opening of ATP-sensitive K$^+$ channels would depolarize the mitochondrial membrane, produce matrix swelling, enhanced respiration, and reduced Ca^{2+} overload in the mitochondria (Gross and Fryer, 1999). Therefore compounds that block ATP-sensitive K$^+$ channels (e.g., glibenclamide) abolish the protection provided by ischemic preconditioning. Moreover, whether ischemic preconditioning protects the myocardium from xenobiotic-induced injury

remains largely unknown.

Oxidative Stress

If a reactive molecule contains one or more unpaired electrons, the molecule is termed a free radical. For many years, much interest has been focused on the biochemistry of oxygen activation and the biological significance of reactive oxygen species. Highly reactive oxygen species are intermediates formed as a normal consequence of a variety of essential biochemical reactions. For example, the univalent stepwise reduction of molecular oxygen to water results in the formation of several potentially toxic intermediates, including superoxide anion radical, hydrogen peroxide, and hydroxyl radical (i.e., prooxidants). Furthermore, superoxide anion can interact with nitric oxide to produce peroxynitrite, which is now recognized as a major contributing radical to oxidative stress-induced damage. Oxidases and electron transport systems are prime and continuous sources of intracellular reactive oxygen species.

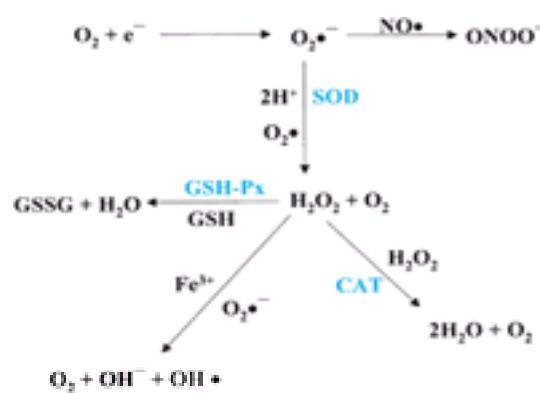
An intracellular oxidative environment denotes a shift in the prooxidant/antioxidant balance in favor of the prooxidants; thus oxidative damage inflicted by reactive oxygen species has been called oxidative stress (Sies, 1991). The extent of tissue damage depends on the balance between the free oxygen radicals generated and the antioxidant protective defenses of the tissue. Antioxidant enzymes such as superoxide dismutase, catalase, and glutathione peroxidase are preventive antioxidants because they inactivate or remove the oxygen species involved in lipid peroxidative damage of membranes, inactivation of sulfhydryl-containing enzymes, and cross-linking of integral proteins. Small-molecule antioxidants such as glutathione, ascorbate, and the tocopherols interact directly with free oxygen radicals to detoxify them. Under normal conditions, reactive oxygen species are broken down rapidly by these tissue defensive mechanisms to protect cells against their deleterious effects. The toxic effects of reactive oxygen species are observed only when their rates of formation exceed their rates of inactivation. Figure 18-6 depicts the formation of these reactive oxygen species and their inactivation by specific enzyme systems.


Figure 18-6. Formation and inactivation of reactive oxygen species.

Single-electron reduction of oxygen (O_2) results in the formation of superoxide anion radical ($O_2\bullet_2$). Although $O_2\bullet_2$ is normally maintained at low intracellular concentrations by spontaneous dismutation and/or catalytic breakdown by the enzyme superoxide dismutase (SOD) to form hydrogen peroxide (H_2O_2), it may react with nitric oxide (NO•) to form peroxynitrite ($ONOO_2$). Three possible events may occur with H_2O_2: (1) in the presence of $O_2\bullet_2$ or transition metals such as iron (Fe^{2+}) and copper, it is reduced to the hydroxyl radical (OH•); (2) it may be catalyzed by catalase (CAT) to form water and oxygen; and/or (3) it may be detoxified by glutathione peroxidase (GSH-Px) in the presence of glutathione (GSH) to form water and oxidized glutathione (GSSG).

A number of studies have indicated that reactive oxygen species are generated during myocardial ischemia and at the time of reperfusion (Simpson and Lucchesi, 1987; Bolli, 1988). In cardiovascular diseases such as atherosclerosis, oxidative alteration of low-density lipoprotein is thought to be involved in the formation of atherosclerotic plaques. Among the major reactive oxygen species, peroxynitrite and hydroxyl radical are thought to be the most toxic, reacting with membrane phospholipids and proteins and leading to increased membrane fluidity and permeability and loss of membrane integrity. Upon reperfusion of ischemic myocardium, the production of oxygen free radicals has been associated with arrhythmias, myocardial stunning, and cardiac myocyte death. However, it is controversial whether oxygen free radicals contribute significantly to cardiac myocyte death in the clinical setting (Kloner and Przyklenk, 1992). At the subcellular and biochemical levels, reactive oxygen species have been shown to alter the activities of enzymes such as Na^+,K^+-ATPase, phospholipase D, glucose-6-phosphatase, and cytochrome oxidase. Calcium homeostasis is also altered by reactive oxygen species, as reflected by modifications in Na^+/Ca^{2+} exchange, sarcoplasmic reticular Ca^{2+} transport, and mitochondrial Ca^{2+} uptake. Figure 18-7 summarizes the adverse effects of reactive oxygen radicals generated during myocardial ischemia and reperfusion.

Figure 18-7. Deleterious effects of reactive oxygen species in myocardial ischemia and reperfusion.

Xenobiotics may induce cardiotoxicity through generation of reactive oxygen species. For example, two drugs—doxorubicin and ethanol—have been shown to have prominent cardiotoxic effects which have been associated with the production of reactive oxygen species. The role of reactive oxygen species in doxorubicin- and ethanol-induced cardiotoxicity is discussed later in the chapter.

Organellar Dysfunction

Sarcolemmal Injury, SR Dysfunction, and Ca^{2+} Overload Investigations into Ca^{2+} regulation of various cellular functions have been an area of productive research for many years (Carafoli, 1987). The role of Ca^{2+} as a second messenger may be considered an integral function of several systems (not limited to excitation-contraction coupling) and is highly influenced by homeostatic mechanisms. All cells contain elaborate systems for the regulation of intracellular Ca^{2+}. Because of the large concentration gradient of Ca^{2+} (extracellular Ca^{2+} concentrations are typically several orders of magnitude higher than resting intracellular free Ca^{2+}), the sarcolemmal membrane must maintain integrity to prevent a rapid influx of Ca^{2+} and subsequent Ca^{2+} overload (sustain- ed elevated intracellular free Ca^{2+} concentration). As discuss- ed previously, the principal Ca^{2+} regulatory organelle in cardiac myocytes is the sarcoplasmic reticulum (SR), and the SR provides the majority of Ca^{2+} required for contraction. This intricate reliance on the SR serves as a protective mechanism from Ca^{2+} overload allowing tight regulation of Ca^{2+} release instead of a veritable flood of extracellular Ca^{2+} that may activate a variety of proteases, endonucleases, and signaling pathways of apoptotic cell death (Marks, 1997). Thus, prevention of Ca^{2+}-induced cell death is dependent upon sarcolemmal membrane integrity and SR function.

Homeostatic regulation of Ca^{2+} is complicated in the cardiac myocyte, primarily because the cell must allow transient increases in intracellular free Ca^{2+} concentration (Ca^{2+} transients) for contraction to occur. Nonetheless, alterations of cardiac Ca^{2+} homeostasis by toxicants may perturb the regulation of cellular functions beyond the normal range of physiologic control. Intracellular Ca^{2+} overload has been proposed to result in a breakdown of high-energy phosphates. Other cytotoxic effects induced by Ca^{2+} overload include blebbing of the plasma membrane, activation of Ca^{2+}-dependent phospholipases, stimulation of Ca^{2+}-dependent neutral proteases,

Ca^{2+}-activated DNA fragmentation, and Ca^{2+} activation of oncocytic and apoptotic cell death as described below.

A variety of xenobiotics may alter Ca^{2+} homeostasis in the heart. As discussed in further detail later in the chapter, doxorubicin may alter Ca^{2+} homeostasis through several mechanisms including altered sarcolemmal integrity through lipid peroxidation, altered mitochondrial Ca^{2+} handling (Chacon and Acosta, 1991), and/or altered expression of RyR in the SR (Marks, 1997). Catecholamines may also alter Ca^{2+} homeostasis by producing altered sarcolemmal integrity through lipid peroxidation or altered Ca^{2+} permeability. Pharmacological modulation of Ca^{2+} homeostasis has been useful for experiments aimed at delineating sites of potential toxicant-induced alterations in Ca^{2+} homeostasis. High concentrations (i.e., millimolar) of caffeine, for example, activate RyR to release SR Ca^{2+} stores resulting in a massive Ca^{2+} transient and subsequent refractory period to contraction. Yet, in the absence of underlying SR dysfunction, the SR will eventually reload the Ca^{2+} that must be released for contraction. In contrast, ryanodine will block RyR channels thus inhibiting SR Ca^{2+} release. In addition, the immunosuppressant drugs FK506 and rapamycin are known to bind to a regulatory protein associated with RyRs: FK506 binding protein (FKBP). When FK506 or rapamycin bind, FKBP dissociates from the RyR, and sensitivity of the RyR to caffeine is enhanced; consequently, these immunosuppressants may exert a cardiotoxic effect associated with leakage of Ca^{2+} from the SR (Marks, 1997).

Mitochondrial Injury Cells are continuously engaged in various biochemical reactions. In particular, the synthesis of the major cell components requires energy. The energy required for work (e.g., contraction in a cardiac myocyte) is derived from food by oxidizing the nutrients and channeling them into the formation of high-energy phosphate compounds such as adenosine triphosphate (ATP). ATP is the immediate energy source required for work in most biological systems and is obtained mainly through the oxidative phosphorylation of adenine diphosphate (ADP). Oxidative phosphorylation (ATP formation) occurs as a function of cellular respiration. Mitochondria possess an inner membrane and an outer membrane and are subcellular organelles in aerobic eukaryotic cells that are sites of cellular respiration. In essence, mitochondria are the energy producers within a cell. In a highly energy demanding organ such as the heart, mitochondria occupy a large proportion of the cell.

Cellular respiration which gives rise to the formation of ATP is dependent on electron transfer reactions and is measured as oxygen consumption (Scarpa, 1979). Various oxidative pathways in a cell utilize coenzymes such as nicotinamide adenine dinucleotide (NAD$^+$) and flavin adenine dinucleotide (FAD$^+$) as electron acceptors, giving rise to their reduced states (NADH and FADH$_2$, respectively). The availability of oxidized coenzymes (NAD$^+$ and FAD$^+$) for use as electron acceptors depends on reoxidation of the reduced coenzymes. Molecular oxygen functions as the terminal electron acceptor for coenzyme oxidation. However, the free-energy change for the direct oxidation of NADH or FADH$_2$ by oxygen is larger than that which is usually encountered in biological reactions, and so the electrons are not passed directly to oxygen. The electrons are transferred in a stepwise fashion by means of a series of reversible oxidizable electron acceptor proteins in the inner mitochondrial membrane. These proteins make up the mitochondrial respiratory chain (electron transport chain). Hence, the total free energy available between reduced coenzymes and oxygen is distributed along the respiratory chain. More specifically, the energy of electron transport is used to build up and maintain an electrochemical potential across the inner membrane, establishing the mitochondrial membrane potential.

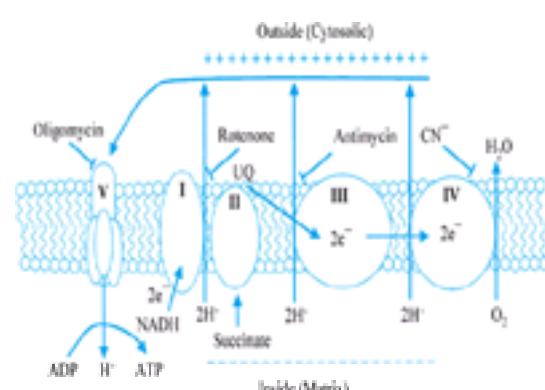
The process of electron transfer coupled with oxidative phosphorylation is a phenomenon described as coupling (Scarpa, 1979). Electron flow and consequently the rate of oxygen consumption in the presence of substrate and ADP are maximally stimulated (state 3 respiration). After the ADP has been consumed, electron flow and rates of oxygen consumption are low (state 4 respiration). The respiratory control ratio (RCR), which is calculated as the ratio of state 3 to state 4 respiration, can be used to determine the extent of coupling, which provides an index of mitochondrial function and integrity. Mitochondria that show no difference between state 3 and state 4 respiration are termed *uncoupled*. The synthesis of ATP occurs at the expense of the free energy available at three distinct sites (shown in Fig. 18-8) designated as site I (between NADH and coenzyme Q), site II (between cytochrome *b* and cytochrome *c*), and site III (between cytochrome oxidase and oxygen). Because oxygen consumption and ATP synthesis proceed in parallel, substrates entering the respiratory chain at site I give rise to the formation of three molecules of ATP (P/O ratio of 3). Hence, substrates entering the respiratory chain at complex II produce only two molecules of ATP (P/O ratio of 2). The P/O ratio can be calculated by the amount of ATP synthesized (nmoles of ADP added) divided by the nano atoms of oxygen in state 3 respiration.


Figure 18-8. Diagram of the electron-transferring complexes I, II, III, and IV and the ATPase (V) present in the inner mitochondrial membrane.

The respective complexes are I, NADH: ubiquinone oxidoreductase; II, succinate: ubiquinone oxidoreductase; III, ubiquinol: ferrocytochrome *c* oxidoreductase; IV, ferrocytochrome *c*: oxygen oxidoreductase; V, ATP synthase. UQ 5 ubiquinone or coenzyme Q. The mitochondrial electron transport chain is coupled at three points so that the electron transfer between carriers is sufficiently exergonic to drive the transport of protons and to establish an electrochemical proton gradient upon which ATP formation depends. Various inhibitors and their sites are also noted.

Oxidative phosphorylation can be affected by several chemical agents (Scarpa, 1979). Respiration can be inhibited at various sites along the respiratory chain by using different chemical inhibitors (Fig. 18-8). Rotenone is an inhibitor that blocks electron transfer between NADH and coenzyme Q (site I). Antimycin A blocks electron transport between coenzyme Q and cytochrome *c* (site II). Cyanide and carbon monoxide block the final step of electron transfer from cytochrome oxidase to oxygen (site III). Conversely, uncouplers stimulate electron flow and respiration but prevent the formation of ATP by short-circuiting the proton current. Uncouplers such as 2,4-dinitrophenol are lipophilic weak acids that may migrate through the lipid membrane and shuttle protons across the membrane, bypassing the normal flow of protons through the ATP synthetase.

In the evaluation of the various cardiac toxicants discussed below (see "Cardiotoxicants," below), mitochondrial injury or dysfunction may be an important element in explaining the mechanism of cardiotoxicity. For a recent review of mitochondrial targets of drug toxicity, see the review article by Wallace and Starkov (2000).

Apoptosis and Oncosis

The processes of apoptosis and oncosis are described in numerous places throughout this textbook with regard to basic mechanisms of toxicity and other target organs. Therefore, the mechanisms known to precipitate these processes in numerous cell types are not reviewed in detail in this chapter; rather, focus is on known events occurring within cardiac myocytes. Apoptosis and oncosis are both described as "prelethal" forms of injury, where cell death may eventually occur through necrosis (Trump et al., 1997). Apoptosis is characterized by cellular shrinkage, cytoplasmic blebbing, nuclear chromatin condensation, redistribution of phosphatidyl-ethanolamine and phosphatidylserine from the inner leaflet to outer leaflet of the lipid bilayer, and DNA fragmentation; whereas, oncosis is characterized by cellular swelling, cytoplasmic blebbing, chromatin clumping, and mitochondrial condensation followed by mitochondrial swelling (Haunstetter and Izumo, 1998; Trump et al., 1997). Cardiac myocyte death associated with apoptosis may occur in the heart following ishemic injury, I/R injury, or toxicant-induced injury. In the early periods following myocardial infarction, cardiac myocyte death likely occurs predominantly through apoptotic pathways, whereas necrosis occurs at later time points following the insult (MacLellan and Schneider, 1997). Moreover, apoptotic cardiac myocyte death was found to be a consistent feature of end-stage heart failure in humans, and was quantitatively associated with the clinical severity of deterioration in dilated cardiomyopathy (Saraste et al., 1999). Because IHD is a leading cause of morbidity and mortality in the United States and other industrialized nations, stimuli and signaling pathways responsible for cardiac myocyte apoptosis are currently under intense laboratory investigation.

Apoptotic Stimuli Several peptides and cytokines directly activate apoptotic signaling pathways and death of cardiac myocytes in vitro. These substances include atrial natriuretic peptide (ANP), angiotensin II (also a hypertrophic growth stimulus), tumor necrosis factor alpha (TNF-a), and Fas ligand (Kajstura et al., 1997; Krown

et al., 1996; Wu et al., 1997). Furthermore, other proinflammatory cytokines may induce the synthesis and/or release of TNF-a including interleukin-1 (IL-1) and interleukin-2 (IL-2) (Pulkki, 1997). Interestingly, these cytokines and peptides are elevated in the blood and myocardium during the progression of various cardiac diseases, and cardiac myocytes may synthesize and secrete them as well (Pulkki, 1997). As discussed later in the chapter, many of these cytokines depress cardiac function, some acting through production of nitric oxide. Lipid stimuli of apoptosis in cardiac myocytes include ceramide and saturated fatty acids (de Vries et al., 1997). Xenobiotics associated with induction of cardiac myocyte apoptosis in vitro include cocaine, daunorubicin, doxorubicin, isoproterenol (and norepinephrine), and staurosporine (Sawyer et al., 1999; Shizukuda et al., 1998; Umansky et al., 1997). Although the list of known apoptotic stimuli in cardiac myocytes is currently limited, on-going research will undoubtedly identify more stimuli in addition to evaluating the role of apoptosis in the mechanisms of toxicity of previously established cardiotoxicants.

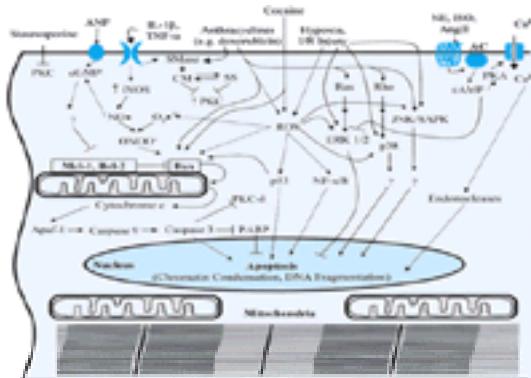
Apoptotic Signal Transduction The literature regarding signaling pathways associated with apoptosis in mammalian cells is colossal. Much less, however, is known about signaling pathways responsible for cardiac myocyte apoptosis. Although these pathways may be relatively conserved among eukaryotes, a greater likelihood of variations of these pathways within cardiac myocytes seems plausible because of the terminally differentiated nature of these cells. As a result, consideration of signaling pathways of apoptosis will be limited to findings in cardiac myocytes. Figure 18-9 is an overview of the known signaling pathways of cardiac myocyte apoptosis. The information in this figure was obtained from investigations spanning 1997–2000. Importantly, variations in these signaling pathways should be expected depending upon species and developmental stage of the cardiac tissue or cells used.


Figure 18-9. Signal transduction pathways involved in apoptotic death of cardiac myocytes.

The figure represents a simplistic view of the signaling pathways involved in apoptotic death of cardiac myocytes. The pathways presented in the figure are from the literature referenced throughout the text, and only those pathways where evidence has demonstrated the presence in cardiac myocytes or heart tissue are presented. Significant "cross-talk" between various pathways is present, and opposing pathways are not shown. Arrows represent activation or increases in second messengers. Question marks represent additional steps leading to the response have not been identified. Abbreviations for stimuli: AngII, angiotensin II; ANP, atrial natriuretic peptide; Ca^{2+}, calcium; IL-1b, interleukin-1b; I/R, ischemia/reperfusion injury; ISO, isoproterenol; NE, norepinephrine. *Abbreviations for pathways*: AC, adenylyl cyclase; Apaf-1, apoptotic protease activating factor-1; Bax, homolog of Bcl-2, a protein originally identified in B cell lymphoma; Ca^{2+},intracellular free calcium; cAMP, cyclic adenosine monophosphate; cGMP, cyclic guanosine monophosphate; CM ceramide; ERK ½ extracellular signal-regulated kinases 1 and 2; iNOS, inducible nitric oxide synthase; JNK/SAPK, c-Jun N-terminal kinase/stress activated protein kinase; Mcl-1, homolog of Bcl-2; NF-^{k}B, nuclear factor-^{k}B; NO•, nitric oxide; $O_2•_2$, superoxide anion radical; $ONOO_2$,peroxynitrite; PARP, poly ADP-ribose polymerase; p38, 38-kDa member of the mitogen-activated protein kinase family; p53, 53-kDa tumor suppressor protein; PKA, protein kinase A; PKC, protein kinase C; Ras, a GTPase; Rho, a GTPase; ROS, reactive oxygen species; Smase, sphingomyelinase; SS, sphingosine.

The first central concept of apoptotic signaling in the heart is that generation of reactive oxygen species (ROS) is intimately involved in many of the pathways. Exposure of cardiac myocytes to cytokines, anthracyclines, cocaine, hypoxia, or I/R injury will lead to production of ROS. In cardiac myocytes, ROS are known to upregulate expression of the mitochondrial protein Bax, upregulate and/or activate the tumor suppressor protein p53, upregulate and/or activate nuclear factor-kappa B (NF-^{k}B), activate MAPKs (ERK 1/2, JNK/SAPK, and p38), and for superoxide anion (O_2^-) interact with nitric oxide (NO) to produce peroxynitrite ($ONOO_2$) which subsequently leads to upregulation of Bax expression (Maulik et al., 1999; Turner et al., 1998; von Harsdorf et al., 1999).

The second central concept of apoptotic signaling in the heart is that the mitochondria are critical regulators of apoptotic death. Several members of the Bcl-2 family of proteins are localized on the outer membrane of mitochondria including proapoptotic proteins that facilitate the release of mitochondrial cytochrome *c* (i.e., Bax, Bad, Bak) and antiapoptotic proteins that inhibit the release of mitochondrial cytochrome *c* (i.e., Bcl-2, Mcl-1, Bcl-X$_L$). Under physiologic conditions, cardiac myocytes express significant quantities of Bcl-2 and other antiapoptotic members of the Bcl-2 family; however, when Bax expression is upregulated, the cells will be at risk of apoptotic death (O'Rourke, 1999). Thus, the Bcl-2/Bax expression ratio has become an indicator of susceptibility to and activation of apoptosis. Release of cytochrome *c* occurs, at least theoretically, through the opening of an inner mitochondrial membrane permeability transition pore and perhaps other ion channels (O'Rourke, 1999). Subsequently, cytochrome *c* in conjuction with apoptotic protease activating factor-1 (Apaf-1) activates the cytosolic aspartate-specific cysteine protease (caspase 9). Caspase 9 then activates caspase 3 which subsequently cleaves a variety of proteins leading to inactivation of poly (ADP-ribose) polymerase (PARP) and protein kinase C-^{d} (PKC-^{d}). Although somewhat controversial, PARP is a DNA repair enzyme that is believed to participate as an antiapoptic enzyme; thus, caspase 3 cleavage of PARP to an inactive form would contribute to the development of apoptosis (Reed and Paternostro, 1999).

Much remains unknown about the role of MAPKs and PKC in the signaling of apoptosis in cardiac myocytes; however, many apoptotic stimuli activate MAPKs (ERK 1/2, JNK/SAPK, and p38) during apoptosis of cardiac myocytes. For example, doxorubicin, I/R injury, and ROS are known to activate MAPKs in cardiac myocytes undergoing apoptosis. Increasing evidence suggests that activation of ERK 1/2 is a protective mechanism in cardiac myocytes (see signaling pathways of hypertrophic growth) because inhibitors of ERK 1/2 activation have been shown to exacerbate apoptosis while inhibitors of JNK/SAPK and p38 have been shown to inhibit apoptosis from a number of different stimuli (Yue et al., 2000). Therefore, activation of JNK/SAPK and p38 may be actively involved in promoting apoptotic death of cardiac myocytes.

Other signaling pathways of apoptosis in cardiac myocytes include effects arising from beta-adrenergic receptor stimulation and activation of cytokine receptors. In cardiac myocytes, stimulation of beta-adrenergic receptors (e.g. from norepinephrine or isoproterenol) leads to activation of adenylyl cyclase with resulting increases in cyclic AMP, activation of protein kinase A (PKA), and phosphorylation and activation of L-type Ca^{2+} channels (Communal et al., 1998). Entry of Ca^{2+} then may lead to activation of Ca^{2+}-dependent proteases and endonucleases culminating in apoptosis. In contrast, cytokine receptor stimulation (e.g., by IL-1b) in cardiac myocytes leads to upregulation of inducible nitric oxide synthase (iNOS), increased production of NO, formation of $ONOO_2$ and upregulation of Bax (Arstall et al., 1999). Furthermore, TNF-a receptor stimulation activates sphingomyelinase (SMase) to increase ceramide (CM) and sphingosine (SS) which subsequently induce apoptosis (Krown et al., 1996).

Often, no single biochemical event can explain the process by which a chemical agent is cardiotoxic. Thus, several of the biochemical mechanisms discussed in this section may be interrelated and may help explain the cardiotoxicity of selected chemical agents. Table 18-1 summarizes the general mechanisms of cardiotoxicity including some of the cellular perturbations involved and organ manifestations.

Table 18-1 General Mechanisms of Cardiotoxicity

CARDIOTOXICANTS

For simplicity, the cardiotoxicants have been classified into three major groups: (1) pharmaceutical agents including drugs of social use and abuse; (2) natural occurring substances including hormones, cytokines, and animal and plant toxins; and (3) industrial chemicals and other miscellaneous agents. Wherever possible, the major biochemical mechanisms of cardiotoxicity proposed for the agents under discussion are emphasized.

Pharmaceutical Agents

The cardiotoxicity of a pharmacologically active cardiovascular drug often represents an overexpression of its principal pharmacologic effect on the heart (Sperelakis, 1992). For example, digitalis, quinidine, and procainamide may induce cardiac arrhythmias as an exaggerated pharmacologic action of the drugs. In contrast, other cardiovascular drugs may produce cardiotoxicity by actions that are not necessarily related to their intended therapeutic use and principal pharmacologic effects. For instance, in addition to their pharmacologic actions on the myocardium and because of their pronounced sympathomimetic actions, the catecholamines may exert cardiotoxicity through their biochemical effects on certain cellular and subcellular processes (e.g., oxidative stress and calcium overload). Furthermore, other pharmaceutical agents, such as antibacterial agents, anthracyclines, and other antineoplastic agents, may produce myocardial injury and other cardiotoxic effects that are not related to their therapeutic and pharmacologic uses. The agents chosen for discussion do not necessarily encompass a comprehensive list of compounds that are potentially cardiotoxic; however, major classes of each group of compounds are discussed, and in many cases cardiotoxicity may be at least a potential concern with similar agents in the same class. Table 18-2 provides a summary of key pharmaceutical agents with their prominent cardiotoxic effects and proposed mechanisms of toxicity.

Table 18-2 Cardiotoxicity of Key Pharmaceutical Agents

Alcohol Ethanol cardiotoxicity can be divided into two categories: acute and chronic (associated with alcoholism). The acute toxicity of ethanol includes a negative dromotropic effect (reduced conductivity) and a decreased threshold for ventricular fibrillation. However, arrhythmias are prominent only after long-term or chronic exposure. The chronic consumption of ethanol by humans has been associated with myocardial abnormalities and dysfunction, a condition or syndrome known as alcoholic cardiomyopathy that may present similar symptoms as congestive heart failure.

Alcoholic Cardiomyopathy Chronic ethanol consumption and its implications in cardiac disease were first reported in the early 1960s. However, for many decades the role of ethanol in the pathogenesis of alcoholic cardiomyopathy was not widely understood, mainly because heart dysfunction was attributed to thiamine deficiency secondary to alcoholism (beriberi heart disease) and other types of malnutrition or to specific additives found in alcoholic beverages, such as cobalt (beer drinker's cardiomyopathy). However, more recent studies have clearly demonstrated that cardiac dysfunction in alcoholics can be dissociated from nutritional deficiencies and beriberi heart disease. In addition, the withdrawal of ethanol from patients with myocardial dysfunction may reverse many of the clinical symptoms, providing more evidence that ethanol is involved in the pathogenesis of the cardiomyopathy.

After years of investigation, it was proposed that the metabolite acetaldehyde is responsible for some of the cardiac injury associated with ethanol consumption. The metabolic enzyme responsible for the conversion of ethanol to acetaldehyde is alcohol dehydrogenase, which is absent in cardiac myocytes. Oxidation of ethanol to acetaldehyde proceeds at a rate that is independent of blood concentration. Studies have indicated that the impaired liver function of alcoholics may be sufficient to generate quantities of acetaldehyde that can reach the heart. The direct effects of acetaldehyde on the myocardium include inhibition of protein synthesis, inhibition of Ca^{2+} sequestration by the SR, alterations in mitochondrial respiration, and disturbances in the association of actin and myosin. The exact mechanism of alcoholic cardiomyopathy is unresolved. It has been suggested that a combination of multiple factors is involved and that certain conditions may predispose an individual to cardiac injury from ethanol. Factors such as chronic ethanol consumption, malnutrition, cigarette smoking, systemic hypertension, and beverage additives have all been implicated as potential contributors that can result in alcoholic cardiomyopathy (Ahmed and Regan, 1992).

Mechanisms of Alcohol-Induced Cardiotoxicity There is suggestive evidence that the generation of reactive oxidative metabolites from the metabolism of ethanol may lead to lipid peroxidation of cardiac myocytes or oxidation of cytosolic and membraneous protein thiols (Ribiere et al., 1992). Additional evidence that reactive oxidative metabolites derived from ethanol may be involved in the pathogenesis of alcoholic cardiomyopathy is provided by the report by Redetzki et al. (1983), who showed that pretreatment of rodents with a-tocopherol (vitamin E) before an acute dose of ethanol prevented increases in lactate dehydrogenase isoenzymes in the plasma and reduced ultrastructural evidence of myocardial injury. Because a-tocopherol can serve as an antioxidant and a free radical scavenger, this study suggested that ethanol-induced heart injury was mediated by the generation of free radicals from ethanol metabolism. Other investigations have shown that ethanol administration may increase the conversion of xanthine dehydrogenase to xanthine oxidase, an enzyme involved in the generation of superoxide anions, and may enhance the activity of peroxisomal acyl-CoA oxidase and catalase in rat myocardium. These two enzymes may increase the production of hydrogen peroxide and acetaldehyde, which may contribute to myocardial lipid peroxidation by ethanol treatment.

Antiarrhythmic and Inotropic Agents Antiarrhythmic agents have historically been classified based upon a primary mechanism of action: Na^+ channel blockers (class I), beta-adrenergic blockers (class II), agents that prolong action potential duration especially K^+ channel blockers (class III), and Ca^{2+} channel blockers (class IV). However, this classification scheme is somewhat confusing given the lack of specificity of most of the agents with one particular channel or receptor. Most of the antiarrhythmic drugs have cardiotoxic actions as a result of their pharmacologic effects. A review of the proarrhythmic mechanisms of antiarrhythmic drugs is provided by Nattel (1998). Inotropic agents include the cardiac glycosides, Ca^{2+} sensitizing agents, catecholamines, and other sympathomimetic agents. As with the antiarrhythmic drugs, inotropic agents may exert cardiotoxic effects through extensions of their pharmacologic mechanism. A brief review of antiarrhythmic and inotropic drug-induced cardiotoxicity is included; however, a wealth of literature regarding the proarrhythmic effects of these agents exists, and where appropriate,

review articles have been suggested.

Na⁺ Channel Blockers The class I antiarrhythmic agents are primarily Na⁺ channel blockers and include disopyramide, encainide, flecainide, lidocaine, mexiletine, moricizine, phenytoin, procainamide, propafenone, quinidine, and tocainide. Blockade of cardiac Na⁺ channels results in reduction of conduction velocity, prolonged QRS duration, decreased automaticity, and inhibition of triggered activity from delayed afterdepolarizations or early afterdepolarizations (Roden, 1996). Excessively slowed conduction may facilitate re-entry arrhythmias thus providing a proarrhythmic effect. As mentioned previously, the primary concern of Na⁺ channel blocker toxicity is that proarrhythmic effects are seen at a much higher incidence in those patients with a previous history of myocardial infarction or with acute myocardial ischemia (Nattel, 1998). Furthermore, the possibility is likely that proarrhythmic effects of these agents would also be more prevalent in patients with other cardiovascular diseases. Importantly, encainide, flecainide, propafenone, and quinidine are all substrates for gastrointestinal and hepatic cytochrome P450 3A4. Therefore, concomitant use of these class I antiarrhythmic agents with other drugs that inhibit cytochrome P450 3A4 is contraindicated because of increased serum concentrations of the antiarrhythmic agents. As discussed throughout this chapter, substrates and/or inhibitors of cytochrome P450 3A4 include, but are not limited to, the macrolide antibacterials, azole antifungals, benzodiazepines, human immunodeficiency virus (HIV) protease inhibitors, non-nucleoside reverse transcriptase inhibitors, astemizole, terfenadine, and cisapride.

K⁺ Channel Blockers The class III antiarrhythmic agents are drugs which prolong action potential duration, primarily by blockade of cardiac K⁺ channels. These agents include amiodarone, bretylium, dofetilide, ibutilide, quinidine, and sotalol. Blockade of K⁺ channels increases action potential duration and increases refractoriness (cell is undergoing repolarization and is refractory to depolarization). Prolonged action potential duration contributes to the development of early afterdepolarizations and promotion of tachycardia, especially polymorphic ventricular tachycardia (torsades de pointes). Most of the agents in this class also affect other ion channels and/or receptors. Amiodarone and quinidine also block Na⁺ channels while sotalol inhibits beta-adrenergic receptors in the heart. Amiodarone prolongs action potential duration and effective refractory period of Purkinje fibers and ventricular myocytes, and the most common adverse cardiovascular effect of amiodarone is bradycardia. However, amiodarone may have cardiotoxic effects by stimulating excessive Ca²⁺ uptake, especially in the presence of procaine (Gotzsche and Pederson, 1994). In addition, amiodarone induces a variety of other adverse effects at relatively high incidence including pulmonary toxicity (interstitial pneumonitis), thyroid toxicity, hepatotoxicity, neurotoxicity, ocular toxicity, and dermatologic toxicity. As with the Na⁺ channel blockers, the proarrhythmic effects of K⁺ channels blockers is enhanced in those patients with other forms of cardiac dysfunction include myocardial infarction and cardiac hypertrophy. Amiodarone and quinidine are substrates for cytochromes P450 3A4. Therefore, the concomitant use of amiodarone or quinidine is contraindicated with other drugs that inhibit cytochromes P450 3A4 (e.g., macrolides, azole antifungals, HIV protease inhibitors, non-nucleoside reverse transcriptase inhibitors, and many other drugs). With the multitude of K⁺ channels expressed in human heart, it seems possible that improved antiarrhythmic agents in this class could be developed.

Ca²⁺ Channel Blockers The class IV antiarrhythmic agents are Ca²⁺ channel blockers and include diltiazem and verapamil. The dihydropyridine Ca²⁺ channel blocking agents are not used to treat arrhythmias because they have a greater selectivity for vascular cells; however, these agents may also alter cardiac ion homeostasis when plasma concentrations of the drugs are elevated. The dihydropyridines interact with Ca²⁺ channels in the inactivated state of the channel, and because vascular smooth muscle resting potentials are lower than cardiac cells, the time spent in the inactivated state is relatively longer in vascular smooth muscle thus providing some preference of dihydropyridines for the vasculature (Galan et al., 1998). As described previously, bepridil, verapamil, and diltiazem exert negative inotropic and chronotropic effects (see "General Mechanisms of Cardiotoxicity," above). As discussed previously, these drugs exert a negative chronotropic effect and may produce bradycardia. In contrast, the dihydropyridine Ca²⁺ channel blockers typically induce a reflex tachycardia subsequent to peripheral vascular dilation and baroreceptor reflex leading to increased sympathetic outflow from the medulla. Verapamil and diltiazem are substrates for cytochrome P450 3A4; therefore, use of these drugs is cautioned in patients who are taking drugs that inhibit cytochrome P450 3A4. Moreover, verapamil and diltiazem may increase serum digoxin concentrations during concomitant use. These drug interactions do not involve inhibition of cytochrome P450 3A4 because digoxin is not significantly metabolized, but rather, altered renal elimination or volume of distribution.

Beta-Adrenergic Receptor Blocking Agents The class II antiarrhythmic agents are beta-adrenergic receptor blocking agents, and those used to treat arrhythmias include acebutolol, esmolol, propranolol, and sotalol. The catecholamines increase contractility, heart rate, and conduction through activation of beta-adrenergic receptors in the heart. These effects can be explained by increased adenylyl cyclase activity, increased cyclic AMP, activation of protein kinase A, and phosphorylation and activation of L-type Ca²⁺ channels thereby increasing intracellular Ca²⁺, and particularly the amplitude of the Ca²⁺ transient (see "Catecholamines and sympathomimetics," below). Therefore, antagonists of beta-adrenergic receptors in the heart lead to effects that are opposite that of catecholamines and are useful for the treatment of supraventricular tachycardia. The main adverse cardiovascular effect of beta-adrenergic receptor antagonists is hypotension. However, these drugs may exacerbate AV conduction deficits (e.g., heart block) and promote arrhythmias during bradycardia. As discussed previously, sotalol also inhibits K⁺ channels in the heart, thus carrying the proarrhythmic effects of class III antiarrhythmic drugs. Propranolol may also block Na⁺ channels (often described as a "membrane stabilizing" effect of propranolol) thereby carrying the proarrhythmic effects of class I antiarrhythmic drugs.

Cardiac Glycosides Cardiac glycosides (digoxin and digitoxin) are inotropic agents used for the treatment of congestive heart failure. Ouabain is a cardiac glycoside commonly used in the laboratory for electrophysiologic experiments in cardiac myocytes. As previously described, the mechanism of inotropic action of cardiac glycosides involves inhibition of Na⁺,K⁺-ATPase, elevation of intracellular Na⁺, activation of Na⁺/Ca²⁺ exchange, and increased availability of intracellular Ca²⁺ for contraction. Consequently, cardiotoxicity may result from Ca²⁺ overload, and arrhythmias may occur. However, the cardiovascular effects of cardiac glycosides are complex because of direct and indirect actions. As to the direct effects in addition to inhibition of Na⁺,K⁺-ATPase, cardiac glycosides initially prolong and then shorten action potential duration, perhaps through Ca²⁺-induced activation of K⁺ channels. Cardiac glycosides may also reduce resting membrane potential (less negative), induce delayed afterdepolarizations perhaps due to Ca²⁺ overload, and induce premature ventricular contraction or ectopic beats when membrane potential is reduced to threshold. As to the indirect effects, cardiac glycosides exhibit parasympatho-mimetic activity through vagal stimulation and facilitation of muscarinic transmission; however, at higher doses, sympathomimetic effects may occur as sympathetic outflow is enhanced. The principal adverse cardiac effects of cardiac glycosides include slowed AV conduction with potential block, ectopic beats, and bradycardia; however, during overdose, when resting membrane potential is significantly altered and ectopic beats are prevalent, ventricular tachycardia may develop and could progress to ventricular fibrillation. Importantly, a wide variety of drug interactions with digoxin have been reported, including both pharmacokinetic interactions (drugs that alter serum concentrations of digoxin) and pharmacodynamic interactions (drugs that alter the cardiac effects of digoxin).

Ca²⁺-Sensitizing Agents The newest class of agents that may be useful inotropic drugs for the treatment of heart failure have been designated as Ca²⁺-sensitizing agents (e.g., adibendan, levosimendan, and pimobendan). The main mechanism by which clinically available inotropic agents work is elevating intracellular free Ca²⁺ ([Ca²⁺]ᵢ) during the Ca²⁺ transient (i.e., increase the amplitude of the Ca²⁺ transient). Several pharmacologic means exist to achieve this effect: Na⁺,K⁺-ATPase inhibitors increase [Ca²⁺]ᵢ by elevating intracellular Na⁺ and activating Na⁺/Ca²⁺ exchange; beta-adrenergic receptor agonists elevate [Ca²⁺]ᵢ by activating adenylyl cyclase (to increase cyclic AMP) and protein kinase A which phosporylate and activate L-type Ca²⁺ channels in the plasma membrane; and phosphodiesterase inhibitors reduce the degradation of cyclic AMP. However, these mechanisms carry the risk of inducing Ca²⁺ overload. Therefore, considerable effort has gone into a search for compounds that increase Ca²⁺ sensitivity of cardiac myocytes, thereby obviating the need to increase [Ca²⁺]ᵢ (Lee and Allen, 1997). Several compounds have been identified that increase the sensitivity of cardiac myocyte contractions to Ca²⁺ without increasing [Ca²⁺]ᵢ, but the mechanism(s) responsible remain elusive and may include inhibition of cardiac phosphodiesterase. Although cardiotoxicity from the Ca²⁺ overload mechanism would not be expected following administration of these new agents, some experimental data suggests that they may still exert proarrhythmic effects—isolated working rat heart models demonstrated enhanced ventricular arrhythmias from some of these compounds (Lee and Allen, 1997). The possibility that such Ca²⁺-sensitizing agents interfere with diastolic function (relaxation) requires further investigation but may contribute to the ventricular arrhythmias associated with these drugs. Other Ca²⁺-sensitizing agents include the xanthine oxidase inhibitors allopurinol and oxypurinol, which have been shown to increase contractile force but decrease Ca²⁺ transient amplitude (Perez et al., 1998). The long clinical history of allopurinol use suggests that cardiotoxicity would be minimal if these drugs were used as inotropic agents.

Catecholamines and Sympathomimetics Catecholamines represent a chemical class of neurotransmitters synthesized in the adrenal medulla (epinephrine and norepinephrine) and in the sympathetic nervous system (norepinephrine). These neurotransmitters exert a wide variety of cardiovascular effects. Because of their ability to activate alpha- and beta-adrenergic receptors, especially in the cardiovascular system, a number of synthetic catecholamines have been developed for the treatment of cardiovascular disorders and other conditions such as asthma and nasal congestion. Inotropic and chronotropic catecholamines used to treat bradycardia, cardiac decompensation following surgery, or to increase blood pressure (e.g. hypotensive shock) include epinephrine, isoproterenol, and dobutamine, and these drugs typically display non-selective activation of adrenergic receptors. More selective beta₂-adrenergic receptor agonists used for bronchodilatory effects in asthma include albuterol, bitolterol, fenoterol, formoterol, metaproterenol, pirbuterol, procaterol, salmeterol, and terbutaline. High oral doses of albuterol or terbutaline or inhalational doses (i.e., enhanced delivery to the stomach instead of the lungs with subsequent systemic absorption) of these agents may lead to non-selective activation of beta₁-adrenergic receptors in the heart with subsequent tachycardia. Sympathomimetic drugs that are more selective for alpha-adrenergic receptors include the nasal decongestants ephedrine, phenylephrine, phenylpropanolamine, and pseudoephedrine. As with the asthma drugs, at high doses of nasal

decongestants can produce tachycardia, and a number of deaths have been reported. Of particular interest is the high concentration of ephedra alkaloids that may be present in some herbal remedies or "neutraceuticals," especially in products containing ma huang (Gurley et al., 1998). Tachycardia may occur from the consumption of large amounts of ephedra alkaloids, which may predispose the myocardium to ventricular arrhythmias. Some catecholamine derivatives (e.g., amphetamines, fenfluramine, phentermine) are used for their CNS-stimulant properties to reduce appetite. Significant concern has arisen regarding the potential for these drugs to induce pulmonary hypertension and cardiac valvular disease perhaps related to elevated serotonin levels in the blood (Fishman, 1999). Recently, however, fenfluramine was found to block Na^+ current in guinea pig heart tissue (Rajamani et al., 2000). Therefore these drugs may also exert a direct cardiotoxic effect, but the mechanisms responsible are not fully understood.

Mechanisms of Catecholamine-Induced Cardiotoxicity High circulating concentrations of epinephrine (adrenaline) and norepinephrine (noradrenaline) and high doses of synthetic catecholamines such as isoproterenol may induce toxic effects on the heart, including cardiac myocyte death. Furthermore, many of the catecholamines and related drugs have been shown to induce cardiac myocyte hypertrophic growth in vitro. The pathogenesis of catecholamine-induced cardiotoxicity is, however, unclear. Dhalla and colleagues (1992) have written a comprehensive review of the cardiotoxicity of catecholamines and related agents. Some of the more important hypotheses that explain the cardiotoxicity of catecholamines are discussed below.

A prominent early hypothesis regarding catecholamine-induced cardiotoxicity involved the pronounced pharmacologic effects of high concentrations of these compounds on the cardiovascular system, including increased heart rate, enhanced myocardial oxygen demand, and an overall increase in systolic arterial blood pressure. In the case of isoproterenol, there is a fall in blood pressure. These actions may cause myocardial hypoxia and, if severe enough, lead to the production of necrotic lesions in the heart. Because isoproterenol has greater cardiotoxic potential than does epinephrine or norepinephrine, it was suggested that the hypotension produced by isoproterenol is a major factor in lesions produced in the myocardium. However, subsequent investigations revealed that hypotension is not essential for the production of cardiac myocyte death by isoproterenol.

Other possible mechanisms for the cardiotoxicity of high concentrations of catecholamines include coronary insufficiency resulting from coronary vasospasm, decreased levels of high-energy phosphate stores caused by mitochondrial dysfunction, increased sarcolemmal permeability leading to electrolyte alterations, altered lipid metabolism resulting in the accumulation of fatty acids, and intracellular Ca^{2+} overload. Although these mechanisms have received support through the years, there are conflicting studies that argue against one or more of these proposed mechanisms (Dhalla et al., 1992).

As discussed under "General Biochemical Mechanisms of Cardiotoxicity," above, oxidative stress is a major factor in cardiac myocyte injury induced by several xenobiotics, and oxidative stress has been implicated in catecholamine-induced cardiotoxicity (Dhalla et al., 1992). Because the oxidation of catecholamines may result in the formation of aminochromes and oxygen free radicals, oxidative stress may play a significant role in catecholamine-induced cardiotoxicity. Antioxidants such as vitamin E and ascorbic acid have been shown to provide protection against the cardiotoxicity of isoproterenol and other catecholamines.

Sarcolemmal Injury and Ca^{2+} Alterations Induced by Catecholamines Another hypothesis to explain the cardiotoxicity of catecholamines such as isoproterenol is derangement of electrolyte homeostasis of cardiac myocytes at the level of the sarcolemma and other subcellular membrane sites. Electrolyte shifts in magnesium (Mg^{2+}) and K^+ have been suggested as possible factors in the myocardial dysfunction and cardiac myocyte death associated with isoproterenol administration. For example, Mg^{2+} may serve as a cofactor in the regulation of phosphate transfers and may cause a decrease in the uptake of Ca^{2+} by isolated respiring mitochondria.

The use of the concept of Ca^{2+} overload to explain isoproterenol-induced cardiac necrosis has generated much interest (Fleckenstein et al., 1973). These investigators showed that there was a six- to sevenfold increase in the rate of Ca^{2+} uptake and a doubling of the net myocardial Ca^{2+} content. It was suggested that this excessive Ca^{2+} overload may initiate a loss of high-energy phosphates through increased activation of Ca^{2+}-dependent intracellular ATPase and impaired mitochondrial oxidative phosphorylation. Accumulation of large amounts of Ca^{2+} in cardiac myocytes may alter the integrity and function of several membrane systems. In addition to affecting mitochondrial energy production, Ca^{2+} may activate neutral proteases, phospholipases, and endonucleases. Activation of these degradative enzymes may inhibit membrane-bound enzymes such as Na^+,K^+-ATPase. As a result, there is an increase in Na^+ levels and a loss of cytoplasmic K^+. The increased Na^+ content would further enhance Ca^{2+} accumulation through the Na^+/Ca^{2+} exchanger. Recently, it has been suggested that oxidative degeneration of membrane lipids results in increased sarcolemmal Ca^{2+} permeability. Because isoproterenol may form oxidative by-products, these metabolites could interact with the lipid bilayer, cause sarcolemmal injury, and alter Ca^{2+} regulatory mechanisms. The summation of these alterations likely contributes to the cellular dysfunction and cardiotoxicity induced by catecholamines.

Apoptosis and Catecholamine-Induced Cardiotoxicity Catecholamines have recently been found to induce apoptosis of cardiac myocytes. Norepinephrine and isoproterenol stimulated apoptosis (as defined by DNA fragmentation and flow cytometry) of adult rat ventricular myocytes (Communal et al., 1998). Furthermore, catecholamine-induced apoptosis was inhibited by a beta-adrenergic receptor antagonist (the non-selective beta-blocker propranolol), protein kinase A inhibitor (H-89), and L-type Ca^{2+} channel blocker (diltiazem); whereas, an adenylyl cyclase activator (forskolin) mimicked the effects of norepinephrine and isoproterenol. Activation of beta-adrenergic receptors increases cyclic AMP and phosphorylates L-type Ca^{2+} channels, leading to Ca^{2+} influx. Subsequent studies by the same group demonstrated that catecholamine-induced apoptosis in this model was mediated by beta$_1$-adrenergic receptor stimulation, while beta$_2$-adrenergic receptor stimulation inhibited apoptosis (Communal et al., 1999). Furthermore, transgenic mice overexpressing Gsa (GTP binding protein coupling beta-adrenergic receptors to adenylyl cyclase) developed cardiomyopathy, and evidence of cardiac myocyte apoptosis was found (Geng et al., 1999). Therefore at least part of the mechanism of catecholamine-induced cardiotoxicity may involve stimulation of beta$_1$-adrenergic receptors, activation of adenylyl cyclase and protein kinase A, phosphorylation of L-type Ca^{2+} channels, increased intracellular Ca^{2+}, and activation of endonucleases, proteases, and/or other enzymes and proteins involved in apoptosis.

Anthracyclines and Other Antineoplastic Agents Cardiotoxicity is recognized as a serious side effect of chemotherapy for malignant cancers, especially with well-known antitumor agents such as doxorubicin, daunorubicin, 5-fluorouracil, and cyclophosphamide. Havlin (1992) has published an excellent review of some of these important antitumor agents and their cardiotoxic effects.

Anthracyclines The anthracyclines—doxorubicin and daunorubicin—are widely used antineoplastic agents for the treatment of breast cancer, leukemias, and a variety of other solid tumors. Unfortunately, the clinical usefulness of these agents is limited because of cardiotoxicity manifest by ECG changes and dose-dependent cardiomyopathy (Doroshow, 1991; Havlin, 1992). Both acute and chronic cardiotoxic effects of anthracyclines have been described. The acute effects mimic anaphylactic-type responses, such as tachycardia and various arrhythmias. These effects are usually manageable and most likely are due to the potent release of histamine from mast cells sometimes observed in acute dosing. Acutely, large doses can also cause left ventricular failure, which responds to inotropic agents (e.g., digitalis, isoproterenol) and high perfusions of Ca^{2+}, suggesting an acute mechanism of toxicity that involves altered Ca^{2+} homeostasis. The greatest limiting factor of the anthracyclines is associated with long-term exposure, which usually results in the development of cardiomyopathies and, in severe stages, congestive heart failure (Havlin, 1992). Morphologically, there is vacuolization of the SR, myofibrillar loss, and swelling of the mitochondria.

Two new anthracyclines were introduced to the U.S. market in 1999, and a lipid formulation of doxorubicin (liposomal doxorubicin) is under development. *Valrubicin* is a semisynthetic derivative of doxorubicin approved for treatment of carcinoma in situ of the bladder. It is administered locally for bladder cancer and therefore induces only mild systemic toxicities; however, systemic absorption from the bladder may occur, but valrubicin seems to exhibit a lower propensity for cardiotoxicity than doxorubicin (Hussar, 2000). *Epirubicin* is a semisynthetic derivative of daunorubicin approved for treatment of breast cancer. Like doxorubicin, epirubicin is given systemically and may induce cardiotoxicity. However, epirubicin is more lipophilic than doxorubicin and is significantly metabolized by the conjugative pathways in the liver, resulting in a shorter half-life and a lower incidence of cardiotoxicity than with doxorubicin (Hussar, 2000).

Mechanisms of Anthracycline-Induced Cardiotoxicity Several major hypotheses have been suggested to account for the onset of anthracycline-induced cardiomyopathy: (1) oxidative stress from redox cycling or mitochondrial Ca^{2+} cycling, (2) defects in mitochondrial integrity and subsequent deterioration of myocardial energetics, (3) alterations in both SR Ca^{2+} currents and mitochondrial Ca^{2+} homeostasis, and (4) altered cardiac myocyte gene expression and induction of apoptosis. The cause-and-effect relationships of the proposed mechanisms of cardiotoxicity have not been determined, and no single theory adequately explains the exact mechanism for anthracycline-induced cardiomyopathy.

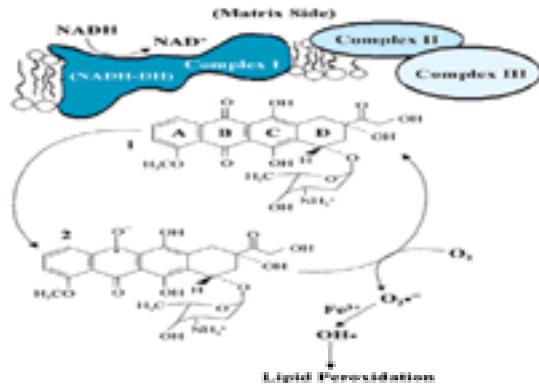
Reactive Oxygen Species and Doxorubicin-Induced Cardio-toxicity Although several hypotheses have been proposed to explain the mechanism of the cardiotoxicity of doxorubicin, the free radical hypothesis has received the most attention. The formation of reactive oxygen species by doxorubicin (schematically shown in Fig. 18-10) has been attributed to redox cycling of the drug (Powis, 1989). Doxorubicin can undergo futile redox cycling that results in the production of oxygen free radicals; these reactive oxygen species may then oxidize proteins, lipids, and nucleic acids and potentially cause DNA strand scission.


Figure 18-10. Production of superoxide radical anions by oxidation-reduction cycling of doxorubicin at the level of the mitochondria.

NADH dehydrogenase (NAD-DH), which is located within complex I, has been proposed as the enzyme that catalyzes the one-electron reduction of doxorubicin (1) to a semiquinone radical (2). The semiquinone then may be reoxidized back to the parent compound by means of the reduction of molecular oxygen (O_2) to the superoxide anion ($O_2 \bullet^-$).

The quinone-like structure of doxorubicin permits this molecule to accept an electron and form a semiquinone radical. Oxidation of the semiquinone back to the parent quinone by molecular oxygen results in superoxide radical ions that are believed to initiate oxidative stress. The enzymatic reduction that is believed to be responsible for the generation of superoxide by doxorubicin (at the level of the mitochondria) has been proposed to occur between complexes I and III of the mitochondrial respiratory chain. Doxorubicin has high affinity for cardiolipin, a phospholipid found on the inner mitochondrial membrane, where NADH dehydrogenase converts the drug to a semiquinone radical (Marcillat et al., 1989). In the presence of oxygen, this radical is responsible for the generation of reactive oxygen species, which then may peroxidize unsaturated membrane lipids and initiate myocardial cell injury. Nonetheless, several observations appear to be inconsistent with the free radical–induced cardiotoxicity of doxorubicin (Olson and Mushlin, 1990).

Mitochondrial Ca^{2+} Homeostasis and Doxorubicin-Induced Cardiotoxicity An alternate hypothesis to explain the cardiotoxicity of doxorubicin implicates a disruption of mitochondrial Ca^{2+} homeostasis without necessarily involving pronounced Ca^{2+} overload (Chacon and Acosta, 1991; Chacon et al., 1992; Solem et al., 1994). This hypothesis suggests that doxorubicin induces a cycling of mitochondrial Ca^{2+} that is associated with the production of reactive oxygen species and dissipation in the mitochondrial membrane potential, which in turn may result in depletion of cellular ATP. Ruthenium red, an inhibitor of the mitochondrial Ca^{2+} uniport, decreased doxorubicin production of reactive oxygen species in mitochondria and isolated cardiac myocytes and protected the cells from doxorubicin-induced cell killing. Therefore, disruption of mitochondrial Ca^{2+} homeostasis may be an important mechanism responsible for the cardiotoxicity of doxorubicin. Furthermore, cyclosporin A, an inhibitor of the Ca^{2+}-dependent Ca^{2+} release channel in mitochondria, inhibited the Ca^{2+}-induced depolarization of membrane potential of mitochondria isolated from rats chronically treated with doxorubicin. These results suggest that doxorubicin may induce futile cycling of Ca^{2+} across the mitochondrial membrane and that this may be responsible for the formation of reactive oxygen species rather than or in addition to redox cycling of the quinone moiety.

Apoptosis and Anthracycline-Induced Cardiotoxicity Increas-ing evidence suggests that at least part of the mechanism of anthracycline-induced cardiotoxicity includes induction of apoptosis. As described under "General Mechanisms of Cardiotoxicity," generation of reactive oxygen species, altered mitochondrial function or permeability, and altered Ca^{2+} homeostasis serve as important stimuli of cardiac myocyte apoptosis. Therefore, apoptosis may be an extension of the previously described possible mechanisms of anthracycline-induced cardiotoxicity. For example, daunorubicin induced apoptosis of cultured neonatal and adult rat cardiac myocytes, and induction of apoptosis was prevented by dexrazoxane, an iron chelator, suggesting that reactive oxygen species were involved with daunorubicin-induced apoptosis (Sawyer et al., 1999). Furthermore, doxorubicin induced Bax expression, activated caspase 3, and induced apoptosis in cultured fetal cardiac myocytes (Wang et al., 1998). In cultured neonatal rat cardiac myocytes, daunorubicin activated the MAPKs, an effect that was inhibited by free radical scavengers and Ca^{2+} chelators (Zhu et al., 1999). In these experiments, ERK 1/2 activation likely occurred through Ras activation and appeared protective; whereas JNK/SAPK and p38 activation (likely through Rho activation) contributed to daunorubicin-induced apoptosis. Ceramide may also be involved in doxorubicin-induced apoptosis, as adult rat ventricular myocytes developed signs of apoptosis associated with increased sphingomyelinase activity and ceramide production (Andrieu-Abadie et al., 1999). Doxorubicin-induced apoptosis has also been demonstrated in whole-animal studies, where intraperitoneal injection in adult Wistar rats produced histologic signs of apoptosis in the heart (Arola et al., 2000).

Other Possible Mechanisms of Doxorubicin-Induced Cardio-toxicity Other possible mechanisms to explain the cardiotoxicity of doxorubicin include Ca^{2+} overload that overwhelms intracellular homeostatic processes, increased production of prostaglandins and platelet-activating factor, increased release of histamine, and the formation of a toxic metabolite of doxorubicin (Olson and Mushlin, 1990).

5-Fluorouracil Clinical evidence of 5-fluorouracil cardiotoxicity ranges from mild precordial pain and ECG abnormalities (ST segment elevation, high peaked T waves, T-wave inversions, and sinus tachycardia) to severe hypotension, atrial fibrillation, and abnormalities of ventricular wall motion. A principal mechanism proposed for the cardiotoxicity of fluorouracil is myocardial ischemia precipitated by coronary vasospasm, but this finding has been disputed because of the short half-life of fluorouracil. More recent studies suggest that the cardiotoxicity of fluorouracil can be attributed to impurities present in commercial products of the drug, one of which is metabolized to fluoroacetate, a compound that might also participate in fluorouracil-induced cardiotoxicity.

Cyclophosphamide High doses of cyclophosphamide given to cancer or transplant patients may lead to severe hemorrhagic cardiac necrosis. The mechanism of the cardiotoxicity of this agent is not clear, but there is suggestive evidence that the toxic metabolite of cyclophosphamide, 4-hydroperoxycyclophosphamide (4-HC), may alter the ion homeostasis in cardiac myocytes, resulting in increased Na^+ and Ca^{2+} content and reduced K^+ levels (Levine et al., 1993). Furthermore, the same investigators showed that the cytotoxicity of 4-HC is markedly altered by the cellular glutathione concentration, suggesting a role for oxidative stress in 4-HC–induced cardiotoxicity.

Antimicrobial and Antiviral Agents Although the clinical use of antimicrobial and antiviral agents usually presents limited cardiovascular problems in routine therapy for uncomplicated infections, the use of some of these agents may result in adverse cardiac effects, especially in instances of overdosage and in patients with preexisting cardiovascular dysfunction. Keller and associates (1992) have presented an excellent review of key antibacterial agents that may have adverse cardiovascular effects.

Aminoglycosides The aminoglycoside class of antibiotics—which includes agents such as amikacin, gentamicin, kanamycin, netilmicin, streptomycin, and tobramycin—is associated with direct cardiodepressant actions in a number of species, although these effects are clinically rare in humans. Gentamicin, a representative aminoglycoside, has been thoroughly investigated for its Ca^{2+}-related myocardial depressant actions. Gentamicin's negative inotropic actions can be antagonized by excess Ca^{2+}, and genta- micin has an inhibitory action on slow inward Ca^{2+} channels in heart muscle. It has been proposed that aminoglycosides inhibit the uptake or binding of Ca^{2+} at sarcolemmal sites, thus reducing the concentration of membrane-bound Ca^{2+} available for movement into the myoplasm during depolarization of the sarcolemma. Other investigators have confirmed these observations and have reported other data that suggest that gentamicin's principal mechanism of cardiodepression is the dislocation of Ca^{2+} from slow-channel binding sites on the external surface of the sarcolemma, which results in a blockade of the channels (Hino et al., 1982).

Macrolides Macrolide antibacterial agents include azithromycin, clarithromycin, dirithromycin, and erythromycin. Erythromycin has been associated, although rarely, with QT interval prolongation and with cardiac dysrhythmias characterized by polymorphic ventricular tachycardia (torsades de pointes). These effects occur primarily in patients with underlying cardiac disease. The clinical findings of erythromycin-induced cardiotoxicity suggest that the drug blocks delayed rectifier K^+ channels. Importantly, erythromycin and other macrolides (most of which are significantly metabolized by and are competitive inhibitors of gastrointestinal and hepatic cytochrome P450 3A4) inhibit the elimination of other agents that are cytochrome P450 3A4 substrates and also inhibit delayed rectifier K^+ current in the heart (as discussed below). Consequently, macrolides were contraindicated for use in patients also taking astemizole, terfenadine, and cisapride (although all three of these drugs have been removed from the market).

Fluoroquinolones In recent years (i.e.,1997–2000), no other class of antibacterial agents has experienced as rapid growth in terms of numbers of new agents

released on the market in the United States than the fluoroquinolones. Fluoroquinolone antibacterial agents include ciprofloxacin, enoxacin, gatifloxacin, gemifloxacin, grepafloxacin, levofloxacin (levo-rotatory isomer of ofloxacin), lomefloxacin, moxifloxacin, norfloxacin, ofloxacin, sparfloxacin, and trovafloxacin (Pickerill et al., 2000). These drugs exhibit a wide variety of toxicities including CNS stimulation from inhibition of g-aminobutyric acid receptors, photosensitivity, hepatotoxicity, arthropathy, and QT interval prolongation. Of the numerous fluoroquinolones, grepafloxacin, moxifloxacin, and sparfloxacin have been associated with QT interval prolongation in perhaps a higher incidence than macrolides. In fact, grepafloxacin was voluntarily removed from the U.S. market because of the relatively high incidence of QT interval prolongation and risk of torsades de pointes. As with erythromycin, the signs of fluoroquinolone-induced cardiotoxicity are consistent with inhibition of delayed rectifier K^+ channels in the heart.

Other Antibacterial Agents Tetracycline and chloramphenicol have been reported to depress myocardial contractility by direct cardiac myocyte interaction or an indirect effect that lowers Ca^{2+} concentrations in the plasma or extracellular spaces, respectively. Indeed, the tetracylcines are Ca^{2+} chelating agents. However, tetracycline or chloramphenicol-induced cardiotoxicity is a rare clinical findings.

Antifungal Agents Some of the polyene group of antifungal agents (e.g., amphotericin B) may depress myocardial contractility by blocking activation of slow Ca^{2+} channels and inhibiting the influx of Na^+. Very high concentrations of amphotericin B increase the permeability of the sarcolemmal membrane, and electrophysiologists use the drug to create perforated patch-clamp models. Ventricular tachycardia and cardiac arrest have been reported in patients treated with amphotericin B. However, the incidence of amphotericin B–induced cardiotoxicity pales in comparison with its prominent toxicity in the kidney (see Chap. 14, " Toxic Responses of the Kidney"). Flucytosine is another antifungal agent that has been associated with cardiotoxicity. In fungal cells, flucytosine is converted to 5-fluorouracil, which then exerts antifungal effects. However, flucytosine may be converted to 5-fluorouracil by gastrointestinal microflora in humans, which then may be absorbed systemically and induce cardiotoxicity (see 5-fluorouracil above, under "Anthracyclines and Other Antineoplastic Agents"). Cardiac arrest has been reported in individuals receiving flucytosine. Finally, concern about azole antifungal drug interactions with astemizole, terfenadine, and cisapride was prevalent, and coadministration of azoles with these drugs was contraindicated. The azole antifungals itraconazole and ketoconazole are not potent cardiotoxicants in humans; however, they are substrates and competitive inhibitors of gastrointestinal and hepatic cytochrome P450 3A4. Because itraconazole and ketoconazole reduce clearance and increase plasma concentrations of astemizole, terfenadine, and cisapride when used concomitantly, these azoles may predispose individuals to astemizole-, terfenadine-, or cisapride-induced QT interval prolongation and risk of torsades de pointes.

Antiviral Agents Antiviral agents that are potentially cardiotoxic include the nucleoside analog reverse transcriptase inhibitors (NRTIs) used for the treatment of human immunodeficiency virus (HIV) infections. However, direct cardiotoxicity of these agents is rare in HIV patients and clinical studies are complicated by the findings that cardiomyopathy is related to disease progression. Nonetheless, zidovudine (AZT) was recently found to induce cardiomyopathy in transgenic mice expressing replication-incompetent HIV (Lewis et al., 2000). Cardiac function was depressed in these mice and accompanied by depressed SERCA mRNA expression, increased atrial natriuretic factor mRNA expression, left ventricular hypertrophy, and damaged mitochondria (swelling, dissolution of cristae, and fragmentation). Therefore, AZT-induced cardiotoxicity in this model may be produced by altered Ca^{2+} homeostasis and/or mitochondrial toxicity. The mitochondrial toxicity of AZT has been shown in skeletal muscle biopsy samples from AIDS patients (Dalakas, et al., 1990). Furthermore, mitochondrial toxicity from the NRTIs has been implicated as a cause of NRTI-induced hepatotoxicity, lipodystrophy, and pancreatic toxicity, and, at least in vitro, several NRTIs (zalcitabine, ddc; stavudine, d4T; and AZT) inhibited mitochondrial DNA polymerase while also decreasing mitochondrial DNA synthesis, DNA content, and ATP production—effects that may be related to the therapeutic mechanism yet resulting in incorporation of NRTIs into mitochondrial DNA (Brinkman et al., 1998).

As with macrolides and azole antifungal agents, some antiviral agents participate in drug interactions with agents that exhibit cardiotoxicity. The HIV protease inhibitors are substrates and competitive inhibitors of cytochromes P450 3A4; therefore amprenavir, indinavir, nelfinavir, ritonavir, and saquinavir are contraindicated for coadministration with astemizole, terfenadine, cisapride, or other drugs that prolong the QT interval and are substrates for cytochrome P450 3A4. Finally, the nonnucleoside reverse transciptase inhibitor (NNRTIs) delaviridine is also an inhibitor of cytochromes P450 3A4 and would produce similar interactions with astemizole, terfenadine, and cisapride. However, the NNRTI nevirapine (and perhaps efavirenz) is an inducer of cytochromes P450 3A4 and would not be expected to interact with these drugs.

Centrally Acting Drugs There are numerous examples of CNS-acting drugs that have considerable effects on the cardiovascular system. Some of the more cardiotoxic agents that have a major pharmacologic action on the brain and nervous system include tricyclic antidepressants, general anesthetics, some of the opioids, and antipsychotic drugs. Other drugs, such as cocaine and ethanol, are discussed in separate sections.

Tricyclic and Other Antidepressants Standard tricyclic antidepressants (TCAs, including amitriptyline, desipramine, doxepin, imipramine, and protriptyline) have significant cardiotoxic actions, particularly in cases of overdose. The effects of TCAs on the heart include ST segment elevation, QT interval prolongation, supraventricular and ventricular arrhythmias (including torsades de pointes), and sudden cardiac death. In addition, as a result of peripheral alpha-adrenergic blockade, they may cause postural hypotension—probably the cardiovascular effect of TCAs that is the most prevalent. Although many of these adverse effects are related to the quinidine-like actions, anticholinergic effects, and adrenergic actions of these agents, the tricyclics also may have direct cardiotoxic actions on cardiac myocytes and Purkinje fibers, including depression of inward Na^+ and Ca^{2+} and outward K^+ currents (Pacher et al., 1998). Furthermore, the risk of TCA-induced cardiotoxicity is significantly enhanced in children and by concomitant administration of other agents that alter ion movement or homeostasis in the heart (e.g., the Na^+ channel–blocking class I antiarrhythmic agents), or use in patients with underlying cardiovascular disease.

In contrast, the selective serotonin reuptake inhibitors (SSRIs including fluoxetine, fluvoxamine, paroxetine, sertraline, and venlafaxine) carry a lower risk of cardiotoxicity than the TCAs. Moreover, the SSRIs have fewer anticholinergic and antihistaminergic effects than the TCAs. Indeed, clinical studies have not revealed any fluoxetine-induced conduction delays in the heart, nor have clinical studies shown any significant effects of fluoxetine on the electrocardiogram (Pacher et al., 1998). Nonetheless, some case reports of atrial fibrillation and bradycardia secondary to fluoxetine administration have surfaced; in animal models, fluoxetine may block Na^+ and/or Ca^{2+} channels (Pacher et al., 1998).

Antipsychotic Agents Many antipsychotic agents exert profound cardiovascular effects, particularly orthostatic hypotension. Currently used antipsychotic agents include the phenothiazines (acetophenazine, chlorpromazine, fluphenazine, mesoridazine, perphenazine, thioridazine, and trifluoperazine), chlorprothixene, thiothixene, and other heterocyclic compounds (clozapine, haloperidol, loxapine, molindone, pimozide, and risperidone). The mechanisms responsible for the cardiovascular effects of antipsychotics are extremely complex because the drugs may alter cardiovascular function through indirect actions on the autonomic and central nervous systems and through direct actions on the myocardium. As with TCAs, the most prominent adverse cardiovascular effect of antipsychotic agents is orthostatic hypotension. However, the phenothiazines (e.g., chlorpromazine and thioridazine) may exert direct effects on the myocardium, including negative inotropic actions and quinidine-like effects (Baldessarini, 1996). Some ECG changes induced by these agents include prolongation of the QT and PR intervals, blunting of T waves, and depression of the ST segment. Through anticholinergic actions, clozapine can produce substantial elevations in heart rate (tachycardia), but the most prominent adverse cardiovascular effect is orthostatic hypotension.

General Anesthetics The inhalational general anesthetics, as exemplified by enflurane, desflurane, halothane, isoflurane, methoxyflurane, and sevoflurane may have adverse cardiac effects, including reduced cardiac output by 20 to 50 percent, depression of contractility, and production of arrhythmias (generally benign in healthy myocardium but more serious in cardiac disease). These anesthetics may sensitize the heart to the arrhythmogenic effects of endogenous epinephrine or to beta-receptor agonists. Investigations suggest that halothane, as a prototype, may block the L-type Ca^{2+} channel by interacting with dihydropyridine binding sites, may disrupt Ca^{2+} homeostasis associated with the SR, and may modify the responsiveness of the contractile proteins to activation by Ca^{2+} (Bosnjak, 1991). Propofol is an intravenously administered general anesthetic that has also been shown to decrease cardiac output and blood pressure. Several investigations have demonstrated that propofol exerts direct actions on cardiac myocytes resulting in a negative inotropic effect. As to the mechanism(s) involved, propofol has been shown to antagonize beta-adrenergic receptors, inhibit L-type Ca^{2+} current, and reduce Ca^{2+} transients (Zhou et al., 1997; Zhou et al., 1999; Guenoun et al., 2000). These effects have been observed in vitro at concentrations that could be achieved following bolus administration of propofol. Furthermore, the adverse cardiovascular effects of propofol may be enhanced in patients with underlying cardiovascular disease.

Local Anesthetics Because of their ability to block conduction in nerve axons, local anesthetics interfere with the conduction or transmission of impulses in other excitable organs, including the heart and circulatory system. In general, local anesthetics such as lidocaine and mepivacaine have few undesirable cardiovascular effects. However, when high systemic concentrations of cocaine and procainamide are attained, these agents may have prominent adverse effects on the heart. Because cocaine is abused by a significant number of individuals, its adverse effects on the myocardium are described in more detail.

Cocaine The cardiotoxicity of cocaine is usually explained by its general pharmacologic effects on excitable tissues, which include its ability to act as a local anesthetic and block conduction in nerve fibers by reversibly inhibiting Na^+ channels and stopping the transient rise in Na^+ conductance. In the heart, cocaine decreases the rate of depolarization and the amplitude of the action potential, slows conduction speed, and increases the effective refractory period. The other major

pharmacologic action of cocaine is its ability to inhibit the reuptake of norepinephrine and dopamine into sympathetic nerve terminals (sympathomimetic effect). Cocaine will, indirectly through its actions on catecholamine reuptake, stimulate beta- and alpha-adrenergic receptors, leading to increased cyclic AMP and inositol triphosphate levels. These second messengers will, in turn, provoke a rise in cytosolic Ca^{2+}, which causes sustained action potential generation and extrasystoles. The local anesthetic action, as described above, impairs conduction and creates a condition for reentrant circuits. The net effect of these two pharmacologic actions is to elicit and maintain ventricular fibrillation.

Whereas the sympathomimetic and local anesthetic actions of cocaine are plausible mechanisms to explain the cardiac arrhythmias experienced by some cocaine abusers, it is still not clear how cardiac myocyte death and myocardial infarction may develop with cocaine use. One explanation is that the increased levels of catecholamines caused by cocaine's inhibition of reuptake leads to myocardial ischemia resulting from coronary artery vasoconstriction by the catecholamines (as described under "General Mechanisms of Cardiotoxicity," above). While the adverse actions of cocaine have been documented in humans with advanced coronary artery disease, cocaine users are often young and have normal coronary arteries. Whether coronary vasoconstriction by cocaine and the catecholamines is sufficient to lead to myocardial ischemia and/or myocardial infarction in the normal population is not known.

A third explanation for the cardiotoxicity of cocaine is that it may be directly toxic to the myocardium beyond the direct effects on the Na$^+$ channel. Peng and coworkers (1989) ultrastructurally examined endomyocardial biopsy specimens from seven patients with a history of cocaine abuse and found that more than 70 percent of these showed multifocal myocyte necrosis. There was extensive loss of myofibrils, and marked sarcoplasmic vacuolization was observed. Peng and coworkers suggested that these toxic manifestations were not secondary to myocardial ischemic events because the amount of myocardial necrosis was small and focal and usually involved individual cells that were occasionally surrounded by inflammatory cell infiltrates—changes that are not associated with myocardial ischemia. In addition, these cardiotoxic manifestations produced by cocaine are similar to those seen in cardiotoxicity due to doxorubicin, an agent known for its direct toxicity to myocardial cells.

The mechanism by which cocaine directly injures myocardial cells is not clear. However, this drug may significantly inhibit mitochondrial electron transport, especially in the NADH dehydrogenase region (Fantel et al., 1990). Alterations in Ca^{2+} homeostasis by excess catecholamine release induced by cocaine or by the direct effects of cocaine on sarcolemmal integrity may also be involved in myocyte necrosis. For example, in neonatal rat cardiac myocyte cultures, cocaine inhibited Ca^{2+} mobilization from the SR, and in adult rat ventricular myocytes, cocaine depressed Ca^{2+} transients and inhibited excitation-contraction coupling (Yuan and Acosta, 1994; Stewart et al., 1991). More recent investigations have found that repeated administration of cocaine to rats decreased cardiac concentrations of glutathione (GSH), GSH peroxidase, GSH S-transferase, catalase, and ATP, and it increased cardiac concentrations of oxidized glutathione (GSSG), protein carbonyls, manganese superoxide disumutase, and malondialdehyde (Devi and Chan, 1999). Therefore repeated cocaine administration may promote oxidative stress in the heart.

Given these changes in cardiac myocytes of the heart following cocaine administration, it is perhaps not surprising that cocaine has also been shown to induce apoptosis of cardiac myocytes. In fetal cardiac myocyte cultures, cocaine exposure induced redistribution of phosphatidylserine from the inner leaflet to the outer leaflet of the sarcolemmal membrane, DNA fragmentation, and release of cytochrome c from the mitochondria (Xiao et al., 2000). Furthermore, inhibitors of caspase 9 and caspase 3 reduced the percentage of apoptotic cells in these experiments, consistent with cocaine-induced cytochrome c release from the mitochondria and activation of these caspases. Other studies have shown that cocaine induces apoptosis of adult rat cardiac myocytes as well (Zhang et al., 1999a). However, chronic cocaine administration to rats has also been shown to induce left ventricular hypertrophy while blood pressure remained normal (Besse et al., 1997). Thus, a combination of actions involving inhibition of Na$^+$ channels, altered Ca^{2+} homeostasis, promotion of oxidative stress, inhibition of mitochondrial function, and induction of hypertrophy and apoptosis may contribute to direct injury of the myocardium by cocaine. Overlying ethanol consumption may exacerbate all of the effects of cocaine on the heart. In the presence of ethanol, cocaine is converted to a benzoylecgonine ethyl ester called cocaethylene (Dean et al., 1992), which may also exert cardiotoxic effects. However, little is known about mechanisms of cocaethylene-induced cardiotoxicity and whether this metabolite contributes to cocaine associated morbidity and mortality.

Other Local Anesthetics Other local anesthetic drugs include benzocaine, bupivacaine, etidocaine, lidocaine, mepivacaine, pramoxine, prilocaine, procaine, procainamide, proparacaine, ro-pivacaine, and tetracaine. Two of these local anesthetic agents are also used as antiarrhythmic agents (discussed previously): lidocaine and procainamide. In general and with the exception of bupivacaine, etidocaine, lidocaine and procainamide, direct cardiotoxic effects of the remaining local anesthetics are rare. However, extremely high doses of these other agents may result in direct cardiotoxicity where decreases in electrical excitability, conduction rate, and force of contraction occur likely through inhibition of cardiac Na$^+$ channels (Catterall and Mackie, 1996). Bupivacaine and etidocaine are more potent cardiotoxicants than lidocaine, and high dose intravenous administration can produce severe ventricular arrhythmias. The more potent cardiotoxic effects of these agents may be related to slower dissociation from the Na$^+$ channel and more prolonged block in comparison with lidocaine (Catterall and Mackie, 1996).

Antihistamines The second-generation histamine H$_1$ receptor antagonists (antihistamines) have been associated with life-threatening ventricular arrhythmias and sudden cardiac death (Simons, 1994). For example, terfenadine and astemizole have been shown to have a number of adverse effects on the electrophysiology of the heart, including altered repolarization, notched inverted T waves, prominent TU waves, prolonged QT interval, first- and second-degree AV block, ventricular tachycardia or fibrillation, and torsades de pointes. Numerous studies have demonstrated that these antihistamines produce cardiac arrhythmias by blocking the delayed rectifier K$^+$ channel and prolonging action potential duration in cardiac myocytes. The prolonged action potential duration promotes early afterdepolarizations and predisposes the myocardium to ventricular arrhythmias. However, terfenadine also inhibits L-type Ca^{2+} channels in rat ventricular myocytes at concentrations near or below that required to inhibit delayed rectifier K$^+$ current (Liu et al., 1997). Therefore, both inhibition of Ca^{2+} and K$^+$ current likely contribute to the cardiotoxic actions of terfenadine. As a result of cardiotoxicity, both astemizole and ter-fenadine have been removed from the United States market. However, the understanding of astemizole- and terfenadine-induced cardiotoxicity continues to be an important consideration in drug development, and other drugs have demonstrated similar clinical limitations (e.g., cisapride and fluoroquinolone antibacterial agents).

As mentioned previously, drug interactions with astemizole and terfenadine have been important components to the case reports of severe cardiotoxicity from these antihistamines. Both astemizole and terfenadine are substrates for gastrointestinal and hepatic cytochrome P450 3A4. First-pass metabolism of astemizole and terfenadine is high, so much so that in a normal patient, serum concentrations of the parent agent terfenadine are extremely low and risk of cardiotoxicity is also low. The active P450 metabolite of terfenadine is terfenadine carboxylate (now sold under the generic name fexofenadine). While terfenadine carboxylate is the active antihistamine following terfenadine administration, it exhibits little to no inhibition of cardiac delayed rectifier K$^+$ current (Rampe et al., 1993). However, in patients with hepatic dysfunction or in those receiving concomitant inhibitors of cytochrome P450 3A4 (e.g., macrolides, azole antifungals, HIV protease inhibitors, and nonnucleoside reverse transriptase inhibitors), metabolism of astemizole or terfenadine may be significantly impaired, such that plasma concentrations of parent drug rises and risk of cardiotoxicity is enhanced. Furthermore, accidental overdose of astemizole or terfenadine in adults or children with no hepatic dysfunction or concomitant inhibitors of cytochrome P450 3A4 has been associated with cardiotoxicity.

Immunosuppressants The immunosuppressants, including the cyclic polypeptide cyclosporin A and the macrolide tacrolimus (FK506), are potent nephrotoxicants and are discussed elsewhere in this textbook (see Chap. 14). However, rapamycin and tacrolimus (both macrolides) may also produce adverse cardiovascular effects, including hypertension, hypokalemia, and hypomagnesemia. All three of these agents alter signal transduction in cardiac myocytes. Specifically, rapamycin and tacrolimus interact with a protein that associates with ryanodine receptors (RyRs), and the protein carries the name FK506-binding protein (FKBP). When rapamycin or tacrolimus binds to FKBP in cardiac myocytes, RyR may become destabilized, resulting in Ca^{2+} leak from the SR (Marks, 1997). Clinically, tacrolimus has been associated with hypertrophic cardiomyopathy in pediatric patients, a condition that was reversed by discontinuation of tacrolimus and administration of cyclosporin A; some of these patients developed severe heart failure (Atkinson et al., 1995). Interestingly, cyclosporin A has been shown to inhibit cardiac myocyte hypertrophy and cardiotoxicity from a number of different stimuli, including doxorubicin.

Miscellaneous Drugs *Cisapride* Cisapride has been used as a prokinetic agent for gastrointestinal hypomotility. However, cisapride has been removed from the U.S. market because of risk of potentially life-threatening arrhythmias (torsades de pointes) associated with its use. Like astemizole and terfenadine, cisapride inhibits delayed rectifier K$^+$ current, prolongs action potential duration, prolongs the QT interval, and predisposes the heart to ventricular arrhythmias.

Methylxanthines The methylxanthines include caffeine, theobromine, and theophylline, all of which can be found in significant quantities in coffee, tea, chocolate, soft-drinks, and other foods. The methylxanthines are rather potent CNS stimulants but exert a wide variety of effects in the body and within the cardiovascular system. Theophylline has been used for many decades for the treatment of asthma, yet the bronchodilatory mechanisms responsible for the clinical benefits of theophylline in asthmatics are still not fully understood. Similarly, whether methylxanthines contribute significant adverse cardiovascular effects in humans is controversial. At the cardiac myocyte level, high concentrations of caffeine stimulate massive release ("dumping") of Ca^{2+} from the SR, an effect that is often utilized experimentally to determine SR function. Yet caffeine consumption by humans has not been clearly associated with any serious arrhythmias. This is likely explained by pharmacokinetics and stimulation of the chemoreceptor trigger zone (CTZ). For example, enormous amounts of caffeine would have to be consumed to achieve

myocardial concentrations sufficient to dump SR Ca^{2+}, and prior to achieving those concentrations, absorption would likely be impaired because of caffeine stimulation of the CTZ and vomiting. Nonetheless, caffeine-associated ventricular arrhythmias have been reported. In contrast, overdose of theophylline or rapid intravenous administration of therapeutic doses of aminophylline (theophylline complexed with ethylenediamine to increase water solubility) may produce life-threatening ventricular arrhythmias; these effects may in part be explained by direct actions of theophylline on cardiac myocyte SR or by inhibition of phosphodiesterase and elevation of cyclic AMP. Moreover, the cardiac effects of methylxanthines observed in vivo (including increases in cardiac output and heart rate) may be explained by elevated catecholamines, as theophylline has been shown to increase plasma epinephrine concentrations (Vestal et al., 1983).

Sildenafil Sildenafil is a relatively specific inhibitor of phosphodiesterase 5 (PDE5), which is responsible for the degradation of cyclic GMP (a vasodilatory second messenger). Interestingly, sildenafil was originally developed as a potential drug for treating angina; however, it was not very effective for this purpose and was subsequently developed for treatment of erectile dysfunction, where it produces vasodilation and filling of the corpus cavernosum. The primary concern regarding adverse effects of sildenafil is nonspecific inhibition of PDE3 in the heart and vasculature (Hussar, 1999). In vitro studies have revealed that sildenafil increases cyclic AMP in cardiac tissue without significant effects on cyclic GMP (Stief et al., 2000); however, whether these effects are associated with cardiotoxicity is not known. Sildenafil will potentiate the vasodilatory effects of nitroglycerin and other organic nitrates or nitric oxide donors; therefore, sildenafil is contraindicated in patients using these drugs. Postmarketing surveillance has found numerous deaths associated with the use of sildenafil, but many of these individuals may have been experiencing underlying cardiovascular disease. Furthermore, sildenafil is a cytochrome P450 3A4 substrate (the primary means of sildenafil metabolism), so concomitant use of sildenafil with drugs that are inhibitors of cytochrome P450 3A4 (e.g., macrolides, azole antifungals, HIV protease inhibitors, nonnucleoside reverse transcriptase inhibitors) is contraindicated.

Radiocontrast Agents Many radiocontrast agents have long been associated with anaphylactic reactions and nephrotoxicity. Recently, however, two iodinated radiocontrast agents (diatrizoate meglumine and iohexol) were shown to induce cardiac myocyte apoptosis and apoptosis of kidney cells (as determined by DNA fragmentation and morphology) in spontaneously hypertensive rats (Zhang et al., 1999b). Furthermore, radiocontrast agent-induced apoptosis in the kidney was associated with increased expression of Bax and p53 while Bcl-2 was down-regulated. Cardiac myocyte apoptosis related to diatrizoate meglumine may contribute to the clinical cardiotoxicity when the dye is inadvertently injected into the myocardium (cardiac arrhythmias, cardiac arrest, and death have been reported).

Naturally Occurring Substances

The compounds discussed in this section are chemical agents that are synthesized by humans, animals, or plants and have significant cardiotoxic effects. These natural products include steroid hormones and some synthetic steroid hormone–like compounds, cytokines, animal toxins, and plant toxins. Because of the diverse nature of these natural compounds, representative examples will be used to illustrate key toxicological actions on the cardiovascular system. Limited discussion will be provided on plant and animal toxins; the reader is directed to the chapters "Toxic Effects of Animal Toxins" and " Toxic Effects of Plants" for more detailed information on the toxicities of these natural products. Table 18-3 summarizes the cardiotoxicity of various naturally occurring substances, including cardiotoxic manifestations and proposed mechanisms of toxicity.

Table 18-3 Cardiotoxicity of Naturally Occurring Substances

Steroids and Related Hormones The principal steroid hormones produced by humans are estrogens, progestins, androgens, and adrenocortical steroids. First, it is important to realize that the myocardium expresses steroid receptors; therefore the heart serves as a target organ for steroid effects. Based upon autoradiography, radioligand binding, immunoblotting, ribonuclease protection assay, and reverse transcriptase polymerase chain reaction, numerous research articles have demonstrated expression of cardiac receptors for estrogens (both alpha and beta), androgens, progestins, mineralocorticoids, and glucocorticoids. These data suggest the presence of these receptors (at least at the mRNA level) in nearly every species examined regardless of sex or age. Moreover, receptors for thyroid hormones are also found in cardiac tissue. Evidence also suggests that cardiac tissue can synthesize steroid hormones, although the capacity for synthesis may be much lower than more classic steroid synthesizing tissue. Steroid and related hormone receptors (e.g., vitamin D and retinoic acid receptors) belong to a superfamily of transcription factors; therefore the hormones exert their effects primarily by altered gene transcription (genomic mechanisms). However, increasing evidence suggests that steroids and/or steroid and receptor complexes may exert nongenomic mechanisms that alter signaling pathways of growth or death, modulate actions of membrane-bound growth factor receptors, or alter ion channel function (Christ and Wehling, 1998). The possibility seems likely that steroid and related hormones participate in development of the heart; however, many questions remain unanswered regarding the effects of these hormones on the fully developed, adult myocardium and their potential roles in cardiac pathogenesis and protection.

Estrogens Estrogens are synthesized in the ovaries, testes, and adrenal glands, and estrogen is an active metabolite of testosterone. Endogenous estrogens include 17b-estradiol (E$_2$), estrone, and estriol. Synthetic estrogens include diethylstilbestrol (non-steroidal), equilin, esterified versions of E$_2$, ethinyl estradiol, mestranol, and quinestrol. Importantly, many other synthetic chemicals have been shown to exert estrogenic activity, including the pesticides DDT and methoxychlor, the plasticizer bisphenol A, other industrial chemicals including polychlorinated biphenyls, and some compounds found in soybeans and tofu (e.g., phytoestrogens). Estrogens (frequently in combination with progestins) have been used for over forty years as oral contraceptive agents. The initial "pill" included relatively high doses of estrogens in comparison with the modern birth control pill. The older versions of estrogenic oral contraceptives were associated with increased risk of coronary thrombosis and myocardial infarction; however, lower doses of estrogens have been found by numerous investigators to impart protective effects on the cardiovascular system, including beneficial effects on lipid metabolism [decreased low-density lipoproteins (LDL cholesterol) and increased high-density lipoproteins (HDL cholesterol)] and direct beneficial actions on cardiac tissue. Interestingly, the well-known gender differences in cardiovascular mortality are not entirely explained by protective effects of estrogens on lipid metabolism. Therefore significant ongoing work is focused on the direct protective effects of estrogens on the heart. Estrogens alter cardiac fibroblast proliferation; they have been shown to both increase and decrease proliferation of these cells. Some data suggest that E$_2$ inhibits L-type Ca^{2+} current in cardiac myocytes (Meyer et al., 1998), while other studies suggest that E$_2$ stimulates Na$^+$,K$^+$-ATPase activity (Dzurba et al., 1997) and may exert some antioxidant activity. Furthermore, antiapoptotic effects of estrogen in cardiac myocytes have been reported. Cultured cardiac myocytes exposed to staurosporine exhibited signs of apoptosis (nuclear staining, DNA fragmentation, and activation of caspase 3 and nuclear factor kappa B) that were inhibited when cells were also treated with E$_2$ (10 nanomolar) (Pelzer et al., 2000). Whether E$_2$ inhibits apoptosis from other stimuli such as xenobiotics, oxidative stress, I/R injury, etc., is unknown. Also important to realize is that E$_2$ may alter cardiac gene expression with deleterious consequences. For example, women have longer QT intervals than men and are at higher risk of torsades de pointes after exposure to antiarrhythmic agents such as quinidine. Currently, the consequences and mechanisms of direct actions of estrogens on the heart are an area of intense research, and clarification is pending.

Progestins Like estrogens, progestins are synthesized in the ovaries, testes, and adrenal glands. Naturally occurring and synthetic progestins include desogestrel, hydroxyprogesterone, medroxyprogesterone, norethindrone, norethynodrel, norgestimate, norgestrel, and progesterone. As part of hormone replacement therapy, progestins serve an opposing role to estrogens. Unfortunately, estrogen treatment opposed with progestins may negate the cardiovascular benefits of estrogens on lipid metabolism (Kalin and Zumoff, 1990). Thus, the effects of progestins on lipid metabolism are similar to those of androgens (see below), particularly those protestins that are similar in structure to 19-nortestosterone (desogestrel, norethindrone, norethynodrel, norgestimate, and nor-gestrel). Very little is known about the direct effects of progestins on the heart. Interestingly, the progesterone receptor antagonist mifepristone (RU-486) was shown to decrease the cardiotoxicity of cocaine as determined in cocaine-exposed papillary muscle preparations from progesterone- and progesterone plus mifepristone–treated rats (Sharma et al., 1993). In rats treated only with progesterone, cocaine-induced contractile dysfunction in papillary muscle was enhanced. These data suggest that progesterone could exert

deleterious direct effects on the heart, but more studies are required to investigate mechanisms.

Androgens The adverse cardiovascular effects of anabolic-androgenic steroids have been reviewed (Rockhold, 1993; Melchert and Welder, 1995). The principal androgens are testosterone—which is synthesized in the testes, ovaries, and adrenal glands—and its active metabolite dihydrotestosterone, which serves as an intracellular mediator of most androgen actions. Precursors of testosterone synthesis include androstenedione and dehydro-epiandrosterone. Synthetic anabolic-androgenic steroids include the alkylated and orally available drugs danazol, fluoxymesterone, methandrostenolone, methenolone, methyltestosterone, oxandrolone, oxymetholone, and stanozolol. The nonalkylated drugs with poor oral bioavailability include androstenedione and dehydroepiandrosterone (both sold in various "nutraceutical" formulations), boldenone (veterinary product), nandrolone (19-nortestosterone), and testosterone. Very limited clinical indications exist for these drugs—with the exception, of course, for use in hypgonadal males. However, nearly all of these agents have received significant illicit use, particularly in extremely high doses with attempts to improve physical appearance or performance. Anabolic-androgenic steroids have been associated with alterations in lipid metabolism, including increased LDL cholesterol and decreased HDL cholesterol; therefore these agents may predispose individuals to atherosclerosis (Melchert and Welder, 1995). Increasing evidence suggests that the anabolic-androgenic steroids may exert direct cardiotoxic actions. Initial studies demonstrated that methandrostenolone given intramuscularly to rats produced mitochondrial (swollen and elongated) and myofibrillar lesions (dissolution of sarcomeric contractile units) (Behrendt and Boffin, 1977). Subsequent studies demonstrated rapid Ca^{2+} fluxes (both directions) in cardiac myocytes induced by testosterone (Koenig et al., 1989), suggesting that androgens may produce nongenomic actions in cardiac myocytes. In more recent studies, testosterone and dihydrotestosterone stimulated hypertrophic growth of neonatal rat cardiac myocytes; this growth effect was blocked by the androgen receptor antagonist cyproterone (Marsh et al., 1998). In humans, high-dose anabolic-androgenic steroid use has been associated with cardiac hypertrophy (case reports and some clinical echocardiography studies) and myocardial infarction (case reports). However, the mechanisms responsible for the cardiotoxic effects of anabolic-androgenic steroids remain poorly understood.

Glucocorticoids and Mineralocorticoids Glucocorticoids and mineralocorticoids are primarily synthesized in the adrenal glands. Endogenous glucocorticoids include corticosterone, cortisone, and hydrocortisone (cortisol), and the endogenous mineralocorticoid is aldosterone. A large number of synthetic glucocorticoids are used for treatment of various autoimmune and inflammatory diseases. These drugs include alclometasone, amcinonide, beclomethasone, betamethasone, clobetasol, desonide, desoximetasone, dexamethasone, diflorasone, fludrocortisone, flunisolide, fluocinolone, fluocinonide, fluorometholone, flurandrenolide, halcinonide, medrysone, methylprednisolone, mometasone, paramethasone, prednisolone, prednisone, and triamcinolone. Most of these agents are primarily used topically, intranasally, or inhalationally. The primary glucocorticoids used systemically include cortisone, hydrocortisone, dexamethasone, methylprednisolone, prednisolone, and prednisone. The mineralocorticoid aldosterone is not used clinically; however, the aldosterone receptor antagonist spironolactone has been used for years to treat hypertension and is now thought to decrease morbidity and mortality associated with congestive heart failure. Chronic administration of these glucocorticoids is associated with a wide variety of adverse effects. For example, chronic glucocorticoid therapy often results in elevated total, LDL, and HDL cholesterol. Furthermore, glucocorticoids are known to cause Na^+ and water retention through mineralocorticoid receptor activation, which could produce hypertension during chronic therapy. Similarly, aldosterone exerts profound effects on Na^+ and water retention and is associated with the pathogenesis of congestive heart failure. In terms of direct effects on the heart, both aldo-sterone and glucocorticoids appear to stimulate cardiac fibrosis by regulating cardiac collagen expression independently of hemodynamic alterations (Robert et al., 1995; Young et al., 1994). Furthermore, aldosterone and glucocorticoids have been found to induce hypertrophic growth and alter expression of Na^+,K^+-ATPase, Na^+/H^+ antiporter, and chloride/bicarbonate exchanger of cardiac myocytes in vitro. Clinically relevant cardiac hypertrophy has been observed in premature infants undergoing dexamethasone treatment. Therefore, glucocorticoids and mineralocorticoids have the ability to alter cardiac gene expression, and complications from direct effects of these agents on the heart have been observed clinically. The mechanisms responsible for the direct effects of these agents remain, however, poorly understood.

Thyroid Hormones The adverse effects of excessive thyroid hormones are reviewed in an article by Williams (1997). The principal thyroid hormones include thyroxine (T_4) and triiodothyronine (T_3), and these hormones exert profound effects on the cardiovascular system. Hypothyroid states are associated with decreased heart rate, contractility, and cardiac output; whereas hyperthyroid states are associated with increased heart rate, contractility, cardiac output, ejection fraction, and heart mass, peripheral vascular resistance is either unchanged or decreases regardless of thyroid status. In those patients with underlying cardiovascular disease, the effects of thyroid hormones may promote arrhythmias. Thyroid hormones are known to promote hypertrophic growth of cardiac myocytes (Hefti et al., 1997). Furthermore, thyroid hormones alter expression of cardiac sarcoplasmic reticulum (SR) Ca^{2+} handling proteins. For example, thyroid hormones increased cardiac expression of SR Ca^{2+} ATPase (SERCA) and decreased the expression of phospholamban, an inhibitory protein of SERCA, and these changes in protein expression corresponded to functional alterations in Ca^{2+} homeostasis (Kaasik et al., 1997).

Cytokines Cytokines represent a diverse and heterogeneous group of proteins with important functions in cellular and humoral immune responses. More than 100 different cytokines have been found, and the cardiovascular effects of these substances can be classified as proinflammatory, anti-inflammatory, or cardioprotective (Pulkki, 1997). Members of the proinflammatory class include tumor necrosis factor-alpha (TNF-a) interleukin-1b (IL-1b), interleukin-2 (IL-2), interleukin-6 (IL-6), interleukin-8 (IL-8), Fas ligand, and chemokines (e.g., C-C chemokines such as MCP-1, macrophage chemoattractant protein-1; MIP-1a, macrophage inflammatory protein-1a; and RANTES, regulated on activation normally T cell–expressed and secreted). Members of the anti-inflammatory class typically down-regulate expression of proinflammatory cytokines and include interleukin-4 (IL-4), interleukin-10 (IL-10), interleukin-13 (IL-13), and transforming growth factor-beta (TGF-b). The cardioprotective cytokines include cardiotrophin-1 (CT-1) and leukemia inhibitor factor (LIF), which have been shown to inhibit cardiac myocyte apoptosis from a number of different stimuli. For a review of the cardiovascular effects of these cytokines, see the article by Pulkki (1997). Many of these cytokines are elevated during cardiovascular diseases such as I/R injury, myocardial infarction, and congestive heart failure. In addition, it is now recognized that cardiac myocytes may serve as the synthetic source of many of these cytokines. Therefore, significant research effort is now aimed at understanding the direct effects of these cytokines on the heart. The clinical impact of the direct effects of individual cytokines on cardiac myocyte viability and function is difficult to predict given the pleiotrophic actions of most of these cytokines and the fact that cardiac myocytes would be exposed to multiple cytokines during disease states.

Interleukin-1b IL-1b is known to exert negative inotropic actions and induce apoptosis of cardiac myocytes. The effects of IL-1b on cardiac myocytes are likely mediated through induction of nitric oxide synthase and/or increased production of nitric oxide. For example, induction of nitric oxide synthase is associated with negative inotropic effects that could be mediated by activation of guanylyl cyclase, in increased cyclic GMP, inhibition of electron transport, nitrosylation of thiol residues on vital proteins, or production of reactive oxygen species such as peroxynitrite (Arstall et al., 1999). Superoxide anion and peroxynitrite formation was associated with reduced left ventricular ejection fraction in dogs treated with microspheres containing IL-1b, and nitrotyrosine residues were found suggesting that several proteins were affected by peroxynitrite (Cheng et al., 1999). Overall, however, little else is known regarding the mechanisms of IL-1b –induced cardiotoxic effects. Complicating the understanding of direct actions of IL-1b on cardiac myocytes is the observation that IL-1b induces cardiac myocyte expression of mRNA encoding for IL-6, and IL-6 may have subsequent deleterious effects on cardiac myocyte function (Gwechenberger et al., 1999).

Tumor Necrosis Factor Alpha TNF-a induces apoptotic death of target cells including cardiac myocytes (Krown et al., 1996). The mechanisms responsible for TNF-a–induced apoptosis of cardiac myocytes are not entirely clear. For example, TNF-a increased ceramide and sphingosine production in cardiac myocytes, and sphingosine exposure also induced apoptotic death (Krown et al., 1996). However, TNF-a also exerts negative inotropic effects on cardiac myocytes at least potentially through increased production of sphingosine (Sugishita et al., 1999). In the studies by Sugishita and colleagues, TNF-a reduced the amplitude of Ca^{2+} transients without detectable changes in L-type Ca^{2+} current in guinea pig ventricular myocytes (although TNF-a did depress isoproterenol-stimulated L-type Ca^{2+} current), and the effects of TNF-a were mimicked by sphingosine. As with IL-1b, complicating the understanding of direct actions of TNF-a on cardiac myocytes is the observation that TNF-a induces cardiac myocyte expression of IL-6, which may have subsequent deleterious effects on cardiac myocyte function (Gwechenberger et al., 1999).

Other Cytokines IL-6 has been shown to induce negative inotropic effects on cardiac myocytes, possibly through induction of nitric oxide synthase expression and increased nitric oxide production (Sugishita et al., 1999). IL-2 may decrease the mechanical performance and metabolic efficiency of the heart, and these myocardial effects may be related to changes in nitric oxide synthesis and Na^+/H^+ exchange. Interferon administration may result in cardiac arrhythmias, dilated cardiomyopathy, and signs of myocardial ischemia. Furthermore, IL-1b and interferon-g act synergistically to increase nitric oxide formation in the heart, and when combined, induce Bax expression and apoptosis in cardiac myocyte cultures (Arstall et al., 1999). Although the mechanisms of cytokine-induced cardiotoxicity are not clearly defined, significant new information is forthcoming.

Animal and Plant Toxins Animal toxins in the venom of snakes, spiders, scorpions, and marine organisms have profound effects on the cardiovascular system. There are also a number of plants—such as foxglove, oleander, and monkshood—that contain toxic constituents and have adverse effects on the cardiovascular system. A description of these toxic cardiovascular effects is found in subsequent chapters.

Industrial Agents

Table 18-4 provides a summary of selected industrial agents with their prominent cardiotoxic effects and proposed mechanisms of cardiotoxicity. For a more

comprehensive review of industrial agents and their cardiotoxic potential, the reader is referred to Zakhari (1992).

Table 18-4 Cardiotoxicity of Selected Industrial Agents

Solvents Cardiotoxicity from industrial solvents can involve multiple mechanisms. Their inherent lipophilicity allows them to act on the nervous system, which in turn is responsible for regulating cardiac electrical activity. In addition, because of high lipid solubility, solvents may disperse into cell membranes and affect membrane fluidity, which is crucial for cellular functions such as signal transduction and oxidative phosphorylation. Hence, solvents may affect physiologic functions such as contraction and energy production. Solvents may disrupt sympathetic and parasympathetic control of the heart either directly or indirectly. Their influence on cardiac function may also involve the release of circulating hormones such as catecholamines, vasopressin, and serotonin. From a more general perspective, industrial solvents typically produce a depressant effect on the CNS and an attenuation of myocardial contractility. Moreover, chronic exposure to solvents in sublethal doses may result in subtle toxicities that may be apparent only after prolonged exposure.

Alcohols and Aldehydes On a molar basis, there is a relationship between increased carbon chain length of the alcohol and cardiotoxicity. Metabolic oxidation of alcohols yields aldehydes. Aldehydes have sympathomimetic activity as a result of their effect on releasing catecholamines. Unlike alcohols, the sympa-thomimetic activity of aldehydes decreases with increased chain length. The acute cardiodepressant effects of alcohols and alde-hydes may be related to inhibition of intracellular Ca^{2+} transport and/or generation of oxidative stress (see "Alcohol," above).

Methanol Methanol (methyl alcohol or wood alcohol) is a common industrial solvent whose effects on the heart are similar to those of ethanol. Methanol is metabolized by alcohol dehydrogenase and aldehyde dehydrogenase to formaldehyde and formic acid. As with ethanol, oxidation of methanol proceeds at a rate that is independent of blood concentration. However, the rate of oxidation is about one-seventh that of ethanol, and complete elimination requires several days. Clinically, blood pressure is usually unaffected but heart rate may be reduced.

Isopropyl Alcohol Isopropyl alcohol (isopropanol) is a common industrial and household solvent whose effects on the heart are similar to those of ethanol. Isopropyl alcohol–induced toxicity typically occurs from ingestion or inhalation. Isopropanol is a potent CNS depressant that causes cardiovascular depression in large doses. Isopropanol is metabolized to acetone, which is also believed to potentiate and lengthen the duration of CNS depression. Acetone is metabolized to formic acid and acetic acid, which have the potential to induce mild acidosis. Tachycardia is the most prominent clinical finding.

Acetaldehyde Acetaldehyde, a hepatic metabolite of ethanol, has negative inotropic effects at concentrations that can be obtained with moderate alcohol consumption. At higher blood levels, acetaldehyde has sympathomimetic effects.

Halogenated Alkanes Halogenated alkanes encompass a wide range of industrial and pharmaceutical agents. Their highly lipophilic nature allows them to cross the blood-brain barrier readily. This action, coupled with their CNS-depressant activity, makes these compounds ideally suited for anesthetics (halothane, methoxyfluorane, and enflurane). Halogenated hydrocarbons depress heart rate, contractility, and conduction. In addition, some of these agents sensitize the heart to the arrhythmogenic effects of beta-adrenergic receptor agonists such as endogenous epinephrine. Fluorocarbons (freons) have been reported to have this sensitizing effect on the myocardium. Trichlorofluoromethane is one of the most toxic fluorocarbons. Table 18-4 summarizes some halogenated hydrocarbons that have been reported to have arrhythmogenic properties. Chronic exposure to halogenated hydrocarbons has been postulated to have degenerative cardiac effects.

Recent interest in halogenated hydrocarbons has focused on the development of more "environmentally friendly" replacements for the fire suppressant halon, which has come under "fire" as an ozone-depleting compound. Ironically, several of the lead agents that have lower ozone depletion potential have proven to be less friendly to the cardiovascular systems of animals. Trifluoroiodomethane (CF3I) and heptafluoro-1-iodopropane (C37I) are two such lead agents. These compounds have been shown to produce cardiac sensitization to adrenergic agonists such as epinephrine. When epinephrine was administered to dogs before and during inhalation of CF3I and C37I, significant ventricular arrhythmias occurred (Dodd and Vinegar, 1998). The mechanisms responsible for halogenated hydrocarbon–induced sensitization of the myocardium to adrenergic agonists are not fully understood.

Heavy Metals The most common heavy metals that have been associated with cardiotoxicity are cadmium, lead, and cobalt. These metals exhibit negative inotropic and dromotropic effects and also can produce structural changes in the heart. Chronic exposure to cadmium has been reported to cause cardiac hypertrophy. Lead has an arrhythmogenic sensitizing effect on the myocardium. In addition, lead has been reported to cause degenerative changes in the heart. Cobalt has been reported to cause cardiomyopathy. The cardiotoxic effects of heavy metals are attributed to their ability to form complexes with intracellular macromolecules and their ability to antagonize intracellular Ca^{2+}.

Other metals that have been reported to affect cardiac function are manganese, nickel, and lanthanum. Their mechanism of action appears to be the blocking of Ca^{2+} channels. However, high concentrations are required to block Ca^{2+} channels (e.g., millimolar range). Barium is another metal that can affect cardiac function. Barium chloride given intravenously in high doses to laboratory animals has been reported to induce arrhythmias. This arrhythmogenic effect of barium chloride has been utilized to screen antirrhythmic agents.

OVERVIEW OF VASCULAR PHYSIOLOGY

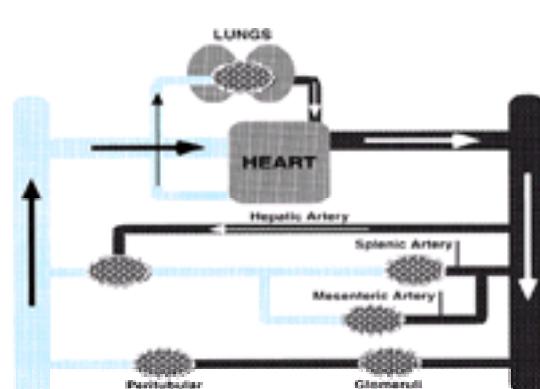
The vascular system consists of a complex network of vessels of varying size and complexity that serve as the circuitry for the delivery of oxygen and nutrients to tissues throughout the body and for the removal of the waste products of cellular metabolism. Oxygenated blood returning from the lungs to the heart is emptied into the aorta, a large conduit vessel, which gradually branches off, giving rise to smaller vessels that reach individual organs (Fig. 18-11). Although the distribution of the cardiac output among different organs depends on their relative resistance to blood flow, in most instances the blood flow to critical regions such as the brain and the kidney remains constant despite changes in arterial pressure or cardiac output. The general laws of hemodynamics govern the movement of blood through the vascular network, although the properties of the blood and those of the vessels impose some modifications. Blood returns to the heart for reoxygenation through the venous system before the reinitiation of subsequent cycles.


Figure 18-11. Schematic diagram of vascular supply to selected organs.

The capillary beds represented by a meshwork connnecting the arteries (*right*) with the veins (*left*); the distribution of the vasculature in several organs (liver, kidney, lung) indicates the importance of the vascular system in toxicology.

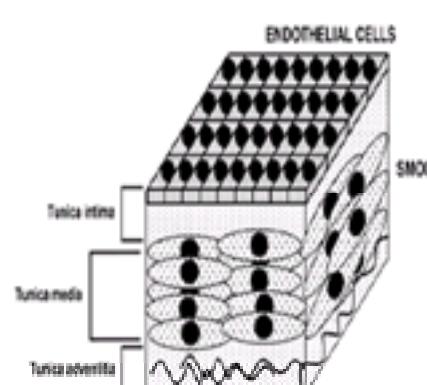
Large and medium-size blood vessels in mammals are organized into three morphologically distinct layers (Fig. 18-12). The innermost layer is referred to as the tunica intima and consists of a single layer of endothelial cells resting on a thin basal lamina and a subendothelial layer. Luminal endothelial cells are flat and elongated, with the long axis parallel to blood flow. These cells act as a semipermeable barrier between the blood and underlying components of the vessel wall. The subendothelial layer is formed by connective tissue bundles and elastic fibrils, in which a few cells of smooth muscle origin may be oriented parallel to the long axis of the vessel. The subendothelial layer is seen only in large elastic arteries such as the human aorta and is not clearly defined in smaller species. The medial layer, or tunica media, is composed of elastin and collagen interwoven between multiple layers of smooth muscle cells. In the majority of vascular beds, smooth muscle cells dominate the media, but these cells may also be present in the intima of some arteries and veins and in the adventitia of veins. The media is separated from the outermost layer, the tunica adventitia, by a poorly defined external lamina. The adventitial layer consists of a loose layer of fibroblasts, collagen, elastin, and glycosaminoglycans. With the exception of capillaries, the walls of smaller vessels also have three distinct layers. However, in smaller vessels the tunica media is less elastic and consists of fewer layers of smooth muscle cells. As described for the muscular arteries, venules are structurally similar to their arteriolar counterparts. Because muscular venules are larger than arterioles, a large fraction of blood is contained in these so-called capacitance vessels. Capillaries are endothelial tubes measuring 4 to 8 mm in diameter that rest on a thin basal lamina to which pericytes are often are attached. When one capillary converges with another, the vessel formed is referred to as a postcapillary venule. The capillary and the pericytic venule are the principal sites of exchange between the blood and tissues.


Figure 18-12. Cross-sectional representation of the vascular wall of large and medium-size blood vessels.

The tunica intima is composed of endothelial cells, facing the vessel lumen, which rest on a thin basal lamina. The tunica media consists mainly of vascular smooth muscle cells interwoven with collagen and elastin. The tunica adventia is a layer of fibroblasts, collagen, elastin, and glycosaminoglycans.

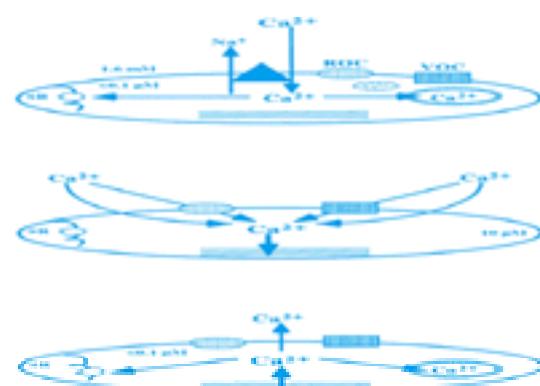
Vascular endothelial cells play an integral role in the regulation of hemostasis, vascular tone, and angiogenesis. Angiogenesis involves the formation of blood vessels secondary to the migration, proliferation, and differentiation of vascular cells. The process of angiogenesis is subject to regulation by hypoxia and has been identified as a likely target for selective toxicity by newly developed antineoplastic agents. Endothelial cells also are involved in the regulation of macromolecular transport across the vessel wall, attachment and recruitment of inflammatory cells, synthesis of connective tissue proteins, and generation of reactive oxygen species. Medial smooth muscle cells are responsible for the regulation of vascular tone. The contractile response of blood vessels is mediated by receptors located primarily on the plasma membrane of smooth muscle cells. Activation of these receptors brings about changes in calcium conductance that lead to activation of the contractile apparatus. Calcium homeostasis is controlled by the interplay of multiple regulatory mechanisms (Fig. 18-13). In contrast to cardiac myocytes, where relatively large stores of calcium are found, vascular smooth muscle depends primarily on extracellular calcium sources for contraction. Increases in cytoplasmic calcium often involve the influx of calcium through either receptor- or voltage-operated channels. Cytoplasmic Ca^{2+} activates a calmodulin-dependent protein kinase that in turn phosphorylates myosin to allow the interaction of myosin and actin and the shortening of the sarcomere.


Figure 18-13. Calcium regulation and homeostasis in vascular smooth muscle cells.

Intracellular calcium is sequestered primarily in the sarcoplasmic reticulum (SR), but contraction of smooth muscle cells is initiated by an influx of extracellular calcium through receptor-operated channels (ROC) or voltage-operated channels (VOC).

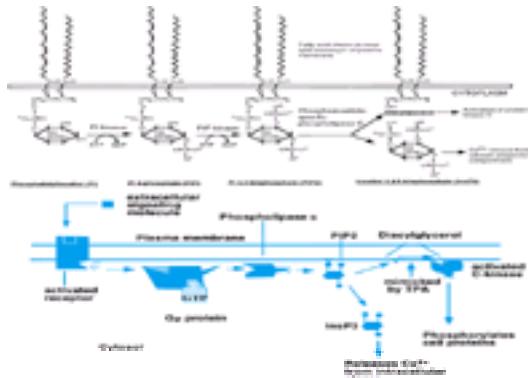
Catecholamines influence vascular function through the activation of surface receptors, among which the alpha $_1$ and beta$_2$ receptors have been the most extensively characterized. Activation of alpha$_1$ receptors in smooth muscle cells increases contractility, while activation of beta $_2$ receptors decreases it. Two alpha$_1$-adrenergic receptor subtypes—alpha $_{1A}$ and the alpha$_{1B}$ —have been identified. Alpha$_{1B}$-adrenergic stimulation elicits smooth muscle contraction by activating phospholipase-mediated hydrolysis of phosphatidylinositol-4,5-bisphosphate to yield diacylglycerol and inositol-1,4,5-trisphosphate (Fig. 18-14). Diacylglycerol binds to and activates protein kinase C, while inositol-1,4,5-trisphosphate binds to an intracellular receptor on the sarcoplasmic reticulum to initiate the release of calcium stores. The alpha$_{1A}$-adrenergic receptor mediates extracellular calcium entry through voltage-sensitive L-type calcium channels. Activation of beta $_2$ receptors leads to G protein-mediated activation of adenylyl cyclase and the production of cyclic AMP (Fig. 18-15). Beta$_2$ agonists induce a conformational change in the receptor, resulting in dissociation of the alpha subunit from the beta-gamma subunits of the G protein. The alpha subunit, in turn, achieves a biologically active conformation that modulates adenylyl cyclase activity after displacement of GDP by GTP. Inactivation occurs through hydrolysis of GTP by the intrinsic GTPase activity of the G protein. Several other neurohormones—such as acetylcholine, angiotensin II, arginine-vasopressin, histamine, thrombin, and endothelin—modulate contractile events by activation of G protein–coupled receptors. Smooth muscle cells are also responsible for the synthesis of extracellular matrix proteins during arterial repair, the metabolism and/or secretion of bioactive substances, and the regulation of monocyte function. Fibroblasts in the adventitial layer secrete some of the collagen and glycosaminoglycans needed to give structural support to the vessel wall.


Figure 18-14. Phosphatidylinositol metabolism and subsequent production of intracellular second messengers in vascular smooth muscle cells.

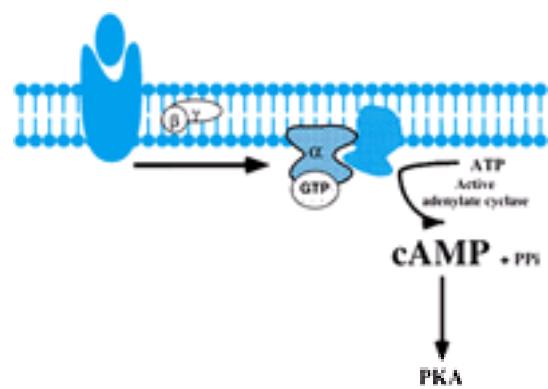
Inositol 1,4,5-trisphosphate (InsP3), which elicits intracellular Ca^{2+} release, is generated from phosphatidylinositol (PI) by the sequential actions of PI kinase, PIP kinase, and phospholipase C (*A*). PI 4,5-bisphosphate (PIP2) can also be cleaved by phospholipase C to form diacylglycerol, which activates protein kinase C (*B*).


Figure 18-15. Depiction of the activation of adenyl cyclase through the activation of a beta $_2$-adrenergic receptor.

Ligand binding results in a conformational change in the receptor, leading to GTP displacement of GDP on the *a* subunit of the receptor-linked G protein. The binding of GTP elicits the release of the *b* and *c* subunits and the binding of the *a* subunit to adenyl cyclase, activating the enzyme. Cyclic AMP (cAMP) is produced, and this can lead to various events, including the activation of protein kinase A.

DISTURBANCES OF VASCULAR STRUCTURE AND FUNCTION

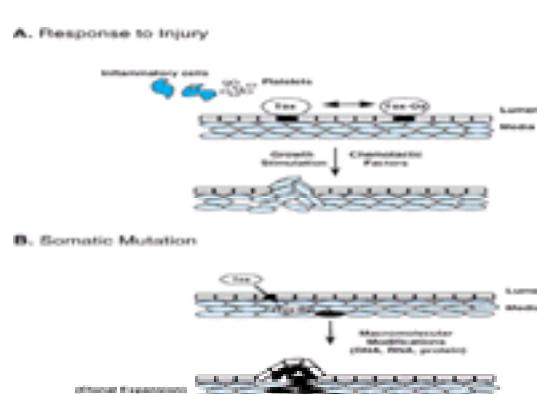
Human epidemiologic studies have established a positive correlation between injury to a blood vessel wall and the occurrence of vascular diseases such as atherosclerosis and hypertension (Rosenman, 1990). Atherosclerosis is a major structural change in the vessel wall that leads to deleterious consequences to the vessel as well as the other organs involved. This disease is a degenerative process involving focal intimal thickenings formed after migration of smooth muscle cells to the intima and uncontrolled proliferation. Extracellular matrix components such as collagen and elastin, intra- and extracellular lipids, complex carbohydrates, blood products, and calcium accumulate to varying degrees as the lesion advances. The plaque also contains inflammatory cells, such as infiltrated monocytes and leukocytes, which participate in the progression of the pathologic response. Figure 18-16 shows two pathways that can mediate the initiation and/or promotion of the atherosclerotic process by toxic chemicals. Lesions generally occur in large and medium-sized blood vessels such as the aorta and the coronary, carotid, and femoral arteries. In young human subjects, atherosclerotic lesions are distributed in the region of the aortic valve ring. The aortic arch and the thoracic and abdominal aorta become more severely affected as a function of age. The principal consequence of atheroma formation is progressive narrowing of the arterial lumen that leads to a restricted blood supply to distal sites. Such changes can result in renal hypertension, stroke, and myocardial ischemia and infarction.


Figure 18-16. Representation of the two major hypotheses for the molecular and cellular events that lead to atherosclerosis.

The response to injury hypothesis (*A*) initially proposed by Ross and subsequently modified (1993) states that injury of endothelial cells triggers a response involving recruitment of platelets and inflammatory cells that stimulate smooth muscle cell migration and proliferation. In contrast, Benditt and Benditt (1973) proposed that atherosclerotic lesions are a result of the monoclonal expansion of a mutated smooth muscle cell (*B*.)

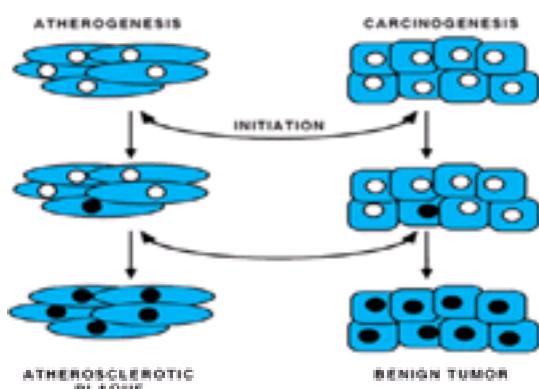
Toxic chemicals can induce or enhance atheroma formation by several mechanisms involving injury to luminal endothelial cells and/or medial smooth muscle cells (Ramos et al., 1994). Such lesions often result from chronic cycles of vascular injury and repair and typically require long latency periods. Mechanical or toxic injury to the endothelium has been associated with initiation of the atherogenic response. Agents such as acrolein, butadiene, cyclophosphamide, heavy metals, and homocysteine have been identified as endothelial toxins. In a wide variety of animal species (including rabbits and rats), vascular endothelial cell injury potentiates the atherogenic process and in some instances precedes the development of atherosclerotic plaques. In humans and animals, a hypercholesterolemic diet causes an increase in plasma lipoproteins, damages the endothelium, and results in proliferation of smooth muscle cells. Recent evidence implicates oxidized forms of LDL in the induction of atherosclerotic lesions by hyperlipoproteinemia. As part of the repair process, smooth muscle cell mitogens and chemotatic agents are released from one or more cell types. Atherosclerotic lesions can also develop as a result of injury to medial smooth muscle cells. Agents such as allylamine, benzo[*a*]pyrene, dinitrotoluenes, and hydrazines have been identified as smooth muscle cell toxins. Proliferation may be secondary to regenerative repair or to genetic changes in a small population of medial cells. After studying the monotypism of glucose-6-phosphate dehydrogenase, Benditt and Benditt (1973) proposed over twenty years ago that smooth muscle cells in the atherosclerotic plaque are the progeny of a single smooth muscle cell. Thus, the atherosclerotic process would resemble benign neoplastic growth of smooth muscle tumors (leiomyomas) (Fig. 18-17). Upon exposure to a toxic agent, smooth muscle cells may exist in a genetically altered state that gives rise to lesions after exposure to chemotatic/growth-promoting factors. Alternatively, mutations could induce the constitutive production of growth factors in smooth muscle cells, resulting in autocrine stimulation of growth. DNA isolated from human atherosclerotic plaques is capable of transforming NIH3T3 cells and producing tumors in nude mice, a finding that suggests that atherosclerotic cells possess intrinsic transforming potential.


Figure 18-17. Representation of the links between atherogenesis and carcinogenesis.

Both disease processes may involve the initiation of a target cell and subsequent promotional events to result in a full response.

Changes in blood pressure are often seen during acute poisonings. Hypotension—a sustained reduction of systemic arterial pressure—is common in poisonings with CNS depressants or antihypertensive agents as well as during anaphylactic reactions. Postural hypotension, particularly in elderly people, can be induced by therapeutic agents such as drugs that lower cardiac output or decrease blood volume. These agents include depressants of the vasomotor center such as morphine-like compounds, antihypertensive agents, sedatives, neuroleptics, and antiparkinsonian agents. In addition, agents that inhibit noradrenaline production and reuptake, such as methyldopa or antidepressants, respectively, also induce postural hypotension. Circulatory insufficiency can be delayed or even prevented by increased sympathoadrenal activity. However, poisonings associated with extreme loss of body fluids caused by persistent vomiting or diarrhea and conditions resulting in marked reductions in plasma, such as hemorrhage, lead to a state of circulatory insufficiency (shock). Other causes of shock include inadequate myocardial contraction resulting from severe arrhythmia and inadequate peripheral circulation brought about by altered vasomotor tone resulting from the effects of chemical mediators, such as histamine, leukotriene, and kinins. Vasodilation, which is mediated by activation of H_1 and H_2 receptors located throughout the resistance vessels, is the most prominent action of histamine in humans. Histamine tends to constrict the larger blood vessels.

Hypertension may result from an increased concentration of circulating vasoconstrictors such as angiotensin II and catecholamines or from disturbances of local regulation mediated by metabolic, myogenic, or angiogenic mechanisms. Increased vascular resistance has been associated with an overall increase in wall thickness caused at least in part by hypertrophy and proliferation of smooth muscle cells. A sustained elevation in blood pressure has also been associated with destruction of capillaries at the tissue level and compensatory angiogenesis. Arterial hypertension may occur in the course of an overdose of sympathomimetic and anticholinergic drugs. Sudden drug-induced hypertension can cause cerebrovascular accidents when diseased blood vessels cannot adapt to high perfusion pressures. Mineralocorticoids can cause excessive sodium retention and lead to sustained elevation of blood pressure by increasing circulatory volume. Licorice, which contains glycyrrhizin, an aldosterone-like substance that exerts mineralocorticoid activity, can cause sustained hypertension. Agents that cause hyperreninemia, such as cadmium, can raise blood pressure through the generation of angiotensinogen II. Depletion of renomedullary vasodilator substances has been implicated in the hypertensive episodes associated with analgesic drug-induced nephropathy. Increased synthesis of angiotensinogen has been considered an important factor in the hypertension produced by high doses of estrogen-containing oral contraceptives. Sustained hypertension is the most important risk factor predisposing a person to coronary and cerebral atherosclerosis. The mechanisms by which hypertension produces vascular degenerative lesions involve increased vascular permeability that leads to entry of blood constituents into the vessel wall.

The vascular toxicity of some therapeutic agents, including antimicrobial drugs and anticoagulants, often involves vasculitis secondary to hypersensitivity reactions. Some chemicals can cause hemorrhage by damaging the large vessels, such as the aneurysms produced by lathyrogens. Damage to capillaries by cytotoxic chemicals leading to petechial hemorrhages is seen in several organs after acute poisonings. A chemically induced defect in the blood-clotting mechanism increases the probability that a hemorrhage will occur. Thrombosis—the formation of a semisolid mass from blood constituents in the circulation—can occur in both arteries and veins as a result of toxicant exposure. Predisposition to thrombosis occurs by means of induction of platelet aggregation, an increase in their adhesiveness, or creation of a state of hypercoagulability through an increase in or activation of clotting factors, as seen with large doses of epinephrine. Other chemicals may lead to thrombosis by interfering with antithrombin III (oral contraceptive steroids) or inhibiting fibrinolysis (corticosteroids, mercurials). Sudden changes in blood flow brought about by excessive vasoconstriction or decreased peripheral resistance can trigger arterial thrombosis. Venous stasis contributes to the development of venous thrombosis. Table 18-5 provides a partial list of thrombogenic agents and their putative mechanisms of action. Injury to the vessel wall by intravenous infusion of an irritating drug produces generalized endothelial damage and leads to thromboses at the sites of lesions. Portions of a thrombus may be released and travel in the vascular system until arrested as an embolus in a vessel with a caliber even smaller than that of its origin. The consequence depends on the site of arrest, but a thrombus can result in death. The most important drugs known to produce thromboembolisms are the contraceptive steroids.

Table 18-5 Compounds Producing Thrombosis

GENERAL BIOCHEMICAL MECHANISMS OF VASCULAR TOXICITY

Epidemiologic and experimental evidence has established a correlation between exposure to toxic chemicals and the incidence of cardiovascular morbidity and mortality. Such a correlation is best exemplified by the role of tobacco smoke as a major contributor to myocardial infarction, sudden cardiac death, arteriosclerotic peripheral vascular disease, and atherosclerotic aneurysm of the aorta. Angiotoxic chemicals are found in the ambient environment as a result of anthropogenic activity or occur as natural variations in the environment, such as fungal toxins in food supplies. Chemicals absorbed through the respiratory, cutaneous, gastrointestinal, and intravenous routes by necessity come in contact with vascular cells before reaching other sites in the body. This property alone puts the vascular system at increased risk of toxic insult. Although this relationship has largely been ignored, the recognition that many target organ toxicities involve a significant microvascular component has become more prevalent.

Chemicals can produce degenerative or inflammatory changes in blood vessels as a consequence of an excessive pharmacologic effect. For example, ergotamine, a naturally occurring alkaloid, causes sustained arterial vasoconstriction that leads to peripheral arterial lesions involving intimal proliferation and medial degenerative changes. Degenerative or inflammatory changes can also occur secondary to the interaction of chemicals or their reactive metabolites with a structural and/or functional component of the vessel wall. For example, endothelial cell death and atherosclerosis can be induced by homocysteine, a sulfur-containing amino acid produced in the biosynthesis of cysteine from methionine. The reactivity of the sulfhydryl group of homocysteine has been implicated in the atherogenic response. Injury to the endothelium leads to recruitment of white blood cells into the affected sites as part of the inflammatory response. The inflammatory response is directed by a variety of signaling molecules that are produced locally by mast cells, nerve endings, platelets, and white blood cells as well as by the activation of complement. In the case of medial smooth muscle cells, injury is associated with degenerative changes in the media of blood vessels. For example, allylamine toxicity is associated primarily with medial changes, but changes in endothelial cells also have been noted. Repeated cycles of vascular injury by this amine result in smooth muscle

hyperplasia and coronary artery and aortic lesions which mimic those found in atherosclerotic vessels. Changes in the collagen of large arteries leading to localized dilation (aneurysms) occur in lathyrism and can be reproduced experimentally by administration of beta-aminopropionitrile.

Angiotoxicity may be expressed at the mechanical, metabolic, or genetic level and in general involves interactions of multiple cellular elements (Table 18-6). Endothelial cells represent the first cellular barrier to the movement of blood-borne toxins from the lumen of the vessel to deeper layers of the wall. This location makes these regions particularly susceptible to toxic insult. Endothelial injury also occurs as a result of the production of oxygen free radicals during reperfusion injury in transplanted organs. Toxic chemicals reaching the subendothelial space may cause injury to medial smooth muscle cells and/or adventitial fibroblasts. Adventitial and medial cells in large elastic arteries such as the human aorta also may be reached via the vasa vasorum, the intrinsic blood supply to the vessel wall. The vasculotoxic response is also dependent on the influence of (1) extracellular matrix proteins that influence cell behavior, (2) coagulation factors that dictate the extent of hemostatic involvement, (3) hormones and growth factors that regulate vascular function, and (4) plasma lipoproteins, some of which modulate cellular metabolism and facilitate the transport and delivery of hydrophobic substances (Ferrario et al., 1985).

Table 18-6 Cell Types Implicated in the Vasculotoxic Response

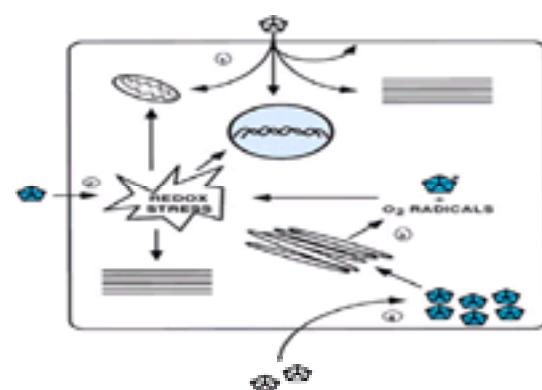
Common mechanisms of vascular toxicity include (1) selective alterations of vascular reactivity mediated by alterations in membrane structure and function; (2) in certain forms of chemically induced vascular toxicity, chemical exposure may be associated redox stress leading to disruption of gene regulatory mechanisms, compromised antioxidant defenses, and generalized loss of homeostasis; (3) vessel-specific bioactivation of protoxicants; (4) preferential accumulation of the active toxin in vascular cells (Fig. 18-18). Multiple mechanisms often operate simultaneously in the course of the toxic response. Interestingly, although vascular injury by toxic chemicals often involves different mechanisms, the modulation of growth and differentiation in vascular cells is a common endpoint of vasculotoxic injury.


Figure 18-18. Toxic injury to vascular cells may involve four common mechanisms.

(1) Vascular injury may involve disruption of cellular membranes or the contractile apparatus of smooth muscle cells by a toxicant. (2) In certain forms of chemically induced vascular toxicity, chemical exposure is associated with redox stress, leading to disruption of gene regulatory mechanisms, compromised antioxidant defenses, and generalized loss of homeostasis. (3) Additionally, vascular cells may bioactivate protoxicants in a vessel-specific manner to generate reactive intermediates and/or oxygen derived free radicals that induce cell injury. (4) Vascular cells also may preferentially accumulate potential toxins.

Vascular reactivity is regulated by the transfer of signals from the surface to the interior of the cell and/or direct modulation of the structure and function of contractile protein. Usually, disorders of vascular reactivity involve generalized disturbances of ionic regulation. Nontoxic chemicals can be converted by vascular enzymes to reactive species that cause injury to both intra- and extracellular targets. Enzyme systems that are present in vascular cells and are involved in the bioactivation of vascular toxins include amine oxidases, cytochrome P450 monooxygenases, and prostaglandin synthetase. Amine oxidases are copper-containing enzymes that catalyze the oxidative removal of biogenic amines from blood plasma, the cross-linking of collagen and elastin in connective tissue, and the regulation of intracellular spermine and spermidine levels. These microsomal enzyme systems are involved in the bioactivation of allylamine to acrolein and hydrogen peroxide. The occurrence of several cytochrome P450 metabolites of arachidonic acid involved in the regulation of vascular tone and sodium pump activity has also been noted. For instance, cytochrome P450 1A1 in endothelial and smooth muscle cells metabolizes benzo[a]pyrene and other polycyclic aromatic hydrocarbons to toxic and genotoxic intermediates. A complex of microsomal enzymes collectively referred to as prostaglandin synthetase catalyzes the formation of biologically active lipids, including prostacyclin and thromboxane A_2. Prostacyclin, the major arachidonic acid metabolite in blood vessels, is a strong vasodilator and an endogenous inhibitor of platelet aggregation, while thromboxane A_2, the major arachidonic acid metabolite in platelets, is a potent vasoconstrictor and a promoter of platelet aggregation. The bioactivation of vascular toxins need not be confined to vascular tissue. Evidence that angiotoxic chemicals can be bioactivated by the liver and lung, with the activated metabolites leaving the metabolizing sites and reaching vascular targets through the systemic circulation, has been presented. Vascular toxicity also may be due to deficiencies in the capacity of target cells to detoxify the active toxin or handle prooxidant states. Key components of the endogenous antioxidant defense system—including the glutathione/glutathione reductase/glutathione peroxidase system, superoxide dismutase—and catalase, are operative in vascular cells.

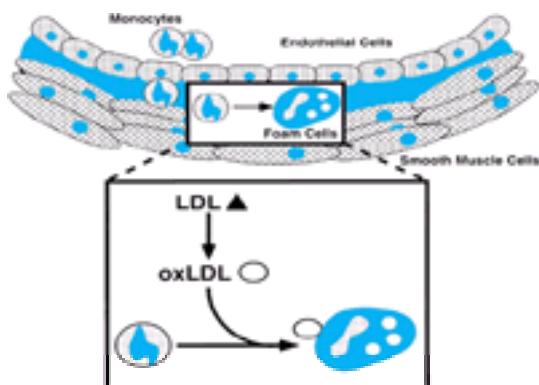
Oxidative metabolism is critical to the preservation of vascular function, as is best exemplified by the role of oxidation in the metabolism and cytotoxicity of plasma lipoproteins. LDLs are oxidized by oxygen free radicals released by arterial cells, and this reaction is considered to be critical in the initiation and progression of the atherosclerotic process (Fig. 18-19). Modified LDLs attract macrophages and prevent their migration from the tissues (Ross, 1993). Oxidation of low-density lipoproteins generates activated oxygen species, which can directly injure endothelial cells and increase adherence and the migration of monocytes and T lymphocytes into the subendothelial space. Subsequent release of growth modulators from endothelial cells and/or macrophages can promote smooth muscle cell proliferation and the secretion of extracellular matrix proteins. In the vasculature, free radicals in vivo can be generated secondary to anoxic/reoxygenation injury, metabolism of xenobiotics, neutrophil/monocyte-mediated inflammation, and oxidative modification of low-density lipoproteins. Superoxide anions inactivate endothelium-derived relaxing factor, while hydrogen peroxide and hydroxyl radicals cause direct vasodilation and stimulate the synthesis and release of relaxation factors. Oxygen radicals are considered important mediators of vascular damage in acute arterial hypertension and experimental brain injury (Wei et al., 1985). Acute exposure of rats to angiotensin II results in a hypertensive episode that results from irregular constriction patterns and in vascular hyperpermeability in small arteries and arterioles (Wilson, 1990). The treatment of hypertensive rats with free radical scavengers inhibits the vascular hyperpermeability and cellular damage associated with angiotensin II–induced hypertension. The release of superoxide from endothelial cells may modulate endothelial functions as well as the functions of other constituents of the vascular wall. In this context, activated endothelial cells have been reported to produce and secrete proteases in association with vessel penetration into surrounding connective tissue in response to angiogenic stimuli (Gross et al., 1983).


Figure 18-19. Oxidized lipoproteins participate in the progression of atherosclerosis.

Low-density lipoproteins (LDL) are oxidized within the vasculature. The uptake of oxidized LDL by macrophage scavenger receptors results in the formation of foam cells, an important cell type found in atherosclerotic plaques.

Vascular toxicity may be due to selective accumulation of chemicals in the vascular wall. Although the mechanisms responsible for preferential accumulation of toxins in the vessel wall are not known, receptor-mediated internalization of LDLs may be critical in this process. This process appears to be critical in the deposition of aromatic hydrocarbons and other ubiquitous environmental contaminants, including organic acids, aldehydes, alcohols, and esters, in the vessel wall (Ferrario et al., 1985). Agents such as nonenal, naphthalene, propylfuranacetaldehyde, DDT, and hexachlorobenzene have been identified in atherosclerotic plaques. The deposition of these toxicants could be accounted for by chemical partitioning into the lipid phase of the atherosclerotic plaques. The consequences of vasculotoxic insult are dictated by the interplay between vascular and nonvascular cells and by noncellular factors such as extracellular matrix proteins, coagulation factors, hormones, immune complexes, and plasma lipoproteins. Furthermore, the toxic response can be modulated by mechanical and hemodynamic factors such as arterial pressure, shear stress, and blood viscosity. An additional consideration is the fact that kinetic and pharmacodynamic differences among different animal species also may alter the toxicological profile of a toxicant.

CLASSIFICATION OF VASCULOTOXIC AGENTS

Pharmaceutical Agents

Autonomic Agents *Sympathomimetic Amines* The sympa-thomimetic amines—including epinephrine, norepinephrine, dopamine, and isoproterenol—can damage the arterial vasculature by a variety of mechanisms. Amphetamine, a noncatecholamine sympathomimetic, damages cerebral arteries in experimental animal models. Large doses of norepinephrine produce toxic effects on the endothelium of the thoracic aorta of rabbits. Degenerative changes in the aortic arch have taken the form of increased numbers of microvilli and many focal areas of unusual endothelial cytoarchitecture. Repeated exposure to catecholamines induces atherosclerotic lesions in several animal species. The atherosclerotic effect of catecholamines probably is related to their ability to induce endothelial cell injury and/or modulate the proliferation of vascular cells. Evidence is available suggesting that the proliferative disturbances induced by catecholamines are mediated via alpha-receptors because prazocin, an alpha-receptor antagonist, effectively prevents the toxic response (Nakaki et al., 1989). However, potentiation of the atherosclerotic process by sympathetic activation is inhibited by beta-adrenergic receptor blockade. Smooth muscle cells subjected to increased stress by diabetes, hypertension, and balloon injury are more susceptible to the effects of catecholamines. Thus, the formation of arteriosclerotic lesions in certain forms of hypertension may be initiated and/or supported by high levels of circulating catecholamines.

Nicotine Nicotine, an alkaloid found in various plants, mimics the actions of acetylcholine at nicotinic receptors throughout the body. At pharmacologic concentrations, nicotine increases heart rate and blood pressure as a result of stimulation of sympathetic ganglia and the adrenal medulla. Epidemiologic and experimental studies have suggested that nicotine is a causative or aggravating factor in myocardial and cerebral infarction, gangrene, and aneurysm. Bull and associates (1985) have shown that repeated subcutaneous infusion of nicotine for 7 days is associated with reduced prostacyclin production in aortic segments. Reduced prostacyclin production has been observed in isolated rabbit hearts, rabbit aortas, human veins, rat aortas, and rat umbilical arteries when incubated with nicotine in vitro. It has been suggested that the effects of nicotine are due to competitive inhibition of cyclooxygenase, which precludes the formation of prostaglandin endoperoxides in vivo.

Cocaine Cardiovascular disorders are among the most common complications associated with cocaine abuse. The central actions of cocaine trigger an increase in the circulating levels of catecholamines and a generalized state of vasoconstriction. Hypertension and cerebral strokes are common vascular complications. In pregnant women, cocaine-induced vascular changes have been associated with abortions and abruptio placentae. Recent studies have shown that cocaine enhances leukocyte migration across the cerebral vessel wall during inflammatory conditions. This effect is exerted through a cascade of augmented expression of inflammatory cytokines and endothelial adhesion molecules and may in fact underlie the cerebrovascular complications associated with cocaine abuse (Gan et al., 1999).

Psychotropic Agents Several agents in the psychotropic class of drugs have been identified as potential atherogens. For instance, trifluoperazine and chlorpromazine have been shown to cause intracellular cholesterol accumulation in cultured cells of the aortic intima (Iakushkin et al., 1992). Enalapril has been shown to cause angioedema in humans. Aside from the atherogenic effects, postural hypotension has been identified as the most common cardiovascular side effect of tricyclic antidepressants.

Antineoplastic Agents The vasculotoxic responses elicited by antineoplastic agents range from asymptomatic arterial lesions to thrombotic microangiopathy. Pulmonary veno-occlusive disease has been reported after the administration of various agents, including 5-fluorouracil, doxorubicin, and mitomycin. Long latencies characterize the occurrence of this disorder. Cyclophosphamide causes cerebrovascular and viscerovascular lesions, resulting in hemorrhages. In studies with 5-fluoro-2-deoxyuridine in dogs, chronic infusions into the hepatic artery resulted in gastrointestinal hemorrhage and portal vein thrombosis.

Analgesics and Nonsteroidal Anti-Inflammatory Agents Aspirin can produce endothelial damage as part of a pattern of gastric erosion. Studies in rats have shown early changes in the basement membrane of endothelial cells of the capillaries and postcapillary venules, leading to obliteration of small vessels and ischemic infarcts in the large intestine. Regular use of analgesics containing phenacetin has been associated with an increased risk of hypertension and cardiovascular morbidity. Nonsteroidal anti-inflammatory drugs may induce glomerular and vascular renal lesions.

Oral Contraceptives Oral contraceptive steroids can produce thromboembolic disorders. An increased incidence of deep vein phlebitis and pulmonary embolism has been reported in young women who use oral contraceptives. Intracranial venous thrombosis and secondary increases in the risk of stroke have also been noted. A combination of cholesterol and estradiol given to experimental animals produced severe degenerative atherosclerotic effects on coronary arteries as well as lipid deposition along the ascending aorta. In an epidemiologic review, Stolley and colleagues (1989) summarized the risks of vascular disease associated with the use of oral contraceptives. Oral contraceptive users have an increased risk of myocardial infarction relative to nonusers, a correlation that is markedly exacerbated by smoking. Oral contraceptive users experience an increased risk of cerebral thrombosis, hemorrhage, venous thrombosis, and pulmonary embolism. Although this has not been established with certainty, several groups have proposed that an immunologic mechanism mediates the vasculotoxic actions of oral contraceptives. However, the mechanism by which oral contraceptives increase the risk of vascular disease is unclear.

Radiologic Contrast Dyes The iodinated radio contrast dyes used for visualization of blood vessels in angiography can cause thrombophlebitis. The cyanoacrylate adhesives used in repairing blood vessels and other tissues have produced degenerative changes in the arteries of dogs. Certain rapidly polymerizing polyurethane preparations used for transcatheter embolization techniques in surgery have produced dissolution of arterial walls. Dermal microvascular lesions have been reported after plastic film wound dressings were applied in various animal species.

Phosphodiesterase Inhibitors The class of compounds that includes phosphodiesterase inhibitors is associated with toxicity in medium-size arteries of the mesentery, testis, and myocardium. Other reports showing that theophylline, an inhibitor of phosphodiesterase, causes cardiovascular lesions in mesenteric arterioles and that isomazole and indolidan cause periarteritis of the media and adventitia of small and medium-size arteries have been presented (Sandusky et al., 1991).

Miscellaneous Agents Interleukin-2 therapy has been associated with a spectrum of cardiovascular toxicities and hemodynamic alterations often indistinguishable from septic shock. Many of these effects may be mediated by overproduction of nitric oxide via cytokine-inducible nitric oxide pathway (Shahidi and Kilbourn, 1998).

Natural Products

Bacterial Endotoxins Bacterial endotoxins produce a variety of toxic effects in many vascular beds. In the liver, they cause swelling of endothelial cells and adhesion of platelets to sinusoid walls. In the lung, endotoxins produce increased vascular permeability and pulmonary hypertension. Infusion of endotoxin into experimental animals produces thickening of endothelial cells and the formation of fibrin thrombi in small veins. In piglets, severe coronary artery damage has been demonstrated. These changes include disappearance of endothelial cells (exfoliation) followed by necrosis of medial smooth muscle cells. The terminal phase of the effects of endotoxin on the systemic vasculature results in marked hypotension. The ability of vitamin E to prevent disseminated intravascular coagulation induced by bacterial endotoxins in the rat suggests that this disorder is related to free radical–mediated mechanisms.

Homocysteine Moderately elevated levels of homocysteine have been associated with atherosclerosis and venous thrombosis. Toxicity may involve oxidative injury to vascular endothelial and/or smooth muscle cells, leading to deregulation of vascular smooth muscle growth, synthesis and deposition of matrix proteins, and adverse effects on anticoagulant systems (Harpel, 1997).

Hydrazinobenzoic Acid Hydrazinobenzoic acid is a nitrogen-nitrogen bonded chemical that is present in the cultivated mushroom *Agaricus bisporus*. McManus and associates (1987) reported that this hydrazine derivative causes smooth muscle cell tumors in the aorta and large arteries of mice when administered over the life span of the animals. These tumors had the characteristic appearance and immunocytochemical features of vascular leiomyomas and leiomyosarcomas. Smooth muscle cell lysis with vascular perforation apparently precedes malignant transformation. The ability of hydrazinobenzoic acid to cause vascular smooth muscle cell tumors is shared by other synthetic and naturally occurring hydrazines. Although angiomyomas (or vascular leiomyomas) derived histogenetically from the media of blood and lymph vessels occur most commonly in the oral cavity and skin, primary leiomyosarcomas occur in the abdominal aorta.

T-2 Toxin Trichothecene mycotoxins, commonly classified as tetracyclic sesquiterpenes, are naturally occurring cytotoxic metabolites of *Fusarium* species. These mycotoxins—including T-2 toxin [4b,15-diacetoxy-8a-(3-methylbutyryloxy)-3a-hydroxy- 12,13-epoxytrichothec-9-ene]—are major contaminants of foods and animal feeds and may cause illness in animals and humans. Acute parenteral administration of T-2 toxin to laboratory animals induces shock, hypothermia, and death from cardiovascular and respiratory failure. Wilson and coworkers (1982) reported that intravenous infusion of T-2 toxin in rats causes an initial decrease in heart rate and blood pressure, followed by tachycardia and hypertension and finally by bradycardia and hypotension. These actions may be related to a central effect on blood pressure and catecholamine release. Acute T-2 toxin exposure causes extensive destruction of myocardial capillaries, while repeated dosing promotes thickening of large coronary arteries.

Vitamin D Vitamin D hypervitaminosis causes medial degeneration, calcification of the coronary arteries, and smooth muscle cell proliferation in laboratory animals. The toxic effects of vitamin D may be related to its structural similarity to 25-hydroxycholesterol, a potent vascular toxin.

A summary of selected agents and their vascular effects can be found in Table 18-7, Table 18-8 and Table 18-9.

Table 18-9 Vasculotoxic Agents: Therapeutic Agents and Related Compounds

Miscellaneous Recent evidence has implicated vascular dysfunction as a contributing factor to Alzheimer's dementia. Thomas et al. (1997) have shown that administration of b-amyloid produces extensive vascular disruption, including endothelial and smooth muscle damage, adhesion and migration of leukocytes across arteries and venules. Most importantly, the vascular actions of b-amyloid appear to be distinct from the neurotoxic properties of the peptide.

Industrial Agents

Alkylamines Aliphatic amines such as allylamine (3-aminopropene) are utilized in the synthesis of pharmaceutical and commercial products. Several allylamine analogs are being developed as antifungal agents for human and veterinary use. Allylamine is more toxic than are other unsaturated primary amines of higher molecular weight. Exposure to allylamine by a variety of routes in various animal species is associated with selective cardiovascular toxicity (Boor et al., 1979; Ramos and Thurlow, 1993). Hines and associates (1960) reported that acute intragastric administration of allylamine causes congestion of blood vessels in rats. The multiple organ toxicities observed after chronic inhalation of allylamine are characterized by a prominent vascular component (Lalich, 1969) involving mesenteric, pancreatic, testicular, and pulmonary artery hypertrophy and occasional alveolar hemorrhage and pulmonary edema. The specificity of the vasculotoxic response may be related to the accumulation of allylamine in elastic and muscular arteries upon administration in vivo. Gross lesions are evident in the myocardium, aorta, and coronary arteries of animals exposed to allylamine. Chronic administration is associated with the development of atherosclerotic-like lesions characterized by proliferation of smooth muscle cells and fibrosis.

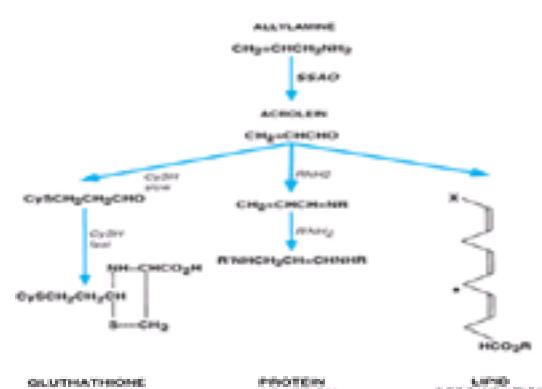
Boor and associates (1990) first proposed that allylamine toxicity results from bioactivation of the parent compound to a toxic aldehyde. The oxidative deamination of allylamine results in the formation of acrolein and hydrogen peroxide, metabolites that mediate the acute and long-term toxic effects of allylamine (Fig. 18-20). Vascular-specific bioactivation of allylamine is a prerequisite for toxicity (Ramos et al., 1988). Benzylamine oxidase, also known as semicarbazide-sensitive amine oxidase, is believed to catalyze the oxidative deamination of allylamine. This enzyme is found in cardiovascular tissue in higher concentrations than is any other tissue. Methylamine and aminoacetone are believed to be endogenous substrates for semicarbize-sensitive amine oxidase (Yu, 1998). Although the endogenous substrates and physiologic function of this enzyme have not been fully characterized, recent studies have shown that chronic enzyme inhibition is associated with disorganization of elastin architecture within the aortic media of weanling rats, degenerative medial changes, and metaplastic changes in vascular smooth muscle cells (Langford et al., 1999). Therefore, excessive deamination reactions may initiate endothelial injury and atherosclerotic plaque formation, induce oxidative stress, and potentiate oxidative injury to the vascular wall by glycation products and oxidized lipoproteins. Allylamine preferentially injures smooth muscle cells relative to other cell types in the vascular wall. Mitochondria have been identified as early targets of allylamine toxicity—an observation that is consistent with the enrichment of amine oxidase activity in this subcellular compartment. Because the cytotoxic response also involves alterations in cellular glutathione status that compromise the integrity of membrane compartments (Ramos and Thurlow, 1993), modulation of glutathione status by acrolein and/or hydrogen peroxide may also disrupt mitochondrial function. Pretreatment of cultured vascular smooth muscle cells with sulfasalazine, a glutathione S-transferase inhibitor, potentiates allylamine and acrolein cytotoxicity, indicating a protective role of this enzyme in vascular injury by a,b unsaturated carbonyls (He et al., 1999). Acrolein is a highly reactive aldehyde that disrupts the thiol balance of target cells, including vascular cells (Ramos and Cox, 1987); denatures proteins; and interferes with nucleic acid synthesis. Although many molecules react with acrolein under physiologic conditions, the main reaction products result from nucleophilic addition at the terminal ethylenic carbon. Acrolein toxicity also may involve conversion by NADPH-dependent microsomal enzymes to glycidaldehyde, a known mutagen and carcinogen. Acrolein is a ubiquitous toxic chemical that is found in engine exhaust and cigarette smoke. Using Dahl hypertension-resistant and hypertension-sensitive rat strains, Kutzman and colleagues (1984) demonstrated that exposure to acrolein for 62 days is more toxic to hypertension-sensitive animals than to their hypertension-resistant counterparts. The indirect sympa-thomimetic activity of aldehydes, including acrolein, acetaldehyde, and formaldehyde, may contribute to the enhanced sensitivity of hypertension-prone animals.


Figure 18-20. Metabolism of allylamine to acrolein by semicarbazide-sensitive amine oxidase in vascular smooth muscle cells.

Acrolein may be conjugated to gluthathione by the action of glutathione- S-transferase or may interact with intracellular proteins to form protein adducts. In addition, acrolein may initiate intracellular lipid peroxidation, which may lead to genotoxic or cell damage.

Repeated cycles of vascular injury upon in vivo exposure of rats to allylamine modulate medial aortic smooth muscle cells from a quiescent to a proliferative state (Cox and Ramos, 1990). Because cells from allylamine-treated rats maintain this altered phenotype after serial propagation in vitro, phenotypic modulation is believed to involve genotypic alterations secondary to chemical insult. The enhanced capacity for proliferation in allylamine cells is associated with modulation of phospholipid metabolism, enhanced protein kinase C activity, increased c-Ha-ras proto-oncogene expression, and differential secretion and deposition of extracellular matrix components (Ramos et al., 1993). Enhanced secretion of osteopontin characterizes the proliferative phenotype induced by allylamine (Parrish and Ramos, 1995). Osteopontin is a secreted phosphoprotein that has effects on gene expression, Ca^{2+} regulation, and nitric oxide production, presumably mediated through the a $_{vb3}$ integrin. Osteopontin has been associated with arterial smooth muscle cell proliferation and migration and is present in atherosclerotic lesions. Although a major contributory role in adhesion and migration has been established with a fair degree of certainty, its role in the regulation of vascular smooth muscle cell proliferation has not yet been fully elucidated. Recent studies established that allylamine treatment in vivo modulates the relative expression of integrin receptors and integrin-coupled NF-kB signaling in vascular smooth muscle cells (Parrish and Ramos, 1995).

Heavy Metals The vascular toxicity of food- and water-borne elements (selenium, chromium, copper, zinc, cadmium, lead, and mercury) as well as airborne elements (vanadium and lead) involves reactions of metals with sulfhydryl, carboxyl, or phosphate groups. Metals such as cobalt, magnesium, manganese, nickel, cadmium, and lead also interact with and block calcium channels. Evidence suggesting that intracellular calcium-binding proteins such as calmodulin are biologically relevant targets of heavy metals, including mercury and lead, has been presented. The contribution of this mechanism to the toxic effects of metals has been questioned because of the inability of beryllium, barium, cobalt, zinc, and cadmium to bind readily to calmodulin in vitro.

The vascular effects of cadmium have been studied in the greatest detail. Although cadmium is not preferentially localized in blood vessels relative to other tissues, when present, cadmium is localized in the elastic lamina of large arteries, with particularly high concentrations at arterial branching points (Perry et al., 1989). A large portion of the cadmium that accumulates in the body is tightly bound to hepatic and renal metallothionein, a known detoxification mechanism. The low metallothionein levels in vascular tissue may actually predispose a person to the toxic effects of cadmium (Perry et al., 1989). Long-term exposure of laboratory animals to low levels of cadmium has been associated with the development of atherosclerosis and hypertension in the absence of other toxic effects. Selenium and zinc inhibit, while lead potentiates, the hypertensive effects of cadmium. Concentrations of cadmium that increase blood pressure do not raise blood pressure in the presence of calcium. In contrast, the protective effects of zinc and selenium may be related to their ability to increase the synthesis of calcium-binding proteins and thus enhance detoxification. Cadmium increases sodium retention, induces vasoconstriction, increases cardiac output, and produces hyperreninemia. Any one of these mechanisms could account for the putative hypertensive effects of cadmium. In rats, chronic administration of cadmium caused renal arteriolar thickening as well as diffuse fibrosis of capillaries. Low levels of cadmium have been associated with a higher frequency of atherosclerosis in humans (Houtman, 1993). Similar vascular changes are also responsible for the development of testicular damage and atrophy. The hypertensive effects of cadmium remain questionable, since population studies in humans have not confirmed the associations made in studies with laboratory animals. Kaji and coworkers have recently shown that the sensitivity of cultured bovine aortic smooth muscle cells to cadmium is considerably greater than that of aortic endothelial cells and renal epithelial cells (1996). In related studies, this group showed that the regulation of fibrinolysis mediated by vascular smooth muscle cells and fibroblasts during hemostasis may be disturbed by cadmium (Yamamoto et al., 1996).

Less work has been conducted to evaluate the vasculotoxic effects of other heavy metals. Because hypertension is not commonly observed during clinical lead intoxication, many investigators consider the existing evidence to be conflicting and inconclusive. Epidemiologic studies have shown that a large percentage of patients with essential hypertension have increased body stores of lead (Batuman et al., 1983). Elevated blood pressure also has been observed during childhood lead poisoning. Although in these children the level of lead burden was not severe, a significant increase in blood pressure was seen on the tenth day of poisoning and persisted for the remainder of the study. The direct vasoconstrictor effect of lead may be related to the putative hypertensive response. This effect can be

complemented by the ability of lead to activate the renin-angiotensin-aldosterone system. Recent investigations have shown direct effects of lead in vascular endothelial and smooth muscle cells. For instance, lead has been shown to inhibit repair process in damaged endothelial cells (Fujiwara et al., 1997) and to modulate spontaneous release of fibrinolytic proteins from subendothelial cells is disturbed by lead through intracellular calcium-independent pathways (Yamamoto et al., 1997).

Inorganic mercury produces vasoconstriction of preglomerular vessels. In addition, the integrity of the blood-brain barrier may be disrupted by mercury. The opening of the blood-brain barrier results in extravasation of plasma protein across vascular walls into adjoining brain tissues. Mercury added to platelet-rich plasma causes a marked increase in platelet thromboxane B_2 production and platelet responsiveness to arachidonic acid. Although it is unlikely that mercury and lead compete with calcium for intracellular binding sites, their accessibility to the intracellular compartment appears to be calcium-dependent (Tomera and Harakal, 1986). Acute lead-induced neuropathy may be due to cerebral capillary dysfunction. Inorganic lead alters arterial elasticity and causes sclerosis of renal vessels. Lead intoxication has been linked to hypertension in humans, but its exact role is questionable.

Acute arsenic poisoning causes vasodilation and capillary dilation. These actions have been associated with extravasation, transudation of plasma, and decreased intravascular volume. It has been proposed that high levels of arsenic in the soil and water of Taiwan are responsible for blackfoot disease, a severe form of arteriosclerosis. Blackfoot disease is an endemic peripheral vascular occlusive disease that exhibits arteriosclerosis obliterans and thromboangiitis. The ability of arsenic to induce these changes has been attributed to its effects on vascular endothelial cells. Arsenic has been reported to cause noncirrhotic portal hypertension in humans. Chromium appears to play an important role in the maintenance of vascular integrity. A deficiency of this metal in animals results in elevated serum cholesterol levels and increased atherosclerotic aortic plaques. Autopsies of humans have revealed virtually no chromium in the aortas of individuals who died of atherosclerotic heart disease compared with individuals dying of other causes.

Nitroaromatics Dinitrotoluene is used as a precursor in the synthesis of polyurethane foams, coatings, elastomers, and explosives. The manufacture of dinitrotoluene generates a technical-grade mixture that consists of 75.8 percent 2,4-dinitrotoluene, 19.5 percent 2,6-dinitrotoluene, and 4.7 percent other isomers. Several chronic toxicity studies in laboratory animals have shown that 2,4- and/or 2,6-dinitrotoluene can cause cancers of the liver, gallbladder, and kidney as well as benign tumors of the connective tissues. In humans, however, retrospective mortality studies in workers exposed daily to dinitrotoluene have shown that dinitrotoluenes cause circulatory disorders of atherosclerotic etiology. As with other chronic occupational illnesses, increased mortality from cardiovascular disorders upon exposure to dinitrotoluenes has been related to the duration and intensity of exposure.

The atherogenic effects of dinitrotoluenes have been examined experimentally. Repeated in vivo exposure of rats to 2,4- or 2,6-dinitrotoluene is associated with dysplasia and rearrangement of aortic smooth muscle cells (Ramos et al., 1990). Dinitrotoluenes are metabolized in the liver to dinitrobenzylalcohol, which is then conjugated to form a glucuronide conjugate that is excreted in bile or urine. This conjugate is hydrolyzed by intestinal microflora and subsequently reduced to a toxic metabolite or the precursor of a toxic metabolite. Dent and colleagues (1981) have shown that rat cecal microflora convert dinitrotoluene to nitrosonitrotoluenes, aminonitrotoluenes, and diaminotoluenes. In vitro exposure of rat aortic smooth muscle cells to 2,4- or 2,6-diaminotoluene inhibited DNA synthesis, a response comparable to that seen in medial smooth muscle cells isolated from dinitrotoluene-treated animals.

Aromatic Hydrocarbons Aromatic hydrocarbons, including polycyclic aromatic hydrocarbons and polychlorinated dibenzo- *p*-dioxins, are persistent toxic environmental contaminants. Several aromatic hydrocarbons have been identified as vascular toxins that can initiate and/or promote the atherogenic process in experimental animals (Ou and Ramos, 1992a, b). Much of the work involved in investigations of aromatic hydrocarbon toxicity have focused on the polycyclic aromatic hydrocarbons, of which benzo[a]pyrene has been examined in the greatest detail. Exposure of avian species to benzo[*a*]pyrene and 7,12-dimethylbenz[*a*]anthracene causes atherosclerosis without altering serum cholesterol levels. The atherogenic effect is associated with cytochrome P450–mediated conversion of the parent compound to toxic metabolic intermediates. The majority of the activity responsible for the biotransformation of these chemicals is associated with the smooth muscle layers of the aorta, although cytochrome P450–dependent monoxygenase activity that can bioactivate carcinogens also has been localized in the aortic endothelium. Interestingly, the activity of aortic aryl hydrocarbon hydroxylase has been correlated with the degree of susceptibility to atherosclerosis in avian species, and Ah-responsive mice are more susceptible to atherosclerosis than are Ah-resistant mice. Recent studies have demonstrated that CYP1B1 is the predominant cytochrome P450 isoform expressed in human (Zhao et al., 1998), as well as rodent (Kerzee and Ramos, 2000) vascular cells.

3-Methylcholantrene increases both the number and the size of lipid-staining lesions in the aorta of animals that are fed an atherogenic diet for 8 weeks, suggesting that aromatic hydrocarbons can also initiate the atherogenic process. Furthermore, focal proliferation of intimal smooth muscle cells can be produced by an initiation-promotion sequence using 7,12-dimethylbenz[*a*]anthracene and the alpha$_1$ selective adrenergic agonist methoxamine. In contrast, Albert and coworkers (1977) and Penn and Snyder (1988) have reported that treatment with several polycyclic hydrocarbons increases the size but not the frequency of atherosclerotic lesions. These observations suggest that polycyclic aromatic hydrocarbons act as promoters of the atherosclerotic process. Although additional studies are required to define the "initiating" versus "promotional" actions of polycyclic aromatic hydrocarbons, their ability to readily associate with plasma lipoproteins may play a critical role in vascular toxicity. In fact, the localization of these and other lipophilic chemicals in blood vessels may depend on lipoprotein-mediated transport.

The enhanced proliferative and migratory potential of smooth muscle cells induced by benzo[*a*]pyrene may involve a mutagenic process, as predicted by the monoclonal theory of atherogenesis (Benditt and Benditt, 1973). Thus, "initiation" of the atherogenic process by benzo[*a*]pyrene and related chemicals would involve mutation of target genes, while promotion would involve modulation of mitogenic signaling, including growth-related gene expression and protein phosphorylation. Because a promotional mechanism of atherogenesis implies the existence of an "initiated" resident cell population in the vessel wall, information about the cellular heterogeneity of vascular smooth muscle cells in the vessel wall is needed.

Benzo[a]pyrene modulates protein kinase C signal transduction in aortic smooth muscle cells of atherosclerosis-susceptible (quail) and atherosclerosis-resistant (rat) species (Ou et al., 1995). Other aromatic hydrocarbons, such as 2,3,7,8-tetrachlorodibenzo- *p*-dioxin, share with benzo[*a*]pyrene the ability to inhibit protein kinase C in aortic smooth muscle cells, but the mechanisms appear to be different. As atherogenesis ultimately involves enhanced smooth muscle cell proliferation, the role of protein kinase C inhibition and the associated suppression of cell growth may involve phosphorylation-dependent changes in DNA repair efficiency. Genotoxic actions of metabolites formed in situ probably contribute to the growth inhibitory response of benzo[*a*]pyrene because sister chromatid exchanges, mutations, and unscheduled DNA synthesis in cultured aortic smooth muscle cells have been noted (Zwijsen et al., 1990; Lu et al., 2000). Benzo[a]pyrene modulates the expression of genes involved in the regulation of coordinated cell cycle progression (Kerzee and Ramos, 2000), antioxidant defense mechanisms (Chen and Ramos, 2000), and genomic stability (Lu et. al., 2000).

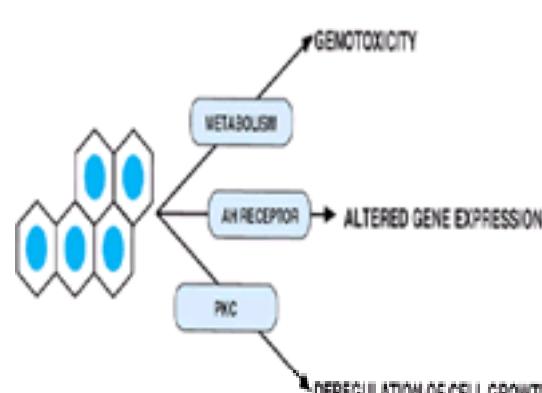
In summary, benzo[a]pyrene elicits alterations of smooth muscle cell proliferation through several mechanisms, including enhanced transcription of growth-related genes through aryl hydrocarbon receptor–mediated pathways, interaction and inactivation of protein kinase C, and conversion of the parent molecule to metabolites that can form covalent DNA adducts (Fig. 18-21).


Figure 18-21. Cellular and molecular targets of benzo[a]pyrene in vascular smooth muscle cells.

Benzo[a]pyrene may be metabolized to reactive intermediates that bind covalently to DNA. Additionally, benzo[*a*]pyrene may bind to cytosolic receptors that act as ligand-activated transcription factors to regulate gene expression. Benzo[*a*]pyrene and/or its metabolites also may interact with protein kinase C to deregulate cell growth.

Gases *Carbon Monoxide* Carbon monoxide induces focal intimal damage and edema in laboratory animals at 180 ppm, a concentration to which humans may be exposed from environmental sources such as automobile exhaust, tobacco smoke, and fossil fuels. Because most sources of carbon monoxide are complex mixtures of chemicals, attempts to distinguish the direct effects of carbon monoxide from those of chemicals such as sulfur oxides, nitrogen oxides, aldehydes, and hydrocarbons have not yielded clear results. This is exemplified by the prominent vasculotoxic effects observed upon exposure of laboratory animals to other complex gas mixtures. For instance, automobile exhaust causes structural changes in the myocardium and aorta of guinea pigs and hemorrhage and infarct in the hemispheres and basal ganglia of spontaneously hypertensive rats. In addition, composition and deposition of lipids in the wall of the aorta of rats can be affected. However, it is not clear which of the many chemicals present in these mixtures mediate the atherogenic effect. Degenerative changes of myocardial arterioles have been produced experimentally in dogs forced to smoke. Similar changes have also been detected in humans who were heavy smokers and died of noncardiac causes (Wald and Howard, 1975; Auerbach and Carter, 1980). Tobacco smoke not only exerts a direct atherogenic effect (endothelial injury, changes in lipid profiles, and proliferation of smooth muscle cells) but also facilitates thrombosis by modulation of platelet function and vascular spasm.

Short-term exposure to carbon monoxide has been associated with direct damage to vascular endothelial and smooth muscle cells. Injury to endothelial cells increases intimal permeability and allows the interaction of blood constituents with underlying components of the vascular wall. This response may account in part for the ability of carbon monoxide to induce atherosclerotic lesions in several animal species. Although carbon monoxide enhances total arterial deposition of cholesterol in animals fed a lipid-rich diet, its vascular effects appear to be independent of serum cholesterol levels. The toxic effects of carbon monoxide have been attributed to its reversible interaction with hemoglobin. The formation of carboxyhemoglobin in vivo is favored because binding of carbon monoxide to hemoglobin is more cooperative than the binding of oxygen. As a result of this interaction, carboxyhemoglobin decreases the oxygen-carrying capacity of blood and shifts the oxyhemoglobin saturation curve to the left. These actions make it more difficult to unload oxygen and eventually cause functional anemia resulting from reduced oxygen availability. More recently, evidence has been presented that carbon monoxide interacts with cellular proteins such as myoglobin and cytochrome *c* oxidase and that carbon monoxide elicits a direct vasodilatory response of the coronary circulation.

Oxygen The administration of oxygen to a premature newborn can cause irreversible vasoconstriction and obliteration of retinal vasculature, resulting in permanent blindness. In squirrel monkeys, exposure to 100% oxygen for 50 to 117 h increases vascular permeability, with leakage and edema of the retina, but these effects are largely reversible. In the pulmonary capillary bed, the volume and thickness of capillary endothelium decrease and perivascular edema is present. Exposure to high oxygen pressures for relatively short periods (less than 8 h) damages pulmonary endothelial cells in several species. Ozone affects the pulmonary vasculature; the injuries usually take the form of pulmonary arterial lesions that lead to thickening of the artery walls.

Carbon Disulfide Carbon disulfide (dithiocarbonic anhydride) occurs in coal tar and crude petroleum and is commonly utilized in the manufacture of rayon and soil disinfectants. This chemical has been identified as an atherogenic agent in laboratory animals. In humans, a two- to threefold increase in coronary heart disease has been reported. Although the mechanism of toxicity is not known, alterations of glucose and/or lipid metabolism and blood coagulation have been suggested. The mechanism for CS_2-atheroma production also may involve direct injury to the endothelium coupled with hypothyroidism, because thiocarbamate (thiourea), a potent antithyroid substance, is a principal urinary metabolite of CS_2. More recently, evidence has been presented that carbon disulfide modifies low density lipoprotein in vitro and enhances arterial fatty deposits induced by a high-fat diet in C57BL/6 mice (Lewis et al., 2000).

1,3-Butadiene Studies have shown that 1,3-butadiene, a chemical used in the production of styrene-butadiene, increases the incidence of cardiac hemangiosarcomas, which are tumors of endothelial origin (Miller and Boorman, 1990). Although hemangiosarcomas have also been observed in the liver, lung, and kidney, cardiac tumors are a major cause of death in animals exposed to this chemical. The toxic effects of 1,3-butadiene are dependent on its metabolic activation by cytochrome P450 to toxic epoxide metabolites. The ultimate outcomes of exposure probably are influenced by the rates of glutathione-mediated detoxification of oxidative metabolites. Although 1,3-butadiene is a carcinogen in rats and mice, mice are considerably more sensitive than are rats to this carcinogenicity. This difference in susceptibility has been attributed to differences in the formation of the toxic mono- and diepoxide metabolites.

CHAPTER 19

TOXIC RESPONSES OF THE SKIN

David E. Cohen and Robert H. Rice

As the body's first line of defense against external insult, the skin's enormous surface area (1.5 to 2 m ^{2}) is exposed routinely to chemical agents and may inadvertently serve as a portal of entry for topical contactants. Recognizing the potential hazards of skin exposure, the National Institute of Occupational Safety and Health (NIOSH) characterized skin disease as one of the most pervasive occupational health problems in the United States. In 1982 NIOSH placed skin disease in the top ten leading work-related diseases based on frequency, severity, and the potential for prevention. Data from the Bureau of Labor Statistics indicate that skin disease attributed to workplace exposures accounts for more than 30 percent of all reported occupational disease. Incidence data from 1990 indicate a rate of 7.9 cases per 10,000 or about 61,000 new cases per year. Exposures in the agricultural and manufacturing industries were responsible for the greatest volume of disease, with incidence rates of 86 and 41 per 10,000, respectively. Skin conditions resulting from exposures to consumer products or occupational illnesses not resulting in lost work time are poorly recorded and tracked. Hence the incidence of such skin diseases is grossly underestimated.

SKIN AS A BARRIER

A large and highly accessible human organ, the skin protects the body against external insults in order to maintain internal homeostasis. Its biological sophistication allows it to perform a myriad of functions above and beyond that of a suit of armor. Physiologically, the skin participates directly in thermal, electrolyte, hormonal, metabolic, and immune regulation, without which a human being would perish. Rather than merely repelling noxious physical agents, the skin may react to them with a variety of defensive mechanisms that serve to prevent internal or widespread cutaneous damage. If an insult is severe or intense enough to overwhelm the protective function of the skin, acute or chronic injury becomes readily manifest in a variety of ways. The specific presentation depends on a variety of intrinsic and extrinsic factors including body site, duration of exposure, and other environmental conditions (Table 19-1).

Table 19-1 Factors Influencing Cutaneous Responses

Skin Histology

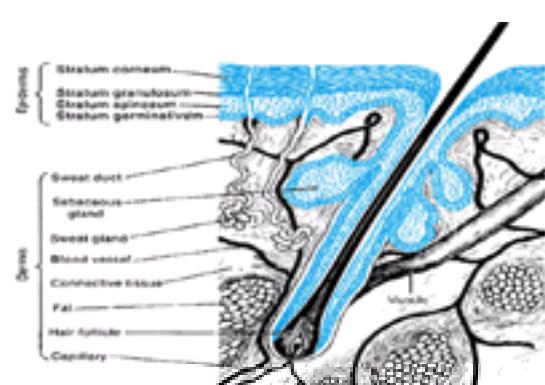
The skin consists of two major components: the outer epidermis and the underlying dermis, which are separated by a basement membrane (Fig. 19-1). The junction ordinarily is not flat but has an undulating appearance (rete ridges). In addition, epidermal appendages (hair follicles, sebaceous glands, and eccrine glands) span the epidermis and are embedded in the dermis. In thickness, the dermis makes up approximately 90 percent of the skin and has largely a supportive function. It has a high content of collagen and elastin, secreted by scattered fibroblasts, thus providing the skin with elastic properties. Separating the dermis from underlying tissues is a layer of adipocytes, whose accumulation of fat has a cushioning action. The blood supply to the epidermis originates in the capillaries located in the rete ridges at the dermal-epidermal junction. Capillaries also supply the bulbs of the hair follicles and the secretory cells of the eccrine (sweat) glands. The ducts from these glands carry a dilute salt solution to the surface of the skin, where its evaporation provides cooling.


Figure 19-1. Diagram of a cross section of human skin.

The epidermis and pilosebaceous unit are shown in blue.

The interfollicular epidermis is a stratified squamous epithelium consisting primarily of keratinocytes. These cells are tightly attached to each other by desmosomes and to the basement membrane by hemidesmosomes. Melanocytes are interspersed among the basal cells and distributed sparsely in the dermis, with occasional concentrations beneath the basal lamina and in the papillae of hair follicles. In the epidermis, these cells are stimulated by ultraviolet light to produce melanin granules. The granules are extruded and taken up by the surrounding epidermal cells, which thereby become pigmented. Migrating through the epidermis are numerous Langerhans cells, which are important participants in the immune response of skin to foreign agents.

Keratinocytes of the basal layer make up the germinative compartment. When a basal cell divides, one of the progeny detaches from the basal lamina and migrates outward. As cells move toward the skin surface, they undergo a remarkable program of terminal differentiation. They gradually express new protein markers and accumulate keratin proteins, from which the name of this cell type is derived. The keratins form insoluble intermediate filaments, accounting for nearly 40 percent of the total cell protein in the spinous layer. At the granular layer, the cells undergo a striking morphologic transformation, becoming flattened and increasing in volume nearly 40-fold. Lipid granules fuse with the plasma membrane, replacing the aqueous environment in the intercellular space with their contents. Meanwhile, the plasma membranes of these cells become permeable, resulting in the loss of their reducing environment and consequently in extensive disulfide bonding among keratin proteins. Cell organelles are degraded, while a protein envelope is synthesized immediately beneath the plasma membrane. The membrane is altered characteristically by the loss of phospholipid and the addition of sphingolipid.

This program of terminal differentiation, beginning as keratinocytes leave the basal layer, produces the outermost layer of the skin, the stratum corneum. No longer viable, the mature cells (called *corneocytes*) are approximately 80 percent keratin in content. They are gradually shed from the surface and replaced from beneath. The process typically takes 2 weeks for basal cells to reach the stratum corneum and another 2 weeks to be shed from the surface. In the skin disease psoriasis, the migration of cells to the surface is nearly tenfold faster than normal, resulting in a stratum corneum populated by cells that are not completely mature. In instances in which the outer layer is deficient due to disease or physical or chemical trauma, the barrier to the environment that the skin provides is inferior to that provided by normal, healthy skin.

Percutaneous Absorption

Until the turn of the century, the skin was believed to provide an impervious barrier to exogenous substances. Gradually, the ability of substances to penetrate the skin, though this process generally is very slow, became appreciated. During the past 50 years, the stratum corneum has been recognized as the primary barrier (Scheuplein and Blank, 1971). Diseases (e.g., psoriasis) or other conditions (e.g., abrasion, wounding) in which this barrier is compromised can permit greatly increased uptake of poorly permeable substances, as does removal of the stratum corneum by tape stripping. The viable layer of epidermis provides a much less effective barrier, because hydrophilic agents readily diffuse into the intercellular water, while hydrophobic agents can partition into cell membranes, and each can diffuse readily to the blood supply in the rete ridges of the dermis.

Probably the best-known biological membrane barrier for this purpose, the stratum corneum, prevents water loss from underlying tissues by evaporation. Its hydrophobic character reflects the lipid content of the intercellular space, approximately 15 percent of the total volume (Elias, 1992). The lipids, a major component being sphingolipids, have a high content of long-chain ceramides, removal of which seriously compromises barrier function as measured by transepidermal water loss. The stratum corneum is ordinarily hydrated (typically 20 percent water), the moisture residing in corneocyte protein, but it can take up a great deal more water upon prolonged immersion, thereby reducing the effectiveness of the barrier to agents with a hydrophilic character. Indeed, occlusion of the skin with plastic wrap, permitting the retention of perspiration underneath, is a commonly employed technique to enhance uptake of agents applied to the skin surface. Although penetration from the air is generally too low to be of concern, protection from skin uptake may be advisable for some compounds (e.g., nitrobenzene) at concentrations high enough to require respirator use.

Finding the rate at which the uptake of agents through the skin occurs is important for estimating the consequences of exposure to many agents we encounter in the environment. Indeed, a regulatory strategy permitting bathing in water considered barely unfit for drinking was revised when it was realized that exposure from dermal/inhalation uptake during bathing could be comparable to that from drinking 2 L of the water (Brown et al., 1984). Uptake through the skin is now incorporated in pharmacokinetic modeling to estimate potential risks from exposures. The degree of uptake depends upon the details of exposure conditions, being proportional to solute concentration (assuming it is dilute), time, and the amount of skin surface exposed. In addition, two intrinsic factors contribute to the absorption rate of a given compound: its hydrophobicity, which affects its ability to partition into epidermal lipid, and its rate of diffusion through this barrier. A measure of the first property is the commonly used octanol/water partitioning ratio (K_{ow}). This is particularly relevant for exposure to contaminated water, such as occurs during bathing or swimming. However, partitioning of an agent into the skin is greatly affected by its solubility in or adhesion to the medium in which it is applied (including soil). The second property is an inverse function of molecular weight (MW) or molecular volume. Thus, hydrophobic agents of low MW permeate the skin better than those of high MW or those that are hydrophilic. For small molecules, hydrophobicity is a dominant factor in penetration.

Although only small amounts of agents may penetrate the stratum corneum, those of high potency may still be very dangerous. For example, hydrophobic organophosphorus pesticides can be neurotoxic by skin contact to humans and domestic animals. Conditions of topical treatment of the latter for pest control must take into consideration not only the tolerance of the animals but also residues in meat and milk resulting from skin penetration. High level skin exposure to agents considered safe at low levels can be dangerous, evident from the nervous system toxicity and deaths of babies exposed to hexachlorophene mistakenly added to talcum powder for their diapers (Martin-Bouyer et al., 1982). Previous findings of *N*-nitrosamines that penetrate skin well (such as *N*-nitrosodiethanolamine) in cutting oils and cosmetics raised concern and led to their monitoring and to reduction of exposure.

Considerable empiric information has been collected on some compounds of special interest (including pharmaceuticals, pesticides, and pollutants) for use in quantifying structure/penetration relationships. From such information, relations can be obtained for skin penetration (P_{cw}) using empirically derived constants (C_1, C_2, C_3) that have the form shown below (Potts and Guy, 1992). Such

$$\log P_{cw} = C_1 - C_2(MW) + C_3 \log K_{ow}$$

relations describe steady-state conditions, in which an agent leaves the stratum corneum at the same rate it enters. Because rates of transfer of very hydrophobic agents into the aqueous phase of the spinous layer are slow, saturation of the stratum corneum provides a depot, leading to continued penetration into the body for relatively long time periods after external exposure to an agent stops.

Diffusion through the epidermis is considerably faster at some anatomic sites than others. A list in order of decreasing permeability under steady state conditions gives the following hierarchy: foot sole>palm>scrotum>forehead>abdomen (Scheuplein and Blank, 1971). Under ordinary circumstances, absorption through the epidermal appendages is generally neglected, despite the ability of agents to bypass the stratum corneum by this route, because the combined appendageal surface area is such a small fraction of the total available for uptake. However, because loading of the stratum corneum is slow, penetration through the appendages can constitute an appreciable fraction of the total for short exposures. In some cases, the effects of appendages can even be dominant. For instance, benzo(a)pyrene penetrates the skin of haired mice severalfold faster than that of hairless strains (Kao et al., 1988).

Transdermal Drug Delivery The ability of the stratum corneum to serve as a reservoir for exogenously applied agents is well illustrated by the recent development of methods to exploit this property for the delivery of pharmaceuticals. Application of drugs to the skin can produce systemic effects, a phenomenon observed fortuitously before the ability of the skin to serve as a delivery system was appreciated. For example, topical exposure of young girls to estrogens has led to reports of pseudoprecocious puberty, while in young or adult males, such exposure has produced gynecomastia (reviewed in Amin et al., 1998). Specially designed patches are currently in use to deliver estradiol, testosterone, nitroglycerin, scopolamine, clonidine, fentanyl, and nicotine for therapeutic purposes, and others are under development. The advantages of this approach over oral dosing include providing a steady infusion for extended periods (typically 1 to 7 days), thereby avoiding large variations in plasma concentration, preventing exposure to the acidic pH of the stomach, and avoiding biotransformation in the gastrointestinal tract or from first-pass removal by the liver. The contrast in plasma concentration kinetics between different methods of delivery is particularly evident for agents that are rapidly metabolized,

such as nitroglycerin, which has a half-life of minutes.

Measurements of Penetration For many purposes, including risk assessment and pharmaceutical design, the most useful subject for experimentation is human skin. Volunteers are dosed, plasma and/or urine concentrations are measured at suitable intervals, and amounts excreted from the body are estimated. Past measurements of penetration, for example of pesticides (Feldman and Maibach, 1974), often used ^{14}C-labeled agents. For most compounds, this approach is not preferred, but use of isotopic labels is now readily feasible when coupled to ultrasensitive detection by accelerator mass spectrometry (Buchholz et al., 1999). For in vitro work, excised split-thickness skin can be employed in special diffusion chambers, though care is needed to preserve the viability of the living layer of epidermis. The agent is removed for measurement from the underside by a fluid into which it partitions, thereby permitting continued penetration. Commonly employed is a simpler setup using cadaver skin with the lower dermis removed. This lacks biotransformation capability but retains the barrier function of the stratum corneum. The pharmacokinetic approach with intact subjects is most commonly employed with experimental animals. Without verification using human skin, such measurements are subject to large uncertainties due to species differences in density of epidermal appendages, stratum corneum properties (e.g., thickness, lipid composition), and biotransformation rates. Because penetration through rodent skin is usually faster than through human skin, the former provides a conservative estimate for behavior of the latter. To simplify determination of penetration kinetics, skin flaps may be employed and the capillary blood flow monitored to measure penetration. For this purpose, pig skin has particular utility (Riviere, 1993). A promising variation minimizing species differences is to use skin grafts on experimental animals for these measurements. Human skin persists well on athymic mice and retains its normal barrier properties (Kreuger and Pershing, 1993).

Biotransformation

The ability of the skin to metabolize agents that diffuse through it contributes to its barrier function. This influences the potential biological activity of xenobiotics and topically applied drugs, leading to their degradation or their activation as skin sensitizers or carcinogens (for a comprehensive review see Hotchkiss, 1998). To this end, the epidermis and pilosebaceous units are the most relevant and indeed are the major sources of such activity in the skin. On a body-weight basis, phase I metabolism in this organ usually is only a small fraction (»2 percent) of that in the liver, but its importance should not be underestimated. For example, when the epidermis of the neonatal rat is treated with benzo(a)pyrene or Aroclor 1254, the arylhydrocarbon hydroxylase (P450) activity in the skin can exceed 20 percent of that in the whole body (Mukhtar and Bickers, 1981). As illustrated in this example, cytochrome P4501A1 is inducible in the epidermis by agents that are inducers in other tissues—TCDD (tetrachlorodibenzo-p-dioxin), polycyclic aromatic hydrocarbons, PCBs (polychlorinated biphenyls), and crude coal tar, which is used in dermatologic therapy. Thus, exposure to such inducers could influence skin biotransformation and even sensitize epidermal cells to other agents that are not good inducers themselves, a phenomenon observable in cell culture (Walsh et al., 1995).

Biotransformation of a variety of compounds in the skin has been detected, including arachidonic acid derivatives, steroids, retinoids, and 2-amino-anthracene, suggesting that multiple P450 activities are expressed. Evidence has been presented for P4502A1 and 2B1 in rat skin, for example, using specific substrates, immunoblotting of the protein, and polymerase chain reaction techniques. These and other P450s are expressed in murine skin, and at least some of them are stimulated by glucocorticoids, commonly used therapeutic agents on human skin (Jugert et al., 1994). Novel cytochrome P450 isozymes 2B12 and 2B19, which use arachidonic acid as a substrate and thus likely participate in signaling pathways, have been detected in the epidermis and pilosebaceous units (Keeney et al., 1998). The TCDD-inducible isozyme P4501B1 has been reported in human keratinocytes and is expressed in a variety of other tissues as well (Sutter et al., 1994). Species differences are apparent in the amounts of P450 activities detectable. For example, measured ethoxycoumarin- O-deethylase activity is 20-fold higher in mouse than human (or rat) skin. Differences of such magnitude help rationalize the observation that the rate of penetration of ethoxycoumarin is sufficient to saturate its metabolism in some species (e.g., the human) but not in others (e.g., the mouse or guinea pig) (Storm et al., 1990).

Enzymes participating in phase II metabolism are expressed in skin. For example, multiple forms of epoxide hydrolase and UDP–glucuronosyl transferase have been detected in human and rodent skin. In general, this activity occurs at a much lower rate than observed in the liver, but exceptions are evident, as in the case of quinone reductase (Khan et al., 1987). Human and rodent skin exhibit qualitatively similar phase II reactions, but rodent skin often has a higher level of activity. An additional consideration is that species express different relative amounts of the various isozymes, which could alter resulting target specificities or degree of responsiveness. Glutathione transferase, for instance, catalyzes the reaction of glutathione with exogenous nucleophiles or provides intracellular transport of bound compounds in the absence of a reaction. It also facilitates the reaction of glutathione with endogenous products of arachidonate lipoxygenation (leukotrienes) to yield mediators of anaphylaxis and chemotaxis, which are elements of the inflammatory response in the skin. Of the three major transferase forms characterized in the liver, the major form in the skin of humans and rodents is the p isozyme. Human skin also expresses the a isozyme, while rat and mouse skin express the μ isozyme and, in much smaller amounts, the a isozyme (Raza et al., 1992).

A variety of other metabolic enzyme activites have also been detected in human epidermal cells, including sulfatases, b-glucuronidase, N-acetyl transferases, esterases, and reductases (Hotchkiss, 1998). The intercellular region of the stratum corneum has catabolic activities (e.g., proteases, lipases, glycosidases, phosphatase) supplied by the lamellar bodies along with their characteristic lipid (Elias, 1992). Such activities can have major effects on agents that penetrate the skin. For example, methyl salicylate readily diffuses through the epidermis and is detected in the dermis, but only as deesterified salicylate, illustrating first-pass metabolism (Cross et al., 1997). The influence of hydroxysteroid dehydrogenases and microsomal reductase activities during percutaneous absorption is evident in studies on mouse skin in organ culture. In one study (Kao and Hall, 1987), 8 h after topical application of testosterone, 59 percent of the permeated steroid was collected unchanged and the rest was transformed into metabolites. In parallel, estrone was converted substantially to estradiol (67 percent), while only 23 percent was collected as the parent compound. By contrast, estradiol was metabolized to a much lower extent (21 percent).

CONTACT DERMATITIS

Of all occupational skin disease, contact dermatitis accounts for over 90 percent of reported causes (American Academy of Dermatology, 1994; Beltrani, 1999). As the single most prevalent occupational skin disease, it is one of the most important occupational illnesses affecting American workers. It comprises two distinct inflammatory processes caused by adverse exposure of the skin, irritant and allergic contact dermatitis. These syndromes have indistinguishable clinical characteristics. Classically, erythema (redness), induration (thickening and firmness), scaling (flaking), and vesiculation (blistering) are present on areas directly contacting the chemical agent. Paraffin-embedded biopsies from affected sites reveal a mixed-cell inflammatory infiltrate of lymphocytes and eosinophils and the hallmark finding of spongiosis (intercellular edema). Unfortunately, these histopathologic features are not sufficient to differentiate allergic from irritant contact dermatitis, atopic dermatitis, or certain other common syndromes. Since their etiology is different, as supported by subtle but clear differences in the inflammatory responses, the two syndromes are presented separately here.

Irritant Dermatitis

Irritant dermatitis is a non-immune-related response caused by the direct action of an agent on the skin. Despite the "nonsensitization" pathways responsible for the genesis of irritant contact dermatitis, specific cytokines have been identified in the pathophysiology of the eruption (Corsini et al., 2000; Morhenn, 1999). Extrinsic variables such as concentration, pH, temperature, duration, repetitiveness of contact, and occlusion impact significantly on the appearance of the eruption. Suffice it to say that chemicals like strong acids, bases, solvents, and unstable or reactive chemicals rank high among the many possible human irritants.

Strongly noxious substances such as those with extreme pH can produce an immediate irreversible and potentially scarring dermatitis following a single exposure. This acute irritant phenomenon is akin to a chemical burn and has been described as an "etching" reaction (Bjornberg, 1987). More commonly, single exposures to potentially irritating chemicals will not produce significant reactions; repeated exposures are necessary to elicit clinically noticeable changes. Such repeated exposures eventually result in either an eczematous dermatitis with clinical and histopathologic changes characteristic of allergic contact dermatitis or a fissured, thickened eruption without a substantial inflammatory component. Chemicals inducing the latter two reactions are termed marginal irritants.

Because the thresholds for irritant reactions vary greatly from person to person, a genetic component to the response has been considered. Monozygotic twins have shown greater concordance than dizygotic twins in their reactions to irritant chemicals like sodium lauryl sulfate and benzalkonium chloride (Holst and Moller, 1975). While young individuals with fair complexion appear more sensitive to irritant chemicals than older individuals with dark complexion, sex does not appear to be a significant factor. Attempts to predict the relative irritancy of substances based upon their chemical relatedness to other irritants have been unsuccessful.

Divergent etiologies make it difficult to assign a specific mechanism for the pathophysiology of irritant dermatitis. Direct corrosives, protein solvents, oxidizing and reducing agents, and dehydrating agents act as irritants by disrupting the keratin ultrastructure or directly injuring critical cellular macromolecules or organelles. Marginal irritants require multifactorial variables to create disease and may not be capable of producing reactions under all circumstances. The varying time courses necessary to produce dermatitis by different known irritants result not merely from differing rates of percutaneous absorption but also depend on the specific agent selected. Thus, "chemicals do not produce skin irritation by a common inflammatory pathway" (Patrick et al., 1987). Supporting this view, tetradecanoylphorbol acetate

(the major active ingredient of croton oil, a potent irritant) induced a tenfold increase in prostaglandin E $_2$ (PGE$_2$) in cultured human keratinocytes, whereas another irritant, ethylphenyl propriolate, induced no change in PGE $_2$ (Bloom et al., 1987). Elevation of prostaglandins and leukotriene B4 in blister fluids correlated with the induction of erythema and the impairment of the epidermal barrier secondary to specific irritants such as benzalkonium chloride and sodium lauryl sulfate. This cytokine and eicosanoid profile was considered important for irritant dermatitis from surfactants but was not characteristic of other common skin irritants like triethanolamine and Tween 80 (Muller-Decker et al., 1998). Forsey demonstrated sodium lauryl sulfate induced keratinocyte proliferation after a 48-h exposure with no effect on Langerhans cell (LC) number or distribution, and keratinocyte apoptosis after 24- and 48-h exposure. Conversely, nonanoic acid decreased keratinocyte proliferation after a 24-h exposure and induced epidermal cell apoptosis after only a 6-h exposure. More significantly, LC number decreased after 24- and 48-h exposures, and induced apoptosis in over half of the LCs present after 24- and 48-h exposures (Forsey et al., 1998). The expression of soluble adhesion molecules, sICAM-1, sVCAM-1, and sE-selectin have been shown to be selectively expressed when comparing irritant contact dermatitis (CD) and the induction and elicitation phases of allergic CD. Allergic contact dermatitis produces a tripling of soluble adhesion molecule output compared to no change in the irritant CD variety (Ballmer-Weber et al., 1997).

No single testing method has been successful in determining the irritancy potential of specific chemicals. Several tests exploit various contributory factors necessary to elicit irritant contact dermatitis. These tests involve either a single or repeated application of the same material to the skin. As discussed below, the single-application patch test has been in use for over 100 years in the United States and is utilized for the determination of allergic-type reactions. The use of animals in the testing of potentially irritant chemicals is based on a variety of epicutaneous (epidermal surface) methods and has continued for decades. Generally, both intact and abraded skin of albino rabbits is tested with various materials under occluded patches. The patches are removed in 24 h and the tested areas of the skin are evaluated at this time and again in 1 to 3 days.

In the Repeat Insult Patch Test, used primarily in humans for the evaluation of potential allergic sensitization, chemicals are placed on the skin under occlusion for 3 to 4 weeks. The test materials are replaced every 2 to 3 days to maintain an adequate reservoir in the patch site. The test is functionally similar to the Cumulative Irritancy Test, where daily patches are applied under occlusion for 2 weeks in parallel with control substances. The Chamber Scarification Test modifies the aforementioned tests by abrading the skin to expose the upper dermis. All of these provocative tests rely on overt clinical changes such as erythema and induration at the site of challenge with a potential irritant. Re-cent work suggests that patch-test chamber size may influence the ability to assess test sites visually, and using a midsize chamber of 12 mm may provide optimal results (Nicholson et al., 1999).

Transepidermal water loss, which is not visually observable, can increase as an early response to irritation and be directly measured with an evaporometer. Hence, subtle changes can be documented even if overt clinical changes cannot be induced (Lammintausta et al., 1988).

Chemical Burns

Extremely corrosive and reactive chemicals may produce immediate coagulative necrosis that results in substantial tissue damage, with ulceration and sloughing. This is distinct from irritant dermatitis, since the lesion is the direct result of the chemical insult and does not rely heavily on secondary inflammation to manifest the cutaneous signs of injury. In addition to the direct effects of the chemical, necrotic tissue can act as a chemical reservoir resulting in either continued cutaneous damage or percutaneous absorption and systemic injury after exposure. Table 19-2 lists selected corrosive chemicals that are important clinically.

Table 19-2 Selected Chemicals Causing Skin Burns

Allergic Contact Dermatitis

Allergic contact dermatitis represents a delayed (type IV) hypersensitivity reaction (Landsteiner and Jacobs, 1935). Since this is a true allergy, only minute quantities of material are necessary to elicit overt reactions. This is distinct from irritant contact dermatitis, where the intensity of the reaction is proportional to the dose applied. An estimated 20 percent of all contact dermatitis is allergic in nature. Currently 3700 chemicals have been described as potential allergens (de Groot, 1994).

For allergic contact dermatitis to occur, one must first be sensitized to the potential allergen. Subsequent contact elicits the classic clinical and pathologic findings. Evidence dating back to the 1940s indicates that the ability to be sensitized to specific agents has a genetic component (Chase, 1941). Recent work has linked the presence of specific HLA alleles to allergy to nickel, chromium, and cobalt (Emtestam et al., 1993; Vollmer et al., 1999; Onder et al., 1995). Thus, to mount an immune reaction to a sensitizer, one must be genetically prepared to become sensitized, have a sufficient contact with a sensitizing chemical, and then have repeated contact later.

In general, low-molecular-weight chemicals (haptens) are responsible for causing allergic contact dermatitis. Most are less than 1000 Da and are electrophilic or hydrophilic. Some of these molecules are not inherently allergenic and must undergo metabolic transformation before participating in an allergic response (Andersen and Maibach, 1989). Since the skin has substantial metabolic capabilities, including many phase I and phase II enzymes, such biotransformation may occur in the skin at the site of contact with the chemical. Haptens, which are not intrinsically allergenic, must penetrate the stratum corneum and link to epidermal carrier proteins to form a complete allergen. The linkage between haptens and epidermal proteins is usually covalent, although metallic haptens may form stable noncovalent linkages with carrier proteins (Belsito, 1989). These binding proteins are probably cell surface molecules on the Langerhans cell (LC), most likely class II antigens encoded by genes of the HLA-DR locus (Weller et al., 1995).

For sensitization to occur, the hapten/carrier protein complex is incorporated into the cytoplasm of an LC by pinocytosis for intracellular processing. Following antigen presentation there are phenotypic changes in the LC including the up-regulation of class II molecules, lymphocyte function–associated antigen (LFA) 3 (CD58), and trafficking molecules including intercellular adhesion molecule-1 (ICAM-1). The LC then migrates to a regional lymph node to present the processed antigen to T-helper cells (CD4 cells). An LC bearing HLA-DR antigen and the hapten on its surface may present this package to a T-helper cell that also must bear an antigen-specific receptor (CD3-Ti) and the cell surface molecule CD4. These virgin T cells also bear the cell surface molecule CD45RA and are referred to as TH0 cells. Concurrent with the antigen presentation, the LC produces interleukins-1 and -12 (IL-1 and IL-12), which directly stimulate the T cell to produce interleukin-2 (IL-2) and interferon gamma. IL-12 probably promotes differentiation of TH0 to the classical allergic contact dermatitis effector cell bearing TH1/CD45RO on their surface (Dilulio et al, 1996). IL-2 activates and causes proliferation of T cells specifically sensitized to that antigen.

Circulating sensitized T cells will slow and egress the vascular compartment when passing activated endothelial cells. These vascular cells will present trafficking surface molecules such as selectins and ICAMS in areas where antigen has contacted the skin, facilitating this outlet. Concurrently keratinocytes themselves play an active role in the pathogenesis of allergic contact dermatitis. They are capable not only of producing a legion of cytokines—including IL-1, IL-2, IL-3, vascular permeability factor (VPF), and granulocyte-macrophage colony-stimulating factor (GM-CSF)—but also of expressing HLA-DR antigen under certain circumstances. The end result is the production of IL-2 and interferon gamma, which ultimately leads to an interplay of recruited lymphocytes and macrophages that creates the vascular and infiltrative changes classic for allergic contact dermatitis. This scheme admittedly simplifies a complex loop of events. Once induction of sensitization occurs, subsequent contact with the identical antigen initiates a similar cascade of events as the aforementioned sensitization process. At that point, however, specifically sensitized T cells are abundant and may present in the skin, so that the immune response occurs with great alacrity.

Contact dermatitis may occur upon exposure to any number of the thousands of allergens that people are potentially exposed to in the course of a day. Table 19-3 lists frequent allergens based on common exposure patterns, and Fig. 19-2 illustrates some potent sensitizers. Typical nonoccupational sources of exposure include the use of topical medications, personal hygiene products, rubber materials, textiles, surfactants, cosmetics, glues, pesticides, and plastics. Contact with esoteric allergens frequently occurs in the workplace. Table 19-4 lists the index of sensitivity for many common allergens in a group of 3974 individuals who were recently patch tested by the North American Contact Dermatitis Group. Such individuals are generally evaluated because they are already affected by contact dermatitis. Thus, the epidemiologic data generated, not based on blinded cross-sectional evaluations, may not be representative of the general population. Nevertheless, such data permit recognition of allergens with high sensitizing potential and strategies for their replacement by substances with low sensitizing potential.

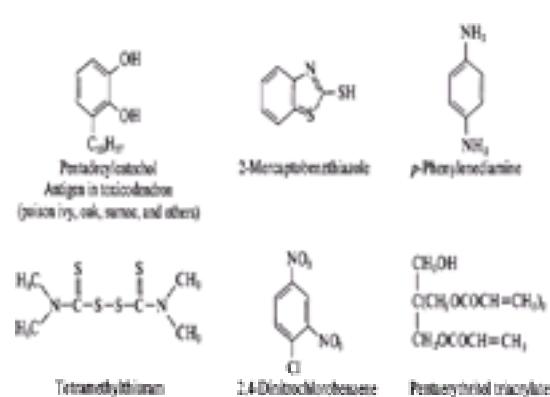
Table 19-3 Common Contact Allergens


Figure 19-2. Structural formulas of some potent contact sensitizers.

Table 19-4 Prevalence of Positive Reactions in Patch Test Patients

Inspection of the chemicals listed in Table 19-3 and Table 19-4 indicates that common causes of allergic contact dermatitis are ubiquitous in the materials that touch human skin regularly. There are, however, several allergens—like nickel, chromium, cobalt, and some food flavorings—that are also ingested with great frequency. In cases where an individual has a contact sensitivity to an agent that is systemically administered (orally), a generalized skin eruption with associated symptoms such as headache, malaise, and arthralgia may occur. Less dramatic eruptions may include flaring of a previous contact dermatitis to the same substance, vesicular hand eruptions, and an eczematous eruption in flexural areas. One unusual clinical presentation has been termed the "baboon syndrome," where a pink to dark-violet eruption occurs around the buttocks and genitalia. Systemic contact dermatitis may produce a delayed-type hypersensitivity reaction and/or deposition of immunoglobulins and complement components in the skin. Such deposits are potent inducers of a secondary inflammatory response and are responsible for the initial pathophysiology of many blistering and connective tissue diseases of the skin (Menne et al., 1994).

Cross-reactions between chemicals may occur if they share similar functional groups critical to the formation of complete allergens (hapten plus carrier protein). These reactions may cause difficulties in controlling contact dermatitis, since avoidance of known allergens and potentially cross-reacting substances are necessary for improvement. Table 19-5 lists common cross-reacting substances, and Fig. 19-3 illustrates three cross-reactors. Proper diagnosis can be hampered by concomitant sensitization to two different chemicals in the same product or simultaneous sensitization to two chemicals in different products.

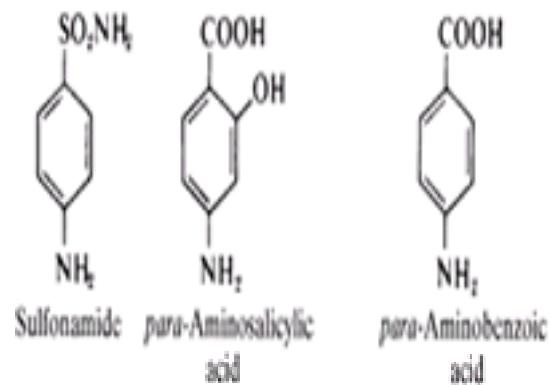
Table 19-5 Common Cross-Reacting Chemicals


Figure 19-3. Structural formulas of selected para-amino compounds that show cross-reactions in allergic contact sensitization.

Testing Methods

Predictive As with irritant dermatitis, animals have been used to determine the allergenicity of chemicals with the hope of correlating the data to humans. The Draize test is an intradermal test where induction of sensitization is accomplished by 10 intracutaneous injections of a specific test material. Subsequent challenges are performed by the same method and local reactions are graded by their clinical appearance. The Guinea Pig Maximization Test attempts to induce allergy by serial intradermal injections of an agent with the addition of Freund's complete adjuvant, an immune enhancer consisting of mycobacterial proteins. Subsequent challenge with the agent alone under an occluded chamber is graded clinically. Variations on this form of provocative testing have been done as well as performing many of them in human volunteers. It should be noted that Freund's adjuvant is not approved for use in humans; however, other techniques, such as use of higher induction concentrations, can be used to boost sensitization. For chemicals with higher allergenicity, epicutaneous skin testing can be performed, thus obviating the need for percutaneous (through the epidermis) sensitization. A variety of animal models have been described utilizing intact and abraded skin to induce sensitization and subsequent elicitation upon rechallenge. The Buehler test, Guinea Pig Maximization Test, and Epicutaneous Maximization Test utilize this form of testing and may occasionally add Freund's complete adjuvant to enhance sensitization (Guillot and Gonnet, 1985). The aforementioned tests have been used successfully to predict the allergenicity of strongly sensitizing substances in human beings. However, weaker allergens are often not discovered until they reach a large human population.

Diagnostic Determining the cause of a contact dermatitis requires a careful evaluation of possible chemical exposures, history of the illness, and distribution of lesions. This alone will only home in on groups or classes of allergens, but it will be insufficient to identify the specific offending chemical. Such evaluation is imperative, since without strict avoidance, the dermatitis will continue. Diagnostic patch testing has been utilized in the United States for almost 100 years. Since its introduction, little has changed in the procedure and its usefulness (Sulzberger, 1940). Standardized concentrations of material dissolved or suspended in petrolatum or water are placed on stainless steel chambers adhering to acrylic tape. Most testing material is commercially available, and the concentrations have been tested in a sufficiently large population to establish a nonirritancy threshold. Chambers are left in place for 48 h, and an initial reading is performed at the time the patches are removed. A subsequent reading 24 to 96 h later is also made, since delayed reactions commonly occur. Reactions are graded as positive if erythema (redness) and induration (skin thickening) occur at the test site. Strict adherence to established protocols are necessary to draw conclusions about the clinical relevance of the reactions (Cronin, 1980). Mere redness without infiltration of the site or the presence of an irritant morphology is not considered a significant reaction. Assigning relevance to a positive reaction is difficult in some situations, but it is vital, since many positive reactions may have a meaningless correlation to the dermatitis being tested. Relevance is determined through history of chemical contactants, distribution of the eruption, and provocative use tests. Use tests or open epicutaneous tests simulate everyday exposures better than other skin tests. Here a product containing a suspect allergen is applied to the same area of the skin for several days. Erythema with induration of the area denotes a positive test and contributes to the determination of relevance. Avoidance and substitution of the offending agent will lead to improvement in the majority of cases in a few weeks.

The adequate predictive and diagnostic abilities of all of the aforementioned tests rest on the use of a human or animal with an intact immune system. In vitro models such as the macrophage migration inhibition assay and the lymphocyte transformation/blastogenesis assay have been of some value for a few strong allergens like dinitrochlorobenzene (Kashima et al., 1993), but their use in predicting chemical allergenicity or their role as diagnostic tools is quite limited at this time.

PHOTOTOXICOLOGY

In the course of life, the skin is exposed to radiation that spans the electromagnetic spectrum, including ultraviolet, visible, and infrared radiation from the sun, artificial light sources, and heat sources. In general, the solar radiation reaching the earth that is most capable of inducing skin changes extends from 290 to 700 nm, the ultraviolet and visible spectra. Wavelengths on the extremes of this range are either significantly filtered by the earth's atmosphere or are insufficiently energetic to cause cutaneous pathology. Adequate doses of artificially produced radiation such as UV-C (<290 nm) or x-ray can produce profound physical and toxicologic skin changes. For any form of electromagnetic radiation to produce a biological change, it must first be absorbed. The absorption of light in deeper, more vital structures of the skin is dependent on a variety of optical parameters (chromophores, epidermal thickness, water content) that differ from region to region on the body. Melanin is a significant chromophore in the skin since it is capable of absorbing a broad range of radiation from UV-B (290 to 320 nm) through the visible spectrum. Other chromophores in the skin include amino acids and their breakdown products, such as tryptophan and urocanic acid, that are able to absorb light in the UV-B band. Biologically, the most significant chromophore is DNA, because the resultant damage from radiation will have lasting effects on the structure and function of the tissue.

Adverse Responses to Electromagnetic Radiation

After exposure, the skin manifests injury in a variety of ways, including both acute and chronic responses. The most evident acute feature of UV radiation exposure is erythema (redness or sunburn). The minimal erythema dose (MED), the smallest dose of UV light needed to induce an erythematous response, varies greatly from person to person. The vasodilation responsible for the color change is accompanied by significant alterations in inflammatory mediators such as prostaglandins D2, E2, and F2a, leukotriene B4, and prostacyclin I2 (Soter, 1993). Also, IL-1 activity is elevated within hours of exposure to UVB and may be responsible for several of the systemic symptoms associated with sunburn, such as fever, chills, and malaise. This cytokine may be released from local inflammatory cells as well as directly from injured keratinocytes. UV-B (290 to 320 nm) is the most effective solar band to cause erythema in human skin. Environmental conditions that affect UV-induced injury include duration of exposure, season, altitude, body site, skin pigmentation, and previous exposure. A substantially greater dosage of UV-A (320 to 400 nm) reaches the earth compared to UV-B (up to 100-fold); however, its efficiency in generating erythema in humans is about 1000-fold less than that of UV-B (Morrison, 1991). Overt pigment darkening is another typical response to UV exposure. This may be accomplished by enhanced melanin production by melanocytes or by photooxidation of melanin. Tanning or increased pigmentation usually occurs within 3 days of UV light exposure, while photooxidation is evident immediately. The tanning response is most readily produced by exposure in the UV-B band, although broader wavelengths of light are also capable of eliciting this response to a lesser degree. Immediate pigment darkening is characteristic of UV-A and visible light exposure. The tanning response serves to augment the protective effects of melanin in the skin; however, the immediate photooxidation darkening response does not confer improved photoprotection.

Commensurate with melanogenesis, UV radiation will provoke skin thickening primarily in the stratum corneum. For light-skinned individuals where melanin is not a major photoprotectant, or in situations where melanin is completely absent (i.e., albinism or vitiligo), this response lends significant defense against subsequent UV insult. Chronic exposure to radiation may induce a variety of characteristic skin changes. For UV light, these changes depend greatly on the baseline skin pigmentation of the individual as well as the duration and location of the exposure. Lighter-skinned people tend to suffer from chronic skin changes with greater frequency than darker individuals, and locations such as the head, neck, hands, and upper chest are more readily involved due to their routine exposures. Pigmentary changes—such as freckling and hypomelanotic areas, wrinkling, telangiectasias (fine superficial blood vessels), actinic keratoses (precancerous lesions), and malignant skin lesions such as basal and squamous cell carcinomas and malignant melanomas—are all consequences of chronic exposure to UV light. One significant pathophysiologic response of chronic exposure to UV light is the pronounced decrease of epidermal Langerhans cells (LCs). Chronically sun-exposed skin may have up to 50 percent fewer LCs compared to photoprotected areas. This decrease may result in lessened immune surveillance of neoantigens on malignant cells and thus allow such transformation to proceed unabated. Exposures to ionizing radiation may produce a different spectrum of disease, depending upon the dose delivered. Large acute exposures will result in local redness, blistering, swelling, ulceration, and pain. After a latent period or following subacute chronic exposures, characteristic changes such as epidermal thinning, freckling, telangiectasias, and nonhealing ulcerations may occur. Also, a variety of skin malignancies have been described years after the skin's exposure to radiation.

Aside from the toxic nature of electromagnetic radiation, natural and environmental exposures to certain bands of light are vital for survival. Ultraviolet radiation is critical for the conversion of 7-dehydrocholesterol to previtamin D3, without which normal endogenous production of vitamin D would not take place. Blue light in the 420- to 490-nm range can be lifesaving due to its capacity to photoisomerize bilirubin (a red blood cell breakdown product) in the skin. Infants with elevated serum bilirubin have difficulty clearing this by-product because of its low water solubility. Its presence in high serum concentrations can be neurotoxic. The photoisomerization by blue light renders bilirubin more water-soluble; hence, excretion in the urine is markedly augmented. In addition, the toxic effects of UV light have been exploited for decades through artificial light sources for treatment of hyperproliferative skin disorders like psoriasis.

Photosensitivity

An abnormal sensitivity to UV and visible light, photosensitivity may result from endogenous or exogenous factors. Illustrating the former, a variety of genetic diseases impair the cell's ability to repair UV light–induced damage. The autoimmune disease lupus erythematosus also features abnormal sensitivity to UV light. In hereditary or chemically induced porphyrias, enzyme abnormalities disrupt the biosynthetic pathways producing heme—the prosthetic building block for hemoglobin, myoglobin, catalases, peroxidases, and cytochromes—leading to accumulation of porphyrin precursors or derivatives throughout the body, including the skin. These compounds in general fluoresce when exposed to light of 400 to 410 nm (Soret band), and in this excited state interact with cellular macromolecules or with molecular oxygen to generate toxic free radicals (Lim and Sassa, 1993). Chlorinated aromatic hydrocarbons such as hexachlorobenzene and TCDD are known to induce this syndrome (Goldstein et al., 1977).

Phototoxicity Phototoxic reactions from exogenous chemicals may be produced by systemic or topical administration or exposure. In acute reactions, the skin may appear red and blister within minutes to hours after ultraviolet light exposure and resemble a bad sunburn. Chronic phototoxic responses may result in hyperpigmention and thickening of the affected areas. UV-A (320 to 400 nm) is most commonly responsible; however, UV-B may occasionally be involved (Johnson and Ferguson, 1990).

Agents most often associated with phototoxic reactions are listed in Table 19-6. These chemicals readily absorb UV light and assume a higher-energy excited state, as described for porphyrins. The oxygen-dependent photodynamic reaction is the most common as these excited molecules return to the ground state. Here, excited triplet-state molecules transfer their energy to oxygen, forming singlet oxygen, or become reduced and form other highly reactive free radicals. These reactive products are capable of damaging cellular components and macromolecules and causing cell death. The resulting damage elaborates a variety of immune mediators from keratinocytes and local white blood cells that recruit more inflammatory cells to the skin and thus yield the clinical signs of phototoxicity.

    Acridine orange
Porphyrin derivatives
    Hematoporphyrin

Table 19-6 Selected Phototoxic Chemicals

Nonphotodynamic mechanisms have been described in the pathogenesis of phototoxicity, with psoralens being prime examples. Upon entering the cell, psoralens intercalate with DNA in a non-photo-dependent interaction. Subsequent excitation with UV-A provokes a photochemical reaction that ultimately results in a covalently linked cycloadduct between the psoralen and pyrimidine bases. This substantially inhibits DNA synthesis and repair, resulting in clinical phototoxic reactions (Laskin, 1994). Psoralens may be found in sufficiently high concentrations in plants (e.g., limes and celery) that contact with their fruit and leaves in the presence of sunlight can cause a significant blistering eruption called phytophotodermatitis. Psoralen-induced phototoxicity may be harnessed and controlled pharmacologically. Topically and orally administered psoralens are used therapeutically to enhance the effects of controlled delivery of UV-A. PUVA (psoralens plus UV-A) is administered to control keratinocyte and lymphocyte hyperproliferative diseases such as psoriasis, eczema, and cutaneous T-cell lymphomas.

The photosensitive nature of porphyrins can also be tempered and utilized therapeutically. Some extraneously administered porphyrins can selectively accumulate in specific target tissues such as neoplasms. Subsequent administration of light of 600- to 700 nm wavelength (absorption spectra of currently available sensitizers) results in the formation of oxygen singlets and cell death (Regula et al., 1994).

Photoallergy In contrast to phototoxicity, photoallergy represents a true type IV delayed hypersensitivity reaction. Hence, while phototoxic reactions can occur with the first exposure to the offending chemical, photoallergy requires prior sensitization. Induction and subsequent elicitation of reactions may result from topical or systemic exposure to the agent. If topical, the reactions are termed *photocontact dermatitis,* while systemic exposures are termed *systemic photoallergy.* In most situations, systemic photoallergy is the result of the administration of medications. Photocontact dermatitis was described over 50 years ago following the use of topical antibacterial agents. Thousands of cases were reported in the 1960s after halogenated salicylanilides were used in soaps as antibacterial additives. Tetrachlorosalicylanilide and tribromosalicylamide were quickly withdrawn from the market after numerous reports of photoallergy surfaced (Cronin, 1980). Generally, the mechanisms of photocontact dermatitis and even that of systemic photoallergy are the same as that described above for allergic contact dermatitis. In this context, however, UV light is necessary to convert a potential photosensitizing chemical into a hapten that elicits an allergic response.

Testing for photoallergy is similar to patch testing for allergic contact dermatitis. Duplicate allergens are placed on the back under occlusion with stainless steel chambers. Approximately 24 h later, one set of patches is removed and irradiated with UV-A. All patches are removed and clinical assessments of patch-test sites are made 48 h and 4 to 7 days following placement. A reaction to an allergen solely on the irradiated side is termed photocontact dermatitis. Reactions occurring simultaneously on the irradiated and nonirradiated sides are consistent with an allergic contact dermatitis. There is disagreement about the presence of coexisting allergic contact and photocontact dermatitis to the same agent since a photopatch test may occasionally exhibit greater reactivity on the irradiated side compared to the nonirradiated side. Table 19-7 lists potential photoallergens used in photo patch testing at New York University Medical Center.

Table 19-7 Photoallergen Series for Photo Patch Testing

ACNE

"Acne is the pleomorphic disease par excellence. Its expressions are multifarious and eloquent" (Plewig and Kligman, 1993). Despite the multifactorial etiology of acne, the influence of sebum, hormones, bacteria, genetics, and environmental factors is well known. In many situations, one of these factors has an overwhelmingly greater influence in the genesis of lesions than the others. Among the literally dozens of different kinds of acne that have been described over the decades, this section concentrates on acne venenata (in Latin, *venenum* means "poison").

Chemicals able to induce lesions of acne are termed *comedogenic.* The clinical hallmark of acne is the comedone, which may be open or closed (blackhead or whitehead, respectively, in the vernacular). Additionally papules, pustules, cysts, and scars may complicate the process. Hair follicles and associated sebaceous glands become clogged with compacted keratinocytes that are bathed in sebum. The pigmentary change most evident in open comedones is from melanin (Plewig and Kligman, 1993). Most commonly, lesions are present on the face, back, and chest, but for acne venenata the location of the lesions may be characteristic, based on the route of topical or systemic exposure.

Oil acne is caused by a variety of petroleum, coal tar, and cutting-oil products. In animal models the application of comedogenic oil will result in biochemical and physiologic alteration in the hair follicle and cell structure leading to the development of comedones. In practical situations, the skin is contaminated with oil that is permitted to remain long enough for adequate penetration into the hair follicle resulting in acneiform alterations.

Chloracne

Chloracne, one of the most disfiguring forms of acne in humans, is caused by exposure to halogenated aromatic hydrocarbons. Table 19-8 lists several chloracnegens, and Fig. 19-4 illustrates some structures. Chloracne is a relatively rare disease; however, its recalcitrant nature and preventability make it an important occupational and environmental illness. Typically, comedones and straw-colored cysts are present behind the ears, around the eyes, and on the shoulders, back, and genitalia. In addition to acne, hypertrichosis (increased hair in atypical locations), hyperpigmentation, brown discoloration of the nail, conjunctivitis, and eye discharge may be present. Since chloracnegens commonly affect many organ systems, concurrent illness in the liver and nervous system may accompany the integumentary findings (U.S. Department of Health and Human Services, 1993). Histologically, chloracne is distinct from other forms of acne with progressive degeneration of sebaceous units, transition of sebaceous gland cells to keratinizing cells, and prominent hyperkeratosis in the follicular canal (Moses and Prioleau, 1985).

Polyhalogenated dibenzofurans

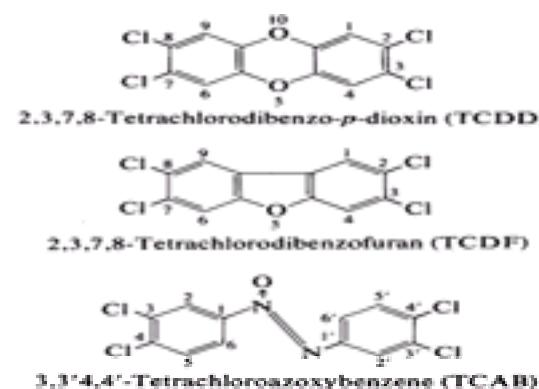
3,3′4,4′-Tetrachloroazoxybenzene (TCAB)


Figure 19-4. Structural formulas of certain potent chloracnegens.

The effects of chloracnegens on humans have become well recognized over the past four decades through a series of industrial disasters. In 1953 a chemical plant in Ludwigshafen exploded, discharging 2,4,5 trichlorophenol; in 1976 in Seveso, Italy, a reactor explosion liberated tetrachlorodibenzo- *p*-dioxin (TCDD); in 1968 and 1979 in Japan and Taiwan, respectively, rice cooking oil was contaminated with polychlorinated biphenyls (PCBs), polychlorinated dibenzofurans (PCDFs), and polychlorinated quaterphenyls; and in 1973 in Michigan, cattle were inadvertently fed a hexabrominated biphenyl flame retardant. These incidents represent only a few of the dozens relating to human poisonings (Wolff et al., 1982). Chloracne was noted soon after exposure and has remained manifest even decades after exposure ceased (Urabe and Asahi, 1985). While reports from such events have indicated that these halogenated hydrocarbons may affect a variety of organs—such as the gastrointestinal, central nervous, reproductive, immune, and cardiovascular systems—epidemiologic studies have failed reproducibly to demonstrate organ-specific illness. Similarly, evidence pointing to human carcinogenicity of the multitude of PCB and TCDD species is also inconclusive. In contrast, chloracne has been an extremely reliable indicator of PCB and TCDD exposure in the large populations that have been studied (Caputo et al., 1988; James et al., 1993). Several incidents of accidental exposure to PCBs probably included other polyhalogenated species, since PCDFs and dioxins may be formed during the combustion of PCBs in fires and explosions.

Chlorinated dioxins and PCBs have significant and reproducible effects on cellular function. TCDD is one of the most potent known inducers of certain cytochrome P450 isozymes (arylhydrocarbon hydroxylase) by virtue of its high affinity for the Ah receptor controlling their expression. Some studies have suggested a more frequent association of chloracne with the more highly chlorinated congeners of PCBs than with the less chlorinated ones. Most levels of chlorination, however, have been associated with this skin problem to some degree. Given the high lipid solubility of these chemicals and their recalcitrance to metabolic clearance, their half-life in humans is quite long. Highly chlorinated PCBs can have a serum half-life of 15 years and less chlorinated PCBs of 5 to 9 years (Wolff et al., 1992). Serum concentrations of PCBs in patients with chloracne are elevated, but the degree of elevation cannot be correlated directly with disease activity.

PIGMENTARY DISTURBANCES

Several factors influence the appearance of pigmentation on the skin. Melanin is produced through a series of enzymatic pathways beginning with tyrosine. Errors in this pathway from genetically deranged enzymes (i.e., albinism) or through tyrosine analogs result in abnormal pigmentation (Fig. 19-5). Other factors—such as the thickness of the epidermis and regional blood flow—impact greatly on the appearance of skin color. Hyperpigmentation results from increased melanin production or deposition of endogenous or exogenous pigment in the upper dermis. Endogenous materials are usually melanin and hemosiderin (breakdown product of hemoglobin), while exogenous hyperpigmentation can arise from deposition of metals and drugs in dermal tissue. Conversely, hypopigmentation is a loss of pigmentation from either melanin loss, melanocyte damage, or vascular abnormalities. Leukoderma and depigmentation denote complete loss of melanin from the skin, imparting a porcelain-white appearance. Many drugs and chemicals are capable of interfering with the normal formation and clearance of pigments as well as being directly toxic to melanocytes. The phenols and catechols are particularly potent melanocidal chemicals and can produce disfiguring depigmented regions. Table

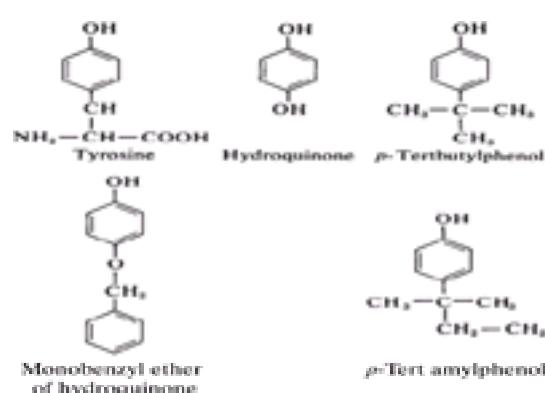
lists common chemicals capable of causing alterations in pigmentation.


Figure 19-5. Chemical structure of tyrosine and of selected hypopigmenting and depigmenting agents.

Table 19-9 Selected Causes of Cutaneous Pigmentary Disturbances

GRANULOMATOUS DISEASE

A variety of dermatologic illnesses produce the histopathologic findings of granulomatous inflammation. In general, a granuloma is an immune mechanism to "wall off" an adverse injury. It is seen in the skin in infectious diseases (i.e. leprosy, tuberculosis), foreign-body reactions, and idiopathic illnesses. Foreign-body reactions may be secondary to a primary irritant phenomenon such as traumatic introduction of talc, silica, or wood into the dermis. More rarely, sensitization may drive a granulomatous reaction, as is the case for beryllium, zirconium, cobalt, mercury, and chromium, sometimes occurring in response to tattoo dyes. The pathophysiology of these granulomatous reactions is not dissimilar to those occurring in other organ systems like berylliosis in the lung (Lever and Schaumburg-Lever, 1990).

URTICARIA

Urticaria (hives) represents an immediate type I hypersensitivity reaction primarily driven by histamine and vasoactive peptide release from mast cells. The mechanism of release may be immune-mediated through IgE allergen binding or by nonimmune mechanisms. Potential nonimmune releasers of histamine from mast cells include curare, aspirin, azo dyes, benzoates, and toxins from plants and animals. The majority of generalized or nonspecific urticarial responses occur either from systemically ingested substances to which the person has a specific allergy or from completely idiopathic mechanisms. Localized urticaria may be elicited by certain substances in the area of epicutaneous contact and is referred to as *contact urticaria.* Some reported causes are described in Table 19-10. Often patients experiencing this phenomenon may describe itching or stinging at the contact site, with clinical manifestations ranging from minimal redness to frank edematous urticarial plaques.

Table 19-10 Selected Substances Reported to Elicit Contact Urticaria

A syndrome of contact urticaria, rhinitis, conjunctivitis, asthma, and rarely anaphylaxis and death has been associated with latex proteins found in rubber. This observation became apparent shortly after the emergence and recognition of the human immuno- deficiency virus (HIV) and the escalating incidence of hepatitis. Universal precautions, a systematic process of personal protection, charged health care personnel to handle all blood and body fluids as if they were infected with a serious transmissible agent. As a result, the use of protective gloves made of latex and, more recently, synthetic materials became widespread. This resulted in a tremendous increase in the number of gloves being used by over 5 million health care workers (Centers for Disease Control, 1987). For workers with occupational exposures to rubber, the newly recognized syndrome proved useful in providing an etiology for their symptoms (Cohen, 1998).

The allergens in natural latex rubber are incompletely characterized water-soluble proteins that perform a variety of cellular functions in the living tree (Table 19-11). These protein are capable of inducing type I allergic responses in sensitized individuals. Contact with rubber products like gloves can cause hives solely in the area of contact with the skin; however, more allergic individuals may experience generalized hiving, asthma, anaphylaxis, and death. This syndrome is distinct from allergic contact dermatitis to rubber components like accelerators and antioxidants, which cause delayed-type hypersensitivity/contact dermatitis. Risk factors have been elucidated in epidemiologic studies and are enumerated in Table 19-12.

ALLERGEN	WEIGHT	SOURCE
Hev b1	14 kDa	Rubber elongation factor
Hev b2	35 kDa	Beta-glucanase
Hev b3	23 kDa	Rubber particle protein
Hev b4	50–57 kDa	Microhelix
Hev b5	≤60 kDa	Homology with some fruit
Hev b6	21 kDa	Prohevein
Hev b7	46 kDa	Patatin
Hev b8	?	Profilin

Table 19-12 Risk Factors for Latex Allergy

Powders used to assist in glove donning can bind latex protein allergens and jettison them when gloves are removed. Subsequently inhaled (mucosal exposure) latex protein can trigger more severe allergic reactions than typical epicutaneous ones. Diagnosis is accomplished through determination of antilatex immunoglobulin E via serum RAST test or through clinical challenge with glove materials.

TOXIC EPIDERMAL NECROLYSIS

Toxic epidermal necrolysis (TEN) represents one of the most immediately life-threatening dermatologic diseases and is most often caused by drugs and chemicals. It is characterized by full-thickness necrosis of the epidermis accompanied by widespread detachment of this necrotic material. After the epidermis has sloughed, only dermis remains, thus severely compromising heat, fluid, and electrolyte homeostasis. Though controversy exists as to their relationship, TEN and severe erythema multiforme (Stevens-Johnson syndrome), another serious reaction to drugs and infections, are often considered part of the same spectrum of disease (Roujeau and Revuz, 1994). The etiology of TEN has remained elusive, with immunologic and metabolic mechanisms popularly entertained. A study evaluating TEN induced by carbamazepine (an anticonvulsive drug) revealed reduced lymphocyte capacity to metabolize cytotoxic carbamazepine intermediates. Lymphocyte toxicity was not demonstrated to native carbamazepine but was shown to carbamazepine metabolized by liver microsomes. Abnormalities in epoxide hydrolase and glutathione transferase may be responsible for the metabolism of the purported toxin, which may be an arene oxide. The inflammatory reaction of CD8 lymphocytes in TEN has suggested that a cytotoxic immune mediated reaction is induced by the abnormal presence of this drug intermediate (Friedmann et al., 1994). Recent work has demonstrated a role of nitric oxide metabolites as mediators of epidermal necrosis in TEN, again suggesting a metabolic pathogenesis over a strictly immunologic one (Lerner et al., 2000).

CARCINOGENESIS

Radiation

Skin cancer is the most common neoplasm in humans, accounting for nearly one-third of all cancers diagnosed each year. At present the major cause of skin cancer (half a million new cases per year in the United States) is sunlight, which damages epidermal-cell DNA. UV-B (290 to 320 nm) induces pyrimidine dimers, thereby eliciting mutations in critical genes (reviewed in Grossman and Leffell, 1997). The $p53$ tumor suppressor gene is a major target in which damage occurs early and is detectable in nearly all resulting squamous cell carcinomas. Because the $p53$ protein arrests cell cycling until DNA damage is repaired and may induce apoptosis, its loss destabilizes the genome of initiated cells and gives them a growth advantage. UV light also has immunosuppressive effects that may help skin tumors survive. Skin cancer incidence is highest in the tropics and in pale-complexioned whites, particularly at sites on the head and neck that receive the most intense exposure. Individuals with xeroderma pigmentosum, who are deficient in repair of pyrimidine dimers, must scrupulously avoid sun exposure to prevent the occurrence of premalignant lesions that progress with continued exposure. Even when it does not cause cancer in normal individuals, sun exposure leads to premature aging of the skin. For this reason, sunbathing is discouraged and the use of sun-block lotions is encouraged, especially those that remove wavelengths up to 400 nm. In a mouse model, sun-block preparations have been shown capable of preventing $p53$ mutations and development of UV light–induced skin carcinomas (Ananthaswamy et al., 1999).

In the recent past, ionizing radiation was an important source of skin cancer. With the discovery of radioactive elements at the turn of the century came the observation that x-rays can cause severe burns and squamous cell carcinomas of the skin. By the 1920s, basal cell carcinomas were also noted. For several decades thereafter, ionizing radiation was used to treat a variety of skin ailments (acne, atopic dermatitis, psoriasis, and ringworm) and for hair removal. The levels of exposure led to an increased risk of skin cancer and sometimes produced atrophy of the dermis (radiodermatitis) from the death or premature aging of fibroblasts that secrete elastic supporting fibrous proteins.

Polycyclic Aromatic Hydrocarbons

A landmark epidemiologic investigation by Percival Pott in 1775 connected soot with the scrotal cancer prevalent among chimney sweeps in England. Since that time, substances rich in polycyclic aromatic hydrocarbons (coal tar, creosote, pitch, and soot) have become recognized as skin carcinogens in humans and animals. The polycyclic aromatic compounds alone are relatively inert chemically, but they tend to accumulate in membranes and thus perturb cell function if they are not removed. They are hydroxylated by a number of cytochrome P450 isozymes, primarily 1A1 and 1B1 in epidermal cells, and conjugated for disposal from the body. Oxidative biotransformation, however, produces electrophilic epoxides that can form DNA adducts. Phenols, produced by rearrangement of the epoxides, can be oxidized further to quinones, yielding active oxygen species, and they are also toxic electrophiles. Occupations at risk of skin cancer from exposure to these compounds (e.g., roofing) often involve considerable sun exposure, an additional risk factor. The combination of coal tar and UV light is useful in treating severe psoriasis, since the toxicity reduces the excessive turnover rate of keratinocytes that characterizies this disease. Repeated treatments are necessary, however, and they carry with them an elevated risk of skin cancer. Using longer-wave UV-A with phototoxic psoralen derivatives in place of coal tar in such protocols is much less messy and avoids UV-B but produces DNA adducts and an elevation of skin cancer risk as well.

Arsenic

An abundant element in the earth's crust, arsenic is encountered routinely in small doses in the air, water, and food. High exposures from smelting operations and from well water derived from rock strata with a high arsenic content are associated with arsenical keratoses (premalignant lesions), blackfoot disease (a circulatory disorder reflecting endothelial cell damage), and squamous cell carcinoma of the skin and several other organs (bladder, lung, liver). In earlier times, high exposures occurred from the medication Fowler's solution (potassium arsenite) and from certain pesticides. Arsenite (+3 oxidation state) avidly binds vicinal thiols and is thought

to inhibit DNA repair, while arsenate (+5 oxidation state) can replace phosphate in macromolecules such as DNA, but the resulting esters are unstable. By such means, both forms give chromosomal breaks and gene amplification (Lee et al., 1988), a plausible basis for their ability to cause transformation of cultured cells and to assist tumor development. Arsenic has also been found to alter DNA methylation (Goering et al., 1999), suppress keratinocyte differentiation markers (Kachinskas et al., 1997), and enhance growth factor secretion in the epidermis (Germolec et al., 1998).

The mechanism of arsenic carcinogenicity remains an enigma, and regulation of human exposure presents challenges from difficulties in estimating carcinogenic risk (reviewed in Goering et al., 1999). Much of the data on carcinogenicity of arsenic to skin comes from populations exposed at high levels for decades in Taiwan. Similarly high exposures have been occurring recently in Bangladesh and India, where skin lesions are now in evidence. Although high exposure levels in drinking water are effective in causing cancer, considerable uncertainty exists regarding the shape of the dose–response curve, an important issue in view of the estimated 100,000 Americans whose water supplies contain arsenic near the 50 ppb standard for drinking water in the United States. This value, set in 1942 and currently under review, has been proposed to entail substantial lifetime risk of skin and other cancer. However, suggestions have been made that the carcinogenic response at lower doses may not be approximated well by linear extrapolation from the known response to high dose levels. Indeed, low doses may be less dangerous than expected and a threshold could even exist. Methylation has been considered the most likely detoxification method, since the observed mono- and dimethyl arsenate isolated in urine from exposed humans and animals are indeed much less toxic. Wide species differences in methylation capability, however, have raised the possibility other detoxification pathways exist. In the absence of a normal animal model showing carcinogenic effects, pharmacokinetic and mechanistic studies are directed to reducing the uncertainty of such speculations.

Mouse Skin Tumor Promotion

Through the work of numerous investigators over the past 50 years, mouse skin has been developed as an important target for carcinogenicity testing. The observed incidence of squamous cell carcinomas has been helpful in providing a biological basis for conclusions from epidemiologic studies. For instance, mouse skin carcinogenicity of tobacco smoke condensate and constituents (Wynder and Hoffman, 1967) strongly supported the conclusion that tobacco smoke is carcinogenic in humans (Report of the Surgeon General, 1979). Carcinogenicity in mouse skin is taken as evidence of a more general carcinogenic risk for humans. Much has been learned about the pathogenesis of squamous cell carcinomas in mouse skin that does have general applicability to human squamous cell carcinomas of the skin and other anatomic sites (Yuspa, 1998).

A complete carcinogen induces tumors by itself at high doses but not at sufficiently low doses. One explanation for the commonly observed nonlinear response is that a large dose does more than initiate carcinogenesis by damaging the DNA in cells. It is also toxic, killing some cells and thereby stimulating a regenerative response in the surviving basal cells. Tumor promoters are agents that do not cause cancer themselves but induce tumor development in skin that has been initiated by a low dose of a carcinogen. Their promoting power is generally parallel to their ability to give sustained hyperplasia of the epidermis with continued treatment. Selective stimulation of tumor growth is envisioned to occur from differential stimulation of initiated cells or due to the insensitivity of initiated cells to toxicity or to terminal differentiation induced by the promoter (DiGiovanni, 1992).

An advantage of the experimental model of mouse skin carcinogenesis is the ability to separate the neoplastic process into stages of initiation, promotion, and progression. With this model, the skin is treated once with a low dose of an initiator—a polycyclic aromatic hydrocarbon, for example. The skin does not develop tumors unless it is subsequently treated with a promoter, which must be applied numerous times at frequent intervals (e.g., twice a week for 3 months). Application of the promoter need not start immediately after initiation; but if it is not continued long enough or if it is applied before or without the initiator, tumors do not develop. A consequence of promotion then is a tendency to linearize the dose–response curve for the initiator. Although an important aspect of promotion is its epigenetic nature, papillomas are characteristically aneuploid. Mutations in the *c-Ha-ras* gene are commonly found in papillomas, particularly those initiated by polycyclic aromatic hydrocarbons. Eventually some of the resulting papillomas become autonomous, continuing to grow without the further addition of the promoter. Genetic damage accumulates in the small fraction of tumors that progress to malignancy.

A number of natural products are tumor promoters, many of which alter phosphorylation pathways. The best-studied example, and one of the most potent, is the active ingredient of croton oil, 12-*O*-tetradecanoylphorbol-13-acetate. This is a member of a diverse group of compounds that give transitory stimulation followed by chronic depletion of protein kinase C in mouse epidermis (Fournier and Murray, 1987). Another group of agents, an example of which is okadaic acid, consists of phosphatase inhibitors. Compounds acting by other routes are known, including thapsigargin (calcium channel modulator) and benzoyl peroxide (free radical generator). Sensitivity to tumor promotion is an important factor in the relative sensitivity to skin carcinogenesis among different mouse strains and even among other laboratory animal species. To cite an intriguing example, TCDD is 100-fold more potent than tetradecanoylphorbol acetate in certain hairless mouse strains but virtually inactive in nonhairless strains (Poland et al., 1982). By elucidating the genetic basis for this difference, we may improve our understanding of TCDD's activity as a promoter.

The desire to reduce the cost and improve the effectiveness of cancer testing in animals has led to development of transgenic mice with useful properties (Spalding et al., 2000). The Tg.AC strain, for example, exhibits a genetically initiated epidermis. Integrated in this mouse genome is a *v-Ha-ras* oncogene driven by part of the z-globin promoter, which in this context fortuitously drives expression only in epidermis that is wounded or treated with tumor promoters (Leder et al., 1990). The mice display enhanced skin sensitivity to a number of genotoxic and nongenotoxic carcinogens and have low backgrounds of spontaneous tumors over a 26-week treatment period. Tg.AC mice can be employed for testing in combination with a different strain that has one of its *p53* alleles inactivated and thus has enhanced sensitivity to genotoxic carcinogens in other tissues in addition to the skin. These genetically modified mice promise to speed up testing using fewer animals and to reduce false-positive results arising from strain or species-specific idiosyncrasies. Trials to validate use of these modified strains are well under way (Spalding et al., 2000).

TOXIC RESPONSES OF THE REPRODUCTIVE SYSTEM

Michael J. Thomas and John A. Thomas

INTRODUCTION

History

The endocrine function of the gonads is primarily concerned with perpetuation of the species. The survival of any species depends on the integrity of its reproductive system. Sexual reproduction involves a very complex process for the gonads. Genes located in the chromosomes of the germ cells transmit genetic information and modulate cell differentiation and organogenesis. Germ cells ensure the maintenance of structure and function in the organism in its own lifetime and from generation to generation.

The twentieth century has undergone an industrial renaissance; through scientific and technical advances, there has been a significant extension in life expectancy and generally an enhanced quality of life. Concomitantly with this industrial renaissance, an estimated 50,000 to 60,000 chemicals have come into common use. Approximately 600 or more new chemicals enter commerce each year. The production of synthetic organic chemicals has risen from less than 1 billion lb in 1920 to over 20 billion lb in 1945, to 75 billion lb in 1960, and to over 200 billion lb in the late 1980s (cf. Lave and Ennever, 1990). Several endocrine disorders are associated with industrial chemicals (cf. Barsano and Thomas, 1992). Overall, occupational diseases in the United States may be responsible for about 60,000 deaths per year (Baker and Landrigan, 1991). The impact of new chemicals (or drugs) on the reproductive system was tragically accentuated by the thalidomide disaster in the 1960s (cf. Fabrio, 1985). This episode led to increased awareness on a worldwide basis and brought forth laws and guidelines pertaining to reproductive system safety and testing protocols. This new awareness of reproductive hazards in the workplace has led to corporate policies and legal considerations (Bond, 1986; McElveen, 1986). In 1985, the American Medical Association (AMA) Council on Scientific Affairs of charged its Advisory Panel on Reproductive Hazards in the Work Place to consider over 100 chemicals with the intent of estimating their imminent hazards (AMA Council on Scientific Affairs, 1985).

Endocrine Disruptors

Large numbers and large quantities of endocrine-disrupting chemicals (e.g., *o,p*-DDT) have been released into the environment since World War II (cf. Colborn, et al., 1993). Exposure to endocrine-disrupting chemicals has been linked with abnormal thyroid function in birds and fish; diminished fertility in birds, fish, shellfish, and mammals; and demasculinization and feminization in fish, gastropods, and birds (Vos et al., 2000). The significance of endocrine-disrupting chemicals, also known as environmental estrogens or xenoestrogens, is unknown at this time. In general, the mechanism(s) of endocrine disruption caused by non-heavy metal agents is due to competition for receptors or inhibition of steroidogenesis.

Concern for reproductive hazards is not new; it dates back to the Roman Empire. Lead, found in high concentration in pottery and water vessels, probably played a role in the increased incidence of stillbirths. Lead is now known to be an abortifacient as well as capable of producing teratospermias. In the United States, male factory workers occupationally exposed to 1,2-dibromo-3-chloropropane (DBCP) became sterile, as evidenced by oligo-spermia, azoospermia, and germinal cell aplasia. Factory workers in battery plants in Bulgaria, lead mine workers in the U.S. state of Missouri, and workers in Sweden who handle organic solvents (toluene, benzene, and xylene) suffer from low sperm counts, abnormal sperm, and varying degrees of infertility. Diethylstilbestrol (DES), lead, chlordecone, methyl mercury, and many cancer chemotherapeutic agents have been shown to be toxic to the male and female reproductive systems and possibly capable of inflicting genetic damage to germ cells (cf. Barlow and Sullivan, 1982; Office of Technology Assessment Report, 1985).

In the past few years, there has been an ongoing debate about a decline in human sperm counts (Carlsen et al., 1992). Carlsen and coworkers (1992) reported that there has been a decline in semen quality over the past 50 years. Additionally, they reported an increased incidence in genitourinary abnormalities, including testicular cancer, cryptorchidism, and hypospadias. The outcome of these studies has been challenged by several groups of investigators (Bromwich et al., 1994; Lipshultz, 1996; Thomas, 1998). The original evidence using meta-analysis failed to support the hypothesis that sperm counts declined significantly between 1940 and 1990 (Bromwich et al., 1994). Sharpe and Skakkeback (1993) have hypothesized that the increasing incidence of reproductive abnormalities in the human male may be related to increased estrogen exposure in utero. Their hypothesis includes an increas-ed exposure to DES and the possible presence of environmental estrogen mimics (e.g., DDT). A number of natural and anthropogenic substances exhibit weak estrogen properties (Muller et al., 1995; Cooper and Kavlock, 1997). There are many naturally occurring phytoestrogens (e.g., coumestans and isoflavonoids) that possess weak estrogen-binding properties (Thomas, 1997). Many botanically derived substances possess estrogen-like activity, including soy proteins. Not only are there compounds in the environment that possess estrogenic properties, but there are also environmental antiandrogens (e.g., vinclozolin) (Kelce and Wilson, 1997).

The etiology of many adverse reproductive outcomes among humans is poorly understood. Generally, studies of epidemiologic and reproductive outcomes have focused upon maternal factors (Olshan and Faustman, 1993). Relatively speaking, only recently have studies begun to examine the role of chemical perturbation of paternal exposures. Male-mediated developmental toxicity has received some recent attention. It has become increasingly clear that reproductive toxicity involves both the male and female (Mattison et al., 1990). Also noteworthy is the fact that nonreproductive endocrine organs can be adversely affected by drugs and chemicals (Thomas, 1994).

Reproductive Hazards

The potential hazard of chemicals to reproduction and the risks to humans from chemical exposure are difficult to assess because of the complexity of the reproductive process, the unreliability of laboratory tests, and the quality of human data. In the human, it is estimated that one in five couples are involuntarily sterile; over one-third of early embryos die, and about 15 percent of recognized pregnancies abort spontaneously. Among the surviving fetuses at birth, approximately 3 percent have developmental defects (not always anatomic); with increasing age, over twice that many become detectable. It should be obvious that even under normal physiologic conditions, the reproductive system does not function in a very optimal state. Not surprisingly, the imposition of chemicals (or drugs) on this system can further interfere with a number of biological processes or events.

GENERAL REPRODUCTIVE BIOLOGY

The developing gonad is very sensitive to chemical insult, with some cellular populations being more vulnerable than others to an agent's toxic actions. Further, the developing embryo is uniquely sensitive to changes in its environment, whether such changes are caused by exposure to foreign chemicals or certain viruses. The toxicologist must be mindful of the teratogenic potential of a chemical as well as be aware of its potential deleterious actions on maternal biochemical processes. The development of normal reproductive capacity may offer particularly susceptible targets for toxins. Environmental factors might alter the genetic determinants of gonadal sex, the hormonal determinants of phenotypic sex, fetal gametogenesis, and reproductive tract differentiation as well as postnatal integration of endocrine

functions and other processes essential for the propagation of the species. The effects of environmental agents on sexual differentiation and development of reproductive capacity are largely unknown. Of the chemicals that have been studied, it is noteworthy that they possess a wide diversity in molecular structure and that they may affect specific cell populations within the reproductive system.

Sexual Differentiation

An understanding of reproductive physiology requires consideration of the process of sexual differentiation or the pattern of development of the gonads, genital ducts, and external genitalia (cf. Simpson, 1980; De La Chapelle, 1987; Goldberg, 1988).

The transformation of androgens into estrogens through the aromatization occurs in the hypothalamus during fetal life; this is one of the key events leading to sexual differentiation. During the last decade, the increased evidence of disorders of male sexual differentiation (e.g., hypospadias, cryptorchidism, micropenis) has raised the possibility that certain environmental chemicals might be detrimental to normal male genital development in utero. Male sexual differentiation is critically dependent on the physiologic action of androgens. Thus, an imbalance of the androgen/estrogen ratio can affect sexual differentiation. Environmental xenoestrogens that mimic estrogens (e.g., certain herbicides, pesticides, plasticizers, nonylphenols, etc.) or environmental antiandrogens [e.g., *p,p'*-DDE (the major metabolite of DDT) vinclozolin, linuron, etc.] that perturb endocrine balance might cause demasculinizing and feminizing effects in the male fetus. Disturbed male sexual differentiation has, in some instances, been purported to be caused by increased exposure to environmental xenoestrogens and/or antiandrogens.

Gonadal Sex A testes-determining gene [sex-determining region of the Y chromosome (SRY)] on the Y chromosome is responsible for determining gonadal sex (cf. De La Chapelle, 1987, Swain and Lovell-Badge, 1999). It converts undifferentiated gonads into a testes. The organization of the gonadal anlage into the seminiferous or spermatogenic tubules of the male may be mediated by the SRY gene. The testes produces two separate hormones: the müllerian inhibiting factor (MIF) and testosterone. Testosterone-induced masculine differentiation is modulated by androgen receptors regulated by genes on the X chromosome. Alterations of the sex chromosomes may be transmitted by either one of the parents (gonadal dysgenesis) or may occur in the embryo itself. Failure of the sex chromosomes of either of the parents to separate during gametogenesis is called nondisjunction and can result in gonadal agenesis. Klinefelter's syndrome is characterized by testicular dysgenesis with male morphology and an XXY karyotype; Turner's syndrome includes ovarian agenesis with female morphology (XO karyotype).

Hermaphroditism (true and pseudo) may occur secondary to nondisjunction of sex chromosomes during the initial cleavage mitosis of the egg. Such a condition is usually due to an XY karyotype and sometimes to sex mosaics of XY/XX or XY/XO. Pseudohermaphrodites are characterized by secondary sex characteristics that differ from those predicted by genotype.

Chemically induced nondisjunction is a common genetic abnormality. Nondisjunction of Y chromosomes may be detected by the presence or absence of fluorescent bodies on the chromatin of sperm (YFF spermatozoa). YFF sperm are increased in patients treated with certain antineoplastic agents and irradiation.

Genotypic Sex The normal female chromosome complement is 44 autosomes and 2 sex chromosomes, XX. The two X chromosomes contained in the germ cells are necessary for the development of a normal ovary. Autosomes are also involved in ovarian development, differentiation of the genital ducts, and external genitalia characteristic of a normal female. This requires the involvement of a single X chromosome with genetic cellular events. Generally, the second X chromosome of a normal XX female is genetically inactive in nongonadal cells, although it has been shown that the tip of the short arm of the chromosome is genetically active.

The Y chromosome is consistent with the male determinant. The normal male has a chromosome complement of 44 autosomes and 2 sex chromosomes, X and Y. An additional X chromosome does not change the male phenotype conferred by the Y chromosome, but the gonads are often dysfunctional (Klinefelter's syndrome, XXY genotype). Genetic coding on the X chromosome may be involved in transforming the gonad into a testis.

The presence of chromatin material on the short (p) arm of the (Y_p) chromosome directs the development of the testes. Chromatin material (Y_q) on the long (q) arm directs the development of spermatogenesis.

Phenotypic (Genital) Sex During the early stages of fetal development, sexual differentiation does not require any known hormonal products. The differentiation of the genital ducts and the external genitalia, however, requires hormones. The onset of testosterone synthesis by the male gonad is necessary for the initiation of male differentiation. Although the testes are required in male differentiation, the embryonic ovaries are not needed to attain the female phenotype. Female characteristics develop in the absence of androgen secretion.

Two principal types of hormones are secreted by the fetal testes—an androgenic steroid responsible for male reproductive tract development and a nonsteroid factor that causes regression of the mullerian ducts. Sertoli cells are the likely source of MIF or antimüllerian hormone (AMH). Leydig cell differentiation and regression correspond well with the onset and subsequent decline in testosterone synthesis by the fetal testis. Thus, the embryonic testis suppresses the development of the mullerian ducts, allows the development of the wolffian duct and its derivatives, and thereby imposes the male phenotype on the embryo.

Three periods for testosterone production are important to sexual differentiation. The first period occurs on days 14 to 17 of gestation in the rat and weeks 4 to 6 in the human. The second period occurs about day 17 of gestation to about 2 weeks postnatal age in the rat and from month 4 of pregnancy to 1 to 3 months of postnatal age in the human. The third period follows a long period of testicular inactivity in both species until testosterone production is reinitiated between 40 and 60 days of age in the rat and between 12 to 14 years of age in the human.

The dynamics of testosterone and dihydrotestosterone production and cellular interactions are an important prerequisite to knowing which chemicals might affect sexual differentiation. Factors that reduce the ability of testosterone to be synthesized and activated, to enter the cell, and/or to affect the cell nucleus's ability to regulate the synthesis of androgen-dependent proteins would have a potential to alter sexual differentiation. Some chemicals are capable of exerting a testosterone-depriving effect on the developing systems. These include effects on the feedback regulation of gonadotropin secretion, gonadotropin effectiveness, testosterone and dihydrotestosterone synthesis, and plasma binding as well as cytoplasmic receptor and nuclear chromatin binding.

Insufficient amounts of androgens can feminize the male fetus with otherwise normal testes and an XY karyotype. Slight deficiencies affect only the later stages of differentiation of the external genital organs and result in microphallus, hypospadias (the urethra opens on undersurface of penis), and a valviform appearance of the scrotum with masculine general morphology. However, a severe androgen deficiency (or resistance) allows the mullerian system to persist and results in external genital organs of a female type (vagina and uterus) that coexist with ectopic testes and normal male efferent ducts. A lack of androgen receptors can also lead to a testicular feminization type of syndrome even when normal levels of testosterone are present. Finally, sexual behavior also appears to be "imprinted" in the central nervous system by androgens from the testis and could be affected by endogenous and exogenous chemicals.

Estrogens exert an important developmental effect. Nearly 30 years have elapsed since the association between maternal DES administration and vaginal adenocarcinoma in female offspring was reported. DES, a synthetic estrogen, was used extensively in the treatment of both humans and livestock. Other nonsteroidal estrogens, namely, the insecticides chlordecone and DDT (and its metabolites) exhibit uterotropic actions in experimental animals (cf. Thomas, 1975). The estrogenicity of chlordecone was first described in workers at a pesticide-producing plant (Cohn et al., 1978). Several so-called xenoestrogens—including herbicides, fungicides, insecticides, and nematocides—have been identified (cf. Colborn, et al., 1993). Similarly, polychlorinated biphenyls (PCBs) are uterotropic. Zearalenone, a plant mycotoxin, also exhibits female sex hormone properties. The effects of environmental hormone-disrupters (namely xenoestrogens) are not restricted to females. Indeed, vinclozolin, a dicarboximide fungicide, has metabolites that can act as androgen antagonists (Kelce et al., 1994).

GONADAL FUNCTION

Central Modulation

Regardless of gender, the gonads possess a dual function: an endocrine function involving the secretion of sex hormones and a nonendocrine function or the production of germ cells (gametogenesis). The testes secrete male sex steroids, including testosterone and dihydrotestosterone. The testes also secrete small amounts of estrogens. The ovaries, depending on the phase of the menstrual cycle, secrete various amounts of estrogens and progesterone. Estradiol is the principal steroid estrogen secreted by the ovary in most mammalian species. The ovary is also the chief source of progesterone. The corpus luteum and the placenta are also primary sites of secretion of progesterone.

Gametogenic and secretory functions of either the ovary or testes are dependent on the secretion of adenohypophyseal gonadotropins, follicle stimulating hormone (FSH), and luteinizing hormone (LH). In the male, LH is also referred to as ICSH (interstitial cell–stimulating hormone). FSH in the female stimulates follicular development and maturation in the ovary. FSH in the male stimulates the process of spermatogenesis. Sertoli cells are the target cells for the action of FSH in the testes of mammals. FSH receptors are present on the Sertoli cells, and the gene for the FSH receptor is predominantly expressed in these cells (cf. Heckert and Griswold, 1993). The secretion of pituitary FSH and LH is modulated by gonadal hormones. Sex steroids secreted by the testes or ovaries regulate the secretion of pituitary gonadotropins. The Sertoli cell of the testes secretes small amounts of estrogen and a proteinaceous hormone called inhibin. Inhibin aids in the modulation of spermatogenesis. ICSH (LH) provokes the process of steroidogenesis in the testes (cf. Herbert et al., 1995).

The onset of puberty results in the cyclic secretion of pituitary gonadotropins in the female. This establishes the normal menstrual cycle. In males, puberty is advanced by the continuous and noncyclic secretion of gonadotropins.

Testicular Function

There are several subpopulations of cells in the mammalian testes, all of which are subject to some degree of local regulation (cf. Maddocks, et al., 1990; Spiteri-Grech and Nieschlag, 1993). These local regulatory factors include peptide growth factors, pro- opiomelanocortin derivatives, neuropeptides, and steroids (Table 20-1). There are many complex cell-to-cell communications, any one of which could serve as a site for chemical or heavy metal perturbation. Many agents that can affect either spermatogenesis or steroidogenesis can also affect leukocytes and other testes-regulating factors produced by cells of the immune system (cf. Murdoch, 1994). The paracrine or local regulation of testicular function is an interesting concept, yet the nature of the testicular architecture and the multiple interactions that can occur at various cellular levels renders this biological system not only complex, but very difficult to study from both a physiologic or a toxicologic standpoint. Nevertheless, these local testicular factors are very important in modulating the paracrine control of the male gonad (Table 20-2). Paracrine and autocrine factors from Sertoli and germ cells are important in the functioning of both cell types (Griswold, 1995).

Table 20-1 Growth Factors Isolated from the Testis

Table 20-2 Local Factors Modulating the Function of Testicular Cells

Apoptosis Apoptosis and necrosis constitute two distinct forms of cell death that differ in morphology, mechanism, and incidence (Fig. 20-1) (see also Chap. 10, "Developmental Toxicology"). Necrosis includes membrane disruption, respiratory hypovia, membrane collapse, cell swelling, and rupture in pathologic tissue. Apoptosis, on the other hand, describes the scattered, apparently random cell deaths in normal cells (cf. Nakano, 1997). The capacity for cell "suicide" appears to be present in most, if not all tissues to maintain a homeostatic state.

Figure 20-1. Comparison of cellular events during apoptosis and necrosis. (Modified from Raffray and Cohen, 1997, with permission.)

During the fertile phase of the life span of mammals, the function of the gonads is hormonally controlled. In addition to the proliferation of somatic and germ cells in the ovary and in the testes during normal gonadal development, degeneration of gonadal cells plays an important physiologic role and leads to a depletion of a majority of germ cells in both sexes (cf. Billig, et al., 1996; Robertson and Orrenius, 2000). In the testes, morphologic signs of germ cell degeneration during spermatogenesis were recognized nearly 100 years ago (Regaud, 1900).

The biochemical pathway(s) that cause apoptosis are not known, but DNA lysis is involved (Thompson, 1994). Several specific genes/gene products have been associated with the apoptosis that follows androgen depletion. For example, one prominent marker is TRPM-2 (a sulfated glycoprotein-2, or "clusterin"), which increases shortly after androgen removal. Likewise, transforming growth factor beta (TGF-b) increases after androgen removal. In the female, the role of TGF-b in uterine apoptosis is unclear.

There is increasing evidence suggesting that apoptosis rather than necrosis predominates in many cytolethal toxic injuries (Raffray and Cohen, 1997). Tissue selectivity of toxicants can stem from the apoptotic or necrotic thresholds at which different cells die.

Physiologically, apoptosis serves to limit the number of germ cells in the seminiferous epithelium (cf. Billig et al., 1995). During the process of spermatogenesis, clonal proliferation of germ cells occurs during the many mitotic divisions, leading to a significantly expanding germ cell population. Left unchecked, the number of germ cells would quickly outgrow the supportive capacity of the Sertoli cell. Hence, a delicate balance exists in the testes between proliferation and apoptosis. About three-fourths of the potential population of mature germ cells in the testes may be lost by active elimination (DeRooÿ and Lok, 1987).

The Sertoli cell of the testes has been suggested to be a controlling factor in germ cell apoptosis (cf. Roberts, et al., 1997). Further, germ cell viability depends on Sertoli cell factors as well as the intimate contact between these two testicular cell types. Sertoli cells appear to regulate germ cell apoptosis directly through a paracrine mechanism. The Sertoli cell may mediate the death of *fas*-bearing germ cells via the expression of *fasL* on its cell membrane.

A number of chemicals reportedly increase the incidence of apoptosis in the rodent testes (Ku et al., 1995; Billig et al., 1995; Richburg and Boekelheide, 1996; Nakagawa et al., 1997). In rats, the Sertoli cell toxicant mono-2-ethylhexyl phthalate (MEHP) causes an early and progressive detachment of germ cells from the seminiferous epithelium (Richburg and Boekelheide, 1996). This MEHP-induced disruption of the Sertoli cell–germ cell physical interaction has been suggested to alter normal Sertoli cell–directed regulation of germ cell apoptosis. Mitomycin C, an antibiotic that inhibits DNA synthesis, induces apoptosis with fragmentation of nuclear DNA in mouse spermatogenic cells, especially spermatogonia (Nakagawa et al., 1997). Why spermatogenic germ cells have a relatively high level of apoptosis is unknown, but it could be a mechanism for eliminating cells with abnormal chromosomes.

Spermatogenesis *Spermatogenesis* is a unique process in which the timing and stages of differentiation are known with a considerable degree of certainty. The dynamics of the process of spermatogenesis as well as the kinetics have been studied extensively and have recently been reviewed by Foote and Berndtson (1992). In producing spermatozoa by the process of spermatogenesis, the germinal epithelium plays a dual role: It must produce millions of spermatozoa each day and also continuously replace the population of cells that give rise to the process, the spermatogonia (cf. Amann, 1989).

Sperm are among the smallest cells in humans, where its length is about 50 µm or only about one-half the diameter of the ovum, the largest cell of the female organism. The relative volume of a sperm is about 1/100,000 that of the egg. The sperm has a head, a middle piece, and a tail, which correspond, respectively, to the following functions: activation and genetics, metabolism, and motility.

Whereas only a few hundred human ova are released as cells ready for fertilization in a life-time, millions of motile sperm are formed in the spermatogenic tubules each day. Several physiologic factors affect the regulation of sperm motility (e.g., spermine, spermidine, "quiescence" factor, cAMP, motility stimulating factor) (Lindemann and Kanous, 1989).

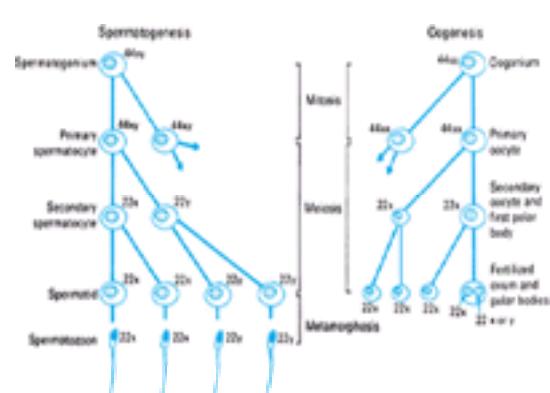
Spermatogenesis starts at puberty and continues almost throughout life. The primitive male germ cells are spermatogonia, which are situated next to the basement membrane of the seminiferous tubules. Following birth, spermatogonia are dormant until puberty, when proliferative activity begins again. The onset of spermatogenesis accompanies functional maturation of the testes. Two major types of spermatogonia are present—type A, which generates other spermatogonia, and type B, which becomes a mature sperm. The latter type develops into primary spermatocytes, which undergo meiotic divisions to become secondary spermatocytes. The process of meiosis results in the reduction of the normal complement of chromosomes (diploid) to half this number (haploid) (Fig. 20-2). Meiosis ensures the biologic necessity of evolution through the introduction of controlled variability. Each gamete must receive one of each pair of chromosomes. Whether it receives the maternal or paternal chromosome is a matter of chance. In the male, meiosis is completed within several days. In the female, meiotic division begins during fetal life but is then suspended until puberty. Meiosis may be the most susceptible stage for chemical insult (cf. Herbert, et al., 1995).


Figure 20-2. Cellular replication (mitosis) and cellular reductive divisions (meiosis) involved in spermatogenesis, oogenesis, and fertilization.

Secondary spermatocytes give rise to spermatids. Spermatids complete their development into sperm by undergoing a period of transformation (spermiogenesis) involving extensive nuclear and cytoplasmic reorganization. The nucleus condenses and becomes the sperm head; the two centrioles give rise to the flagellum or axial filament. Part of the Golgi apparatus becomes the acrosome, and the mitochondria concentrate into a sheath located between two centrioles.

Seminiferous tubules contain germ cells at different stages of differentiation and also Sertoli cells. In a cyclic fashion, spermatogonia A of certain areas of a tubule become committed to divide synchronously, and the cohorts of the resulting cells differentiate in unison. Thus, a synchronous population of developing germ cells occupies a defined area within a seminiferous tubule. Cells within each cohort are connected by intercellular bridges.

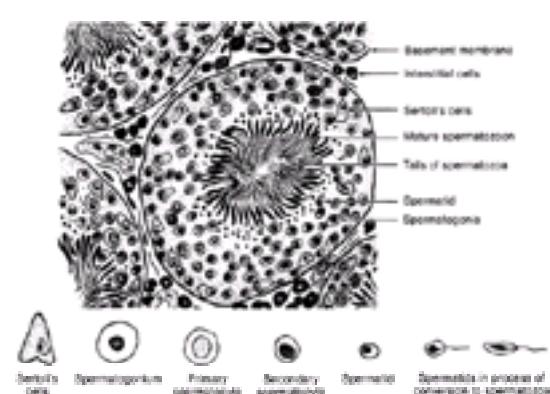
The anatomic relationships of the mammalian testes reveal that the process of spermatogenesis occurs within the seminiferous tubules (Fig. 20-3). The germ cells, along with the Sertoli cells, are contained within the membranous boundaries of the seminiferous tubules. Conversely, the Leydig cells are situated in the interstitium or outside the seminiferous tubules. Several different species display a single cellular association of the seminiferous tubules; in humans, however, such cellular associations differ and are intermingled in a mosaic-like pattern. Several cellular associations, varying among species, may be detected. Each cellular association contains four or five types of germ cells organized in a specific, layered pattern. Each layer represents one cellular generation. Fourteen cellular associations are observed in the seminiferous epithelium in the rat (LeBlond and Clermont, 1952; Heller and Clermont, 1964).


Figure 20-3. Schematic cross section of seminiferous tubules of testes.

Morphology of the Sertoli cell along with the cellular events involved in spermatogenesis (spermatogonium through spermatid).

Presuming a fixed point within the seminiferous tubule could be viewed in the developing germ cell, there would be a sequential appearance of each of these cellular

associations that would be characteristic of the particular species. This progression through the series of cellular associations would continue to repeat itself in a predictable fashion. The interval required for one complete series of cellular associations to appear at one point within a tubule is termed *the duration of the cycle of the seminiferous epithelium*. The duration of one such cycle depends on the cell turnover rate of spermatogonia and is thus equal to it. Thus, the duration of the cycle of seminiferous epithelium varies among mammals, being a low of about 9 days in the mouse to a high of about 16 days in humans (Table 20-3) (Galbraith, et al., 1982). Spermatids, emanating from spermatogonia committed to differentiate approximately 4.5 cycles earlier, are continuously released from the germinal epithelium.

Table 20-3 Criteria for Spermatogenesis in Laboratory Animals and Humans

Maturation changes occur in the sperm as they traverse along the tubules of the testes and the epididymides. During this passage, sperm acquire the capacity for fertilization and become more motile. There is a progressive dehydration of the cytoplasm, decreased resistance to cold shock, changes in metabolism, and variations in membrane permeability. Each ejaculate contains a spectrum of normal sperm as well as those that are either abnormal or immature.

Normalcy of spermatogenesis can be evaluated from two standpoints: the number of spermatozoa produced per day and the quality of spermatozoa produced. The number of spermatozoa produced per day is defined as daily sperm production (Amann, 1981). The efficiency of sperm production is the number of sperm produced per day per gram of testicular parenchyma. The efficiency of sperm production in humans is only about 20 to 40 percent of that in other mammals (Amann, 1986). Sperm production in a young man is about 7 million sperm per day per gram; by the fifth to ninth decade of life, it drops to approximately one-half or about 3.5 million per day per gram (cf. Johnson, 1986).

Blazak et al. (1985)—using several parameters including sperm production, sperm number, sperm transit time, and sperm motility—have provided an assessment of the effects of chemicals on the male reproductive system. These authors concluded that testes weights and epididymal sperm numbers were unreliable indicators of sperm production.

Sertoli Cells The Sertoli cell is now recognized as playing an important role in the process of spermatogenesis (cf. Foster, 1992; Griswold, 1995). In early fetal life, the Sertoli cells secrete anti-müllerian hormone (AMH). Their exact physiologic role is not understood, but after puberty, these cells begin to secrete the hormone inhibin, which may aid in modulating pituitary FSH.

Germ cell development occurs in close association with the Sertoli cells, which provide them with structural support, nutrients, and regulatory/paracrine factors. Brinster and Zimmerman (1994) described the interaction between germ cells and Sertoli cells within the seminiferous tubules. Recent experiments indicate that spermatogenesis can be restored in infertile testes through germ cell tranplantation (Ogawa et al., 1999).

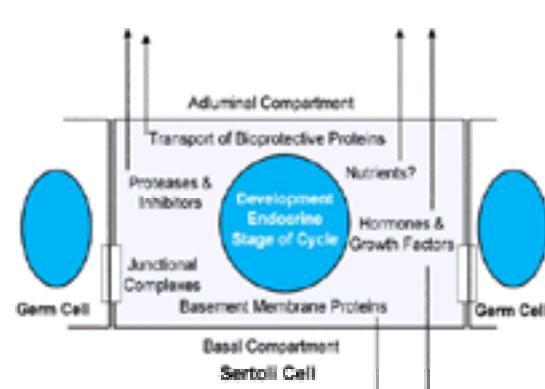
The Sertoli cell junctions form the blood-testis barrier that partitions the seminiferous epithelium into a basal compartment containing spermatogonia and early spermatocytes and an adluminal compartment containing more fully developed spermatogenic cells. An ionic gradient is maintained between the two tubular compartments. Nutrients, hormones, and other chemicals must pass either between or through Sertoli cells in order to diffuse from one compartment to another. Germinal cells are found either between adjacent pairs of Sertoli cells or inside their luminal margin (see Fig. 20-4).


Figure 20-4. Cellular sites of action of chemical or drugs in the testes.

Secretion may occur to both the adluminal and basal compartments in the seminiferous tubules. The type, amount, and detection of Sertoli cell secretion may be influenced by the stage of testicular development endocrine status and the stage of cycle of the seminiferous epithelium (Griswold, 1995). Note the anatomic proximity of the Sertoli cell and the germ cell. See also Table 20-1 and Table 20-2 for various hormonal and growth factor interactions between the various subpopulations of testicular cells.

Sertoli cells secrete a number of hormones and/or proteins. These secretory products can be used to measure Sertoli function in the presence of chemical insult. The Sertoli cells secrete tissue plasminogen activator, androgen-binding protein (ABP), inhibin, AMH, transferrin, and other proteases. ABP is a protein similar to plasma sex steroid–binding globulin (SSBG). In rodents, ABP acts as a carrier for testosterone and dihydrotestosterone. Sertoli cells probably synthesize estradiol and estrone in response to FSH stimulation.

Normal spermatogenesis requires Sertoli cells. Many chemicals affecting spermatogenesis act indirectly through their effect on the Sertoli cell [e.g., dibromochloropropane (DBCP), monoethylhexyl phthalate (MEHP)] rather than directly on the germ cells. Tetrahydrocannabinol (THC) acts at several sites in the reproductive system, including the Sertoli cell, where it acts by inhibiting FSH-stimulated cAMP accumulation (Heindel and Keith, 1989).

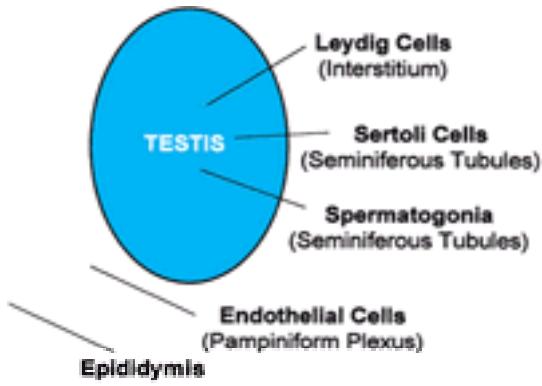
Interstitium (Leydig Cells) The Leydig or interstitial cells are the primary sites of testosterone synthesis (Fig. 20-5) (cf. Ewing, 1992). These cells are closely associated with the testicular blood vessels and the lymphatic space. The spermatic arteries to the testes are tortuous; their blood flows parallel to blood in the pampiniform plexus of the spermatic veins but in the opposite direction (Fig. 20-5). This anatomic arrangement seems to facilitate a countercurrent exchange of heat, androgens, and other chemicals.


Figure 20-5. Schematic representation of secretory elements from the Sertoli cell.

Extratesticular sites include the epididymis and the endothelial cells of the pampiniform plexus.

LH stimulates testicular steroidogenesis (Zirkin and Chen, 2000). Androgens are essential to spermatogenesis, epididymal sperm maturation, the growth and secretory activity of accessory sex organs, somatic masculinization, male behavior, and various metabolic processes. Surprisingly, there are a large number of diverse chemicals/drugs that can cause Leydig cell hyperplasia/neoplasia. This chemically induced proliferation of Leydig cells is particularly evident in the rodent (Table 20-4) (Thomas, 1995b; Cook et al., 1999).

Table 20-4 Chemicals/Drugs Causing Leydig Cell Hyperplasia/Neoplasia in Rodents

A number of nongenotoxic agents can produce Leydig cell hyperplasia in rats, mice, and dogs (Cook et al., 1999). Androgen receptor antagonists (e.g., flutamide), 5a-reductase inhibitors (e.g., finasteride), testosterone biosynthesis inhibitors (e.g., cimetidine, metronidazole, vinclozolin, etc.), aromatase inhibitors (e.g., formestane), dopamine agonists (e.g., mesulergine), estrogen agonists/antagonists (e.g., DES, tamoxifen, etc.), and GnRH agonists (e.g., leuprolide, etc.) are all capable of producing Leydig cell hyperplasia. It is obvious that they exhibit vastly different modes of action. Agents that produce Leydig cell hyperplasia in experimental animals can also be grouped according to their chemical activity (e.g., antihypertensives, calcium channel blockers, fungicides, goitrogens, etc.) as well as by their chemical class (e.g., flurochemicals, nitroaromatics, organochlorines, etc.). Nongenotoxic compounds that induce Leydig cell tumors in rats most likely have little relevance to humans under most exposure conditions because humans are quantitatively less sensitive than rats (Cook et al., 1999).

Posttesticular Processes

The end product of testicular gametogenesis is immature sperm. Posttesticular processes involve ducts that move maturing sperm from the testis to storage sites where they await ejaculation. A number of secretory processes exist that control fluid production and ion composition; secretory organs contribute to the chemical composition (including specific proteins) of the semen.

Efferent Ducts The fluid produced in the seminiferous tubules moves into a system of spaces called the rete testis. The chemical composition of the rete testis fluid is unique and has a total protein concentration much lower than that of the blood plasma. The efferent ducts open into the caput epididymis.

Although the rete testis fluid normally contains inhibin, ABP, transferrin, myoinositol, steroid hormones, amino acids, and various enzymes, only ABP and inhibin appear to be specific products and useful indicators of the functional integrity of the seminiferous epithelium or Sertoli cells (Mann and Lutwak-Mann, 1981). However, relative concentrations of other constituents may indicate alterations in membrane barriers or active transport processes. The concentration of chemicals in the rete testis fluid relative to unbound plasma concentration has been used to estimate the permeability of the blood-testis barrier for selected chemicals (Okumura et al., 1975).

Epididymides The epididymis is a single, highly coiled duct measuring approximately 5 m in humans. It is arranged anatomically into three parts called the caput, the corpus, and the cauda epididymides (cf. Cooper, 1986).

From the rete testis, testicular fluid first enters efferent ducts and then the epididymides. Here the sperm are subjected to a changing chemical environment as they move through the organ.

The first two sections together (the caput and the corpus) are regarded as making up that part of the epididymis involved with sperm maturation, whereas the terminal segment (the cauda) is regarded as the site of sperm storage. There are, however, differences in the position and extent of the segments in various species of mammals.

From 1.8 to 4.9 days are required for sperm to move through the caput to the corpus epididymis, where maturation takes place. In contrast, the transit time for sperm through the cauda epididymis in sexually rested males differs greatly among species and ranges from 3.7 to 9.7 days. Average sperm transit time for a 21- to 30-year-old man is 6 days. The number of sperm in the caput and corpus epididymis is similar in sexually rested males and in males ejaculating daily. The number of sperm in the cauda epididymis is more variable, being lower in sexually active males.

Active transport processes affect the amount of fluid flowing through the epididymis. Because much of the fluid produced by the testis is apparently absorbed in the epididymis, the relative concentration of sperm is increased.

Hence, important functions of the epididymis are reabsorption of rete testis fluid, metabolism, epithelial cell secretions, sperm maturation, and sperm storage. The chemical composition of the epididymal plasma plays an important role in both sperm maturation and sperm storage. Environmental chemicals perturb these processes and can produce adverse effects.

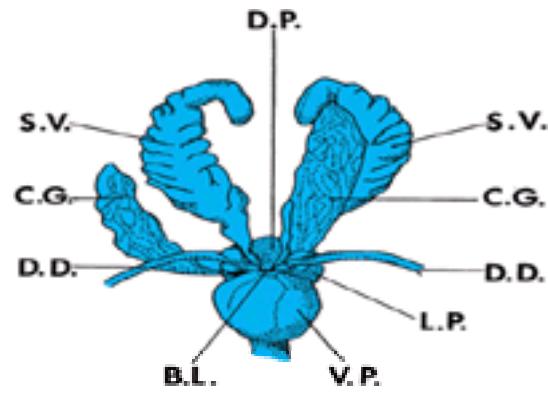
Accessory Sex Organs The anatomic relationship of accessory sex organs in the male rodent is depicted in Fig. 20-6. Most mammals possess seminal vesicles (exceptions: cats and dogs) and most have prostate glands. However, the physiologic and anatomic characteristics of the prostate gland may vary considerably among mammals (Wilson, 1995).


Figure 20-6. Anatomic relation of components of rodent sex accessory glands.

D.D., ductus deferens; B.L., bladder; V.P., ventral prostate; L.P., lateral prostate; C.G., coagulating gland (also called the anterior prostate); S.V., seminal vesicle; D.P., dorsal prostate. (From Hayes, 1982, with permission.)

The seminal plasma functions as a vehicle for conveying the ejaculated sperm from the male to the female reproductive tract. This plasma is produced by the secretory organs of the male reproductive system, which, along with the epididymides, include the prostate, seminal vesicles, bulbourethral (Cowper's) glands, and urethral (Littre's) glands. Any abnormal function of these organs can be reflected in altered seminal plasma characteristics. Seminal plasma is normally an isotonic, neutral medium, which, in many species, contains sources of energy such as fructose and sorbitol, that are directly available to sperm. Functions of the other constituents, such as citric acid and inositol, are not known. In general, the secretions from the prostate and seminal vesicles contribute little to fertility (Mann and Lutwak-Mann, 1981).

The accessory sex organs are androgen-dependent. They serve as indicators of the Leydig cell function and/or androgen action. The weights of the accessory sex glands are an indirect measure of circulating testosterone levels. The ventral prostate of rats has been used to study the actions of testosterone and to investigate the molecular basis of androgen-regulated gene function.

Human semen emission initially involves the urethral and Cowper's glands, with the prostatic secretion and sperm coming next and the seminal vesicle secretion delivered last. There is a considerable overlap between the presperm, sperm-rich, and postsperm fractions. Therefore even if an ejaculate is collected in as many as six (split ejaculate) fractions, it is rarely possible to obtain a sperm-free fraction consisting exclusively of prostatic or vesicular secretions.

Acid phosphatase and citric acid are markers for prostatic secretion; fructose is an indicator for seminal vesicle secretion. It is estimated that about one-third of the entire human ejaculate is contributed by the prostate and about two-thirds by the seminal vesicles. Both the vas deferens and the seminal vesicles apparently synthesize prostaglandins. Semen varies both in volume and composition between species. Human, bovine, and canine species have a relatively small semen volume (1 to 10 mL); semen of stallions and boars is ejaculated in much larger quantities. Sperm move from the distal portion of the epididymis through the vas deferens (ductus deferens) to the urethra. Vasectomy is the surgical removal of the vas deferens or a portion of it. The semen of some animals, including rodents and humans, tends to coagulate on ejaculation. The clotting mechanism (e.g., "copulatory plug") involves enzymes and substrates from different accessory organs.

Although all male mammals have prostates, the organ differs anatomically, physiologically, and chemically among species, and lobe differences in the same species may be pronounced. The rat prostate is noted for its complex structure and its prompt response to castration and androgen stimulation. The human prostate is a tubuloalveolar gland made up of two prominent lateral lobes that contribute about one-third of the ejaculate.

Prostatic secretion in humans and many other mammalian species contains acid phosphatase, zinc, and citric acid. The prostatic secretion is the main source of acid phosphatase in human semen; its concentration provides a convenient method for assessing the functional state of the prostate. The human prostate also produces spermine. Prostate-specific antigen (PSA) is a 33-kDa protein synthesized primarily by the prostatic epithelium (Polascik et al., 1999). It is a tumor marker for prostate cancer. Certain proteins and enzymes (acid phosphatase, g-glutamyl transpeptidase, glutamicoxaloacetic transaminase), cholesterol, inositol, zinc, and magnesium have also been proposed as indicators of prostatic secretory function. Radioactive zinc (^{65}Zn) uptake by rodent prostate glands has been used as an index for androgenic potency (Gunn and Gould, 1956). An ionic antagonism exists between zinc and cadmium. Cadmium can induce metallothionein in the prostate glands of experimental animals (Waalkes et al., 1982; cf. Waalkes, et al., 1992).

The anatomic structure of the seminal vesicle varies among animals. The seminal vesicle is a compact glandular tissue arranged in the form of multiple lobes that surround secretory ducts. Like the prostate, the seminal vesicle is responsive to androgens and is a useful indicator of Leydig cell function. The vesicular glands can be used as a gravimetric indicator for androgens.

In humans, the seminal vesicle contributes about 60 percent of the seminal fluid. The seminal vesicles also produce more than half of the seminal plasma in laboratory and domestic animals such as the rat, guinea pig, and bull. In the human, bull, ram, and boar (but not the cat), most of the seminal fructose is secreted by the seminal vesicles; consequently, in these species the chemical assay of fructose in semen is a useful indicator of the relative contribution of the seminal vesicles to whole semen. Seminal vesicle secretion is also characterized by the presence of proteins and enzymes, phosphorylcholine, and prostaglandins. PSA occurs in high concentration in seminal fluid.

Erection and Ejaculation These physiologic processes are controlled by the central nervous system (CNS) but are modulated by the autonomic nervous system. Parasympathetic nerve stimulation results in dilatation of the arterioles of the penis, which initiates an erection. Erectile tissue of the penis engorges with blood, veins are compressed to block outflow, and the turgor of the organ increases. In the human, afferent impulses from the genitalia and descending tracts, which mediate erections in response to erotic psychic stimuli, reach the integrating centers in the lumbar segments of the spinal cord. The efferent fibers are located in the pelvic splanchnic nerves (Andersson and Wagner, 1995).

Ejaculation is a two-stage spinal reflex involving emission and ejaculation. Emission is the movement of the semen into the urethra; ejaculation is the propulsion of the semen out of the urethra at the time of orgasm. Afferent pathways involve fibers from receptors in the glans penis that reach the spinal cord through the internal pudendal nerves. Emission is a sympathetic response effected by contraction of the smooth muscle of the vas deferens and seminal vesicles. Semen is ejaculated out of the urethra by contraction of the bulbocavernosus muscle. The spinal reflex centers for this portion of the reflex are in the upper sacral and lowest lumbar segments of the spinal cord; the motor pathways traverse the first to third sacral roots of the internal pudendal nerves.

Little is known concerning the effects of chemicals on erection or ejaculation (Woods, 1984). Pesticides, particularly the organophosphates, are known to affect neuroendocrine processes involved in erection and ejaculation. Many drugs act on the autonomic nervous system and affect potency (Table 20-5) (see also Papadopoulas, 1980; Buchanan and Davis, 1984; Stevenson and Umstead, 1984; Keene and Davies, 1999). Impotence, the failure to obtain or sustain an erection, is rarely of endocrine origin; more often, the cause is psychological. The occurrence of nocturnal or early-morning erections implies that the neurologic and circulatory pathways involved in attaining an erection are intact and suggests the possibility of a psychological cause.

Table 20-5 Drug-Induced Impotence

Normal penile erection depends upon the relaxation of smooth muscles in the corpora cavernosa. In response to sexual stimuli, cavernous nerves and endothelial cells release nitric oxide, which stimulates the formation of cyclic guanosine monophosphate (GMP) by guanylate cyclase. The drug sildenafil (Viagra) is used to treat erectile dysfunction; its mechanism of action resides in its ability to selectively inhibit cGMP-specific phosphodiesterase type 5. By selectively inhibiting cGMP catabolism in cavernosal smooth muscle cells, sildenafil restores the natural erectile response (cf. Goldstein, et al., 1998; Lu, 2000).

Ovarian Function

Oogenesis Ovarian germ cells with their follicles have a dual origin; the theca or stromal cells arise from fetal connective tissues of the ovarian medulla, the granulosa cells from the cortical mesenchyme (Fig, 20-7).

About 400,000 follicles are present at birth in each human ovary. After birth, many undergo atresia, and those that survive are continuously reduced in number. Any agent that damages the oocytes will accelerate the depletion of the pool and can lead to reduced fertility in females. About one-half of the number of oocytes present at birth remain at puberty; the number is reduced to about 25,000 by 30 years of age. About 400 primary follicles will yield mature ova during a woman's reproductive life span. During the approximately three decades of fecundity, follicles in various stages of growth can always be found. After menopause, follicles are no longer present in the ovary.

Follicles remain in a primary follicle stage following birth until puberty, when a number of follicles start to grow during each ovarian cycle. However, most fail to achieve maturity. For the follicles that continue to grow, the first event is an increase in size of the primary oocytes. During this stage, fluid-filled spaces appear among the cells of the follicle, which unite to form a cavity or antrum, otherwise known as the graafian follicle.

Primary oocytes undergo two specialized nuclear divisions, which result in the formation of four cells containing one-half the number of chromosomes (Fig. 20-2). The first meiotic division occurs within the ovary just before ovulation, and the second occurs just after the sperm fuses with the egg. In the first stage of meiosis, the primary oocyte is actively synthesizing DNA and protein in preparation for entering prophase. The DNA content doubles as each of the prophase chromosomes produces its mirror image. Each doubled chromosome is attracted to its homologous mate to form tetrads. The members of the tetrads synapse or come to lie side by side. Before separation, the homologous pairs of chromosomes exchange genetic material by a process known as crossing over. Thus, qualitative differences occur between the resulting gametes. Subsequent meiotic stages distribute the members of the tetrads to the daughter cells in such a way that each cell receives the haploid number of chromosomes. At telophase, one secondary oocyte and a polar body have been formed, which are no longer genetically identical.

The secondary oocyte enters the next cycle of division very rapidly; each chromosome splits longitudinally; the ovum and the three polar bodies now contain the haploid number of chromosomes and half the amount of genetic material. Although the nuclei of all four eggs are equivalent, the cytoplasm is divided unequally. The end products are one large ovum and three rudimentary ova (polar bodies), which subsequently degenerate. The ovum is released from the ovary at the secondary oocyte stage; the second stage of meiotic division is triggered in the oviduct by the entry of the sperm.

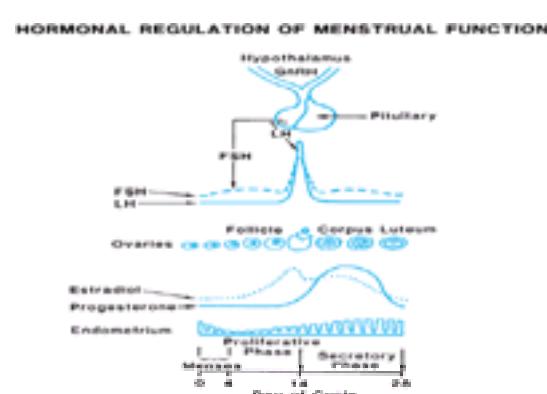
Ovarian Cycle The cyclic release of pituitary gonadotropins involving the secretion of ovarian progesterone and estrogen is depicted in Fig. 20-8. These female sex steroids determine ovulation and prepare the female accessory sex organs to receive the male sperm. Sperm, ejaculated into the vagina, must make their way through the cervix into the uterus, where they are capacitated. Sperm then migrate into the oviducts, where fertilization takes place. The conceptus then returns from the oviducts to the uterus and implants into the endometrium.


Figure 20-8. Hormonal regulation of menstrual function.

FSH, follicle stimulating hormone; *GnRH*, gonadotropin releasing hormone: *LH*, luteinizing hormone.

Postovarian Processes

Female accessory sex organs function to bring together the ovulated ovum and the ejaculated sperm. The chemical composition and viscosity of reproductive tract fluids, as well as the epithelial morphology of these organs, are controlled by ovarian (and trophoblastic) hormones.

Oviducts The oviducts provide the taxis of the fimbria, which is under muscular control. The involvement of the autonomic nervous system in this process, as well as in oviductal transport of both the male and female gametes, raises the possibility that pharmacologic agents known to alter the autonomic nervous system may alter function and therefore fertility.

Uterus Uterine endometrium reflects the cyclicity of the ovary as it is prepared to receive the conceptus. The myometrium's major role is contractile. In primates, at the end of menstruation, all but the deep layers of the endometrium are sloughed. Under the influence of estrogens from the developing follicle, the endometrium increases rapidly in thickness. The uterine glands increase in length but do not secrete to any degree. These endometrial changes are called proliferative. After ovulation, the endometrium becomes slightly edematous, and the actively secreting glands become tightly coiled and folded under the influence of estrogen and progesterone from the corpus luteum. These are secretory (progestational) changes (Fig. 20-8).

When fertilization fails to occur, the endometrium is shed and a new cycle begins. Only primates menstruate. Other mammals have a sexual or estrus cycle. Female animals come into "heat" (estrus) at the time of ovulation. This is generally the only time during which the female is receptive to the male. In spontaneously ovulating

species (e.g., rodents), the endocrine events are comparable with those in the menstrual cycle. In the rabbit, ovulation is a reflex produced by copulation.

Cervix The mucosa of the uterine cervix does not undergo cyclic desquamation, but there are regular changes in the cervical mucus. Estrogen, which makes the mucus thinner and more alkaline, promotes the survival and transport of sperm. Progesterone makes the mucus thick, tenacious, and cellular. The mucus is thinnest at the time of ovulation and dries in an arborizing, fernlike pattern on a slide. After ovulation and during pregnancy, it becomes thick and fails to form the fern pattern. Disruptions of the cervix may be expressed as disorders of differentiation (including neoplasia), disturbed secretion, and incompetence. Exfoliative cytologic (Papanicolaou's stain) and histologic techniques are currently used to assess disorders of differentiation. Various synthetic steroids (e.g., oral contraceptives) can affect the extent and pattern of cervical mucus.

Vagina Estrogen produces a growth and proliferation of vaginal epithelium. The layers of cells become cornified and can be readily identified in vaginal smears. Vaginal cornification has been used as an index for estrogens. Progesterone stimulation produces a thick mucus and the epithelium proliferates, becoming infiltrated with leukocytes. The cyclic changes in the vaginal smear in rats are easily recognized. The changes in humans and other species are similar but less apparent. Analysis of vaginal fluid or cytologic studies of desquamated vaginal cells (quantitative cytochemistry) reflects ovarian function. Vaginal sampling of cells and fluid might offer a reliable and easily available external monitor of internal function and dysfunction. Alteration in vaginal flora can indicate a toxicologic condition associated with the use of vaginal tampons [namely toxic shock syndrome (TSS)].

Fertilization During fertilization, the ovum contributes the maternal complement of genes to the nucleus of the fertilized egg and provides food reserves for the early embryo. The innermost of the egg is the vitelline membrane. Outside the ovum proper lies a thick, tough, and highly refractile capsule termed the zona pellucida, which increases the total diameter of the human ovum to about 0.15 mm. Beyond the zona pellucida is the corona radiata, derived from the follicle; it surrounds the ovum during its passage in the oviduct.

Formation, maturation, and union of a male and female germ cell are all preliminary events leading to a combined cell or zygote. Penetration of ovum by sperm and the coming together and pooling of their respective nuclei constitute the process of fertilization.

Only minutes are required for the sperm to penetrate the zona pellucida after passing through the cumulus oophorus in vitro, and probably less in vivo. The sperm traverse along a curved oblique path. Entering the perivitelline space, the sperm head immediately lies flat on the vitellus; its plasma membrane fuses with that of the vitellus and then embeds into the ovum. The cortical granules of the egg disappear, the vitellus shrinks, and the second maturation division is reinitiated, which results in extrusion of the second polar body. A specific factor in the ovum appears to trigger the development of the male pronucleus; the chromatin of the ovum forms a female pronucleus.

As syngamy approaches, the two pronuclei become intimately opposed but do not fuse. The nuclear envelopes of the pronuclei break up; nucleoli disappear, and chromosomes condense and promptly aggregate. The chromosomes mingle to form the prometaphase of the first spindle, and the egg divides into two blastomeres. From sperm penetration to first cleavage usually requires about 12 h in laboratory animals.

From a single fertilized cell (the zygote), cells proliferate and differentiate until more than a trillion cells of about a hundred different types are present in the adult organism.

Implantation The developing embryo migrates through the oviduct into the uterus. Upon contact with the endometrium, the blastocyst becomes surrounded by an outer layer or syncytiotrophoblast, a multinucleated mass of cells with no discernible boundaries, and an inner layer of individual cells, the cytotrophoblast. The syncytiotrophoblast erodes the endometrium, and the blastocyst implants. Placental circulation is then established and trophoblastic function continues. The blastocysts of most mammalian species implant about day 6 or 7 following fertilization. At this stage, the differentiation of the embryonic and extraembryonic (trophoblastic) tissues is apparent.

Trophoblastic tissue differentiates into cytotrophoblast and syncytiotrophoblast cells. The syncytiotrophoblast cells produce chorionic gonadotropin, chorionic growth hormones, placental lactogen, estrogen, and progesterone, which are needed to achieve independence from the ovary in maintaining the pregnancy. Rapid proliferation of the cytotrophoblast serves to anchor the growing placenta to the maternal tissue.

The developing placenta consists of proliferating trophoblasts, which expand rapidly and infiltrate the maternal vascular channels. Shortly after implantation, the syncytiotrophoblast is bathed by maternal venous blood, which supplies nutrients and permits an exchange of gases. Histotrophic nutrition involves yolk sac circulation; hemotrophic nutrition involves the placenta. Placental circulation is established quite early in women and primates and relatively much later in rodents and rabbits. Interestingly, placental dysfunction due to vascular compromise caused by cocaine leads to increased fetal risk, causing growth retardation and prematurity. Fetal loss due to abruptio placentae may occur (cf. Doering, et al., 1989).

Placentation Morphologically, the placenta may be defined as the fusion or opposition of fetal membranes to the uterine mucous membrane (cf., Slikker and Miller, 1994). In humans, the placenta varies considerably throughout gestation. The integral unit of the placenta is the villous tree. The core of the villous tree contains the fetal capilaries and associated endothelium.

Placentation varies considerably among various domestic animals, experimental animals, and primates (Slikker and Miller, 1994). Humans and monkey possess a hemochorial placenta. Pigs, horses, and donkeys have an epitheliochorial type of placenta, whereas sheep, goats, and cows have a syndesmochorial type of placenta. In laboratory animals (e.g., rat, rabbit, and guinea pig), the placenta is termed a hemoendothelial type. Among the various species, the number of maternal and fetal cell layers ranges from six (e.g., pig, horse) to a single one (e.g., rat, rabbit). Primates, including humans, have three layers of cells in the placenta that a substance must pass across. Thus, the placentas of some species are "thicker" than others.

Generally, the placenta is quite impermeable to chemi-cals/drugs with molecular weights of 1000 Da or more. Most medications have molecular weights of 500 Da or less. Hence, molecular size is rarely a factor in denying a drug's entrance across the placenta and into the embryo/fetus. Placental permeability to a chemical is affected by placental characteristics including thickness, surface area, carrier systems, and lipid-protein concentration of the membranes. The inherent characteristics of the chemical itself, such as its degree of ionization, lipid solubility, protein binding, and molecular size also affect its transport across the placenta.

INTEGRATIVE PROCESSES

Hypothalamo-Pituitary-Gonadal Axis

FSH and LH are glycoproteins synthesized and released from a subpopulation of the basophilic gonadotropic cells of the pituitary gland. Hypothalamic neuroendocrine neurons secrete specific releasing or release-inhibiting factors into the hypophyseal portal system, which carries them to the adenohypophysis, where they act to stimulate or inhibit the release of anterior pituitary hormones. Luteinizing hormone-releasing hormone (LHRH) acts on gonadotropic cells, thereby stimulating the release of FSH and LH. LHRH and follicle stimulating hormone-releasing hormone (FSHRH) appear to be the same substance. Native and synthetic forms of LHRH stimulate the release of both gonadotrophic hormones; thus, it has been proposed to call this compound gonadotropin-releasing hormone (GnRH).

The neuroendocrine neurons have nerve terminals containing monoamines (norepinephrine, dopamine, serotonin) that impinge on them. Reserpine, chlorpromazine, and monoamine oxidase (MAO) inhibitors modify the content or actions of brain monoamines that affect gonadotropins.

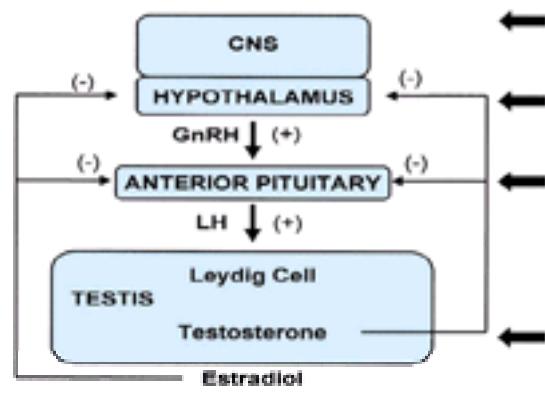
FSH probably acts primarily on the Sertoli cells, but it also appears to stimulate the mitotic activity of spermatogonia. LH stimulates steroidogenesis. A defect in the function of the testis (in the production of spermatozoa or testosterone) will tend to be reflected in increased levels of FSH and LH in serum because of the lack of the "negative feedback" effect of testicular hormones (Fig. 20-9).


Figure 20-9. Hormonal relationship between the adenohypopyseal-hypothalamic-gonadal axis.

Inhibitory actions (–) and stimulatory actions (+) are depicted along with sites of chemical/drug perturbation (*Large black arrows*).

The hypothalamo-pituitary-gonadal feedback system is a very delicately modulated hormonal process. Several sites in the endocrine process can be perturbed by drugs (e.g., oral contraceptives) and by different chemicals (Fig. 20-9). Gonadotoxic agents may act on neuroendocrine processes in the brain or they may act directly on the target organ (e.g., gonad). Toxicants that adversely or otherwise alter the hepatic and/or renal biotransformation of endogenous sex steroid might be expected to interfere with the pituitary feedback system (cf. Cooper, et al., 1998).

Puberty

From the early newborn period to the onset of puberty, the testes remain hormonally dormant. After birth, the androgen-secreting Leydig cells in the mammalian fetal testes become quiescent, and a period follows in which the gonads of both sexes await final maturation of the reproductive system.

The onset of puberty begins with secretion of increasing levels of gonadotropins. The physiologic trigger for puberty is poorly understood, but somehow a hypothalamic gonadostat changes the rate of secretion of LHRH, resulting in increases in LH. As puberty approaches, a pulsatile pattern of LH and FSH secretion is observed. The gonad itself is not required for activating FSH or LH at the onset of puberty. It is a CNS phenomenon. Female puberty is affected by a wide range of influences including climate, race, heredity, athletic activity, and degree of adiposity.

SEXUAL BEHAVIOR AND LIBIDO

Physiologic processes that account for sexual behavior are poorly understood. The external environment greatly affects sexual behavior, and libido components of reproductive activity depend on a close interplay between neural and endocrine events. For example, a correlation of behavior and receptivity for insemination is attained by complex neuroendocrine mechanisms involving the brain, the pituitary, and sex steroid hormones. This complexity varies even among higher vertebrates. Thus, in reproductive studies involving rodents, the investigator must determine whether the animals actually mate. In the rat, this can be determined by inspecting females each day for vaginal plugs. The number of mountings, thrusts, and ejaculations each can be quantified as indicators of reproductive behavior. It is also important to determine whether the male animal mounts females or other males. If the male copulates and is still sterile, indicators of male fertility such as testicular function should be considered. Failure to copulate suggests either a neuromuscular and/or behavioral defect in the experimental animal.

GENERAL TOXICOLOGIC/ PHARMACOLOGIC PRINCIPLES

Many of the principles that govern absorption, distribution, metabolism, and excretion of a chemical or drug also apply to the reproductive system. There are, however, some rather unique barriers that affect a chemical's action on the mammalian reproductive system. The maternal-fetal interface occurring at the placenta represents a barrier to chemicals coming in contact with the developing embryo. Unfortunately, the placenta is not so restrictive as to prevent most chemicals from crossing the placenta. Most chemicals are not denied entrance into a number of compartments or secretions of the reproductive tract. Indeed, xenobiotic and certain drugs can be readily detected in uterine secretions, in milk of the lactating mother, and in seminal fluid (Mann and Lutwak-Mann, 1981). No specialized barriers appear to prevent chemicals or drugs from acting on the ovary. Several drugs are known to interfere with ovarian function (Table 20-6) (Gorospe and Reinhard, 1995). Unlike the female gonad, the male gonad has a somewhat specialized barrier. This specialized biological barrier is referred to as the blood–testis barrier.

Table 20-6 Inhibitors of Steroidogenic Enzymes

Blood–Testis Barrier

There are a number of specialized anatomic barriers in the body. Tissue permeability barriers include the blood–brain barrier, the blood–thymus barrier, and the blood–bile barrier. Important barriers within the endocrine system are the placental barrier and the blood–testis barrier. The blood–testis barrier is situated somewhere between the lumen of an interstitial capillary and the lumen of a seminiferous tubule (Neaves, 1977). Several anatomically related features intervene between the two luminal spaces, including the capillary endothelium, capillary basal lamina, lymphatic endothelium, myoid cells, basal lamina of the seminiferous tubule, and Sertoli cells. The barrier that impedes or denies the free exchange of chemicals/drugs between the blood and the fluid inside the seminiferous tubules is located in one or more of these structures. The apparent positioning of distances relative to transepithelial permeability can affect the passage (or blockage) of a substance through the blood–testis barrier. These epithelial cell anatomic relationships can affect the tightness of fit between cells and the extent to which a chemical's passage can occur. Such junctions or cell unions are often leaky and may allow for a substance's passage. These so-called gap junctions may even be less developed in the immature or young mammalian testes, hence affording greater opportunities for foreign chemicals to permeate the seminiferous tubule. Steinberger and Klinefelter (1993) have developed a two-compartment model for culturing testicular cells that similates a blood–testis barrier. This culture model has been proposed to study Sertoli cell and Leydig cell dysfunction in vitro.

Setchell and coworkers (1969) first demonstrated that immunoglobulins and iodinated albumin, inulin, and a number of small molecules were excluded from the seminiferous tubules by the blood–testis barrier. Dym and Fawcett (1970) suggested that the primary permeability barrier for the seminiferous tubules was composed of the surrounding layers of myoid cells while specialized Sertoli cell-to-Sertoli cell junctions within the seminiferous epithelium constituted a secondary cellular barrier. Certain classes of adhesive molecules (e.g., E- and N-cadherin, a- and b-catenin, plakoglobin, etc.) may act to promote Sertoli-to-Sertoli cell adhesion and tight junction formation (Byers, et al., 1994) (see also Fig. 20-4).

Okumura and coworkers (1975) quantified permeability rates for nonelectrolytes and certain chemicals/drugs. Low-molecular-weight molecules (e.g., water, urea) can readily cross the blood–testis barrier; larger-sized substances (e.g., inulin) are impeded. The degree of lipid solubility and ionization are important determinants as to whether a substance can permeate the blood–testis barrier. A number of factors are known to affect the permeability of the blood–testis barrier, including ligation of the efferent ductules, autoimmune orchiditis, and vasectomy (cf. Sundaram and Witorsch, 1995).

Biotransformation of Exogenous Chemicals

Testes The mammalian gonad is capable of metabolizing a host of foreign chemicals that have traversed the blood–testis barrier. While mixed-function oxidases and epoxide-degrading enzymes may not be as active as hepatic systems, they are nevertheless present in the testes. Cytochrome P450, in general, is quite sensitive to the effects of a number of chemicals. Gonadal cytochrome P450 is no exception. Arylhydrocarbon hydroxylase (AHH) is present in testicular microsomes (Lee et al., 1981). Consequently, the pathways for steroidogenesis contain a number of enzymes that are affected by chemicals or drugs (Table 20-6). Like the process of steroidogenesis in the gonads, the adrenal cortex is also vulnerable to chemical insult (cf. Colby, 1988). Both the parent compound and its metabolite(s) can adversely affect the gonad (Table 20-7). Whether biotransformation occurs gonadally or extragonadally, the end result can be interference with spermatogenesis and/or steroidogenesis. Their mechanisms of toxicity vary considerably.

Table 20-7 Biotransformation of Drugs, Chemicals, and Their Metabolites—Ability to Exert Toxic Actions on the Male Gonad

The microsomal ozidation of *n*-hexane yields 2,5-hexanedione (2,5-HD). *N*-hexane, an environmental toxicant, causes peripheral polyneuropathy and testicular atrophy (Boekelheide, 1987, 1988). The testicular toxicity is separate from its neurotoxicity. 2,5-HD produces gonadal toxicity by altering testicular tubulin. The HD testicular toxicity results from alterations in Sertoli cell microtubules and the altered microtubules result from pyrole-dependent cross-linking (cf. Li and Heindel, 1998). HD toxicity is slow in onset. Initially, HD affects the cross-linking of cytoskeletal elements leading to altered protein secretions and trafficking in the Sertoli cell. Consequently, there is altered Sertoli cell–germ cell contacts and a loss of Sertoli cell paracrine support of the germ cells (Richburg, et al., 1994; Li and Heindel, 1998).

Ethylene glycol monoethyl ether, along with its metabolites, is a gonadal toxin (Nagano et al., 1979; Wang and Chapin, 2000). Metabolites such as 2-methoxy-ethanol (2-ME) and 2-etho-xyethanol (2-EE) induce testicular toxicity. They may cause testicular atrophy, decreased sperm motility, and an increased incidence of abnormal sperm. Most likely, the metabolism of monoalkyl glycol ethers occurs via alcohol and aldehyde dehydrogenases, leading to the formation of methoxyacetic acid (MAA). MAA is believed to be the ultimate toxic metabolite of 2-ME. However, methoxyacetaldehyde (MALD), an intermediate metabolite of 2-ME, can also produce testicular lesions (Foster et al., 1986; Feuston et al., 1989). Although the site of action was thought to be upon the late spermatocyte, it now appears that the Sertoli cells are the prime target for 2-ME (cf. Li and Heindel, 1998). It is unclear whether the mechanism of testicular toxicity of 2-ME induces germ cell death by reducing the available purine bases causing decreased RNA synthesis in spermatocytes or that 2-ME induces germ cell death by interfering with interregulating signal transduction pathways within either Sertoli cells or germ cells, causing a disruption of cell-to-cell communication (Li and Heindel, 1998).

Dinitrobenzene (DNB) or 1,3 dinitrobenzene can cause testicular toxicity in rats. The toxicity is species- and age-dependent and can be partially reversible (cf. Li and Heindel, 1998). DNB causes vacuolization of the Sertoli cells and the detachment of germ cells (Foster et al., 1992). The mechanism of toxicity of DNB is unclear, but both Sertoli cells and germ cells may be affected.

Several heavy metals are known to adversely affect testicular function (cf. Thomas, 1995a). Cadmium causes testicular toxicity, which consists of a loss of endothelial tight junctional barriers, leading to edema, increased fluid pressure, ischemia, and tissue necrosis. Cadmium's effect on Sertoli cell tight junctions (namely the blood–tubule barriers) may be due to its actions on the actin filaments associated with these junctions (cf. Li and Heindel, 1998). Like other Sertoli toxicants (e.g., HD, DNB, 2-ME, and phthalates), testicular toxicity is age-related. Some species are more sensitive than others. Cadmium-induced capillary toxicity (e.g., pampiniform plexus) leads to necrosis and ischemia. Cadmium, at least at low doses, appears to be a stage-specific Sertoli cell toxicant.

Esters of *c*-phthalic acid (phthalate esters or PAEs) are used extensively in medical devices and other consumer products as plasticizers. Because the PAEs are not convalently bound to the plastic, they can leach into the environment (cf. Thomas and Thomas, 1984). There are several different PAEs exhibiting varying degrees of testicular toxicity, particularly in rats and mice. Diethyl hexyl phthalate (DEHP) and its metabolite monoethyhexyl phthalate (MEHP) cause early sloughing of spermatids and spermatocytes and severe vacuolization of Sertoli cell cytoplasm. Gray and Beamand (1984) proposed that the mechanism of DEHP-induced testicular atrophy involves a membrane alteration leading to separation of germ cells (spermatocytes and spermatids) from the underlying Sertoli cells. The action of MEHP has been attributed to its ability to reduce FSH binding to Sertoli cell membranes (Grasso, et al., 1993). The separation of spermatocytes and spermatids interferes with the transfer of nutrients from the Sertoli cells, leading to death and disintegration of the germ cells. MEHP, and not DEHP, is most likely the proximate testicular toxicant (Albro, et al., 1989). MEHP increases germ cell detachment from the Sertoli cell. MEHP is the only phthalate monoester that reduced Sertoli cell ATP levels. It specifically inhibits FSH-stimulated cAMP accumulation in Sertoli cell cultures (cf. Li and Heindel, 1998). The collapse of vimentin filaments in Sertoli cells by MEHP appears to lead to a loss of Sertoli–germ cell contacts (Richburg and Boekelheide, 1996). Finally, DEHP is not only a reproductive toxicant in the male (e.g., rodents) but it can significantly suppress preovulatory follicle granulosa cell estradiol production (Davis et al., 1994a).

Many other chemicals can produce testicular toxicity, but less information is generally available about their mechanism(s) than some of the more well-studied Sertoli cell toxicants (e.g., HD, DNB, PAE, cadmium, and glycol ethers). Vinclozolin, a fungicide that undergoes biotransformation, produces at least two major metabolites that can effectively act as antagonists to the androgen receptor (Kelce et al., 1994). Epichlorohydrin, a highly reactive electrophile used in the manufacture of glycerol and epoxy resins, produces spermatozoal metabolic lesions (cf. Toth et al., 1989). Tri-*o*-cresyl phosphate (TOCP), an industrial chemical used as a plasticizer in lacquers and varnishes, decreases epididymal sperm motility and density. TOCP interferes with spermatogenic processes and sperm motility directly and not via an androgenic mechanism or decreased vitamin E (Somkuti et al., 1987).

The male reproductive system can be adversely affected by 2,3,7,8-tetrachlorodibenzo- *p*-dioxin (TCDD) (cf. Bjerke and Peterson, 1994; Zacharewski and Safe, 1998). TCDD can alter germ cells at all developmental stages in the testes (Chahoud et al., 1992). Dioxin can reduce Leydig cell volume, but at doses that do not appear to affect spermatogenesis (Johnson et al., 1992). In rodents, TCDD is both embryotoxic and teratogenic (cf. Dickson and Buzik, 1993). TCDD has an avidity for the estrogen receptor (cf. Hruska and Olson, 1989) and other receptors (e.g., Ah receptor). Recently, the safety assessment of the polychlorinated biphenyls (PCBs), with particular reference to reproductive toxicity, has been reviewed (Battershill, 1994; Birnbaum, 1998).

2-Methoxylethanol (2-ME), an industrial solvent, is toxic to both the male and female reproductive system (Mebus et al., 1989). 2-ME must be metabolized to 2-methoxyacetic acid (2-MAA) by alcohol and aldehyde dehydrogenases in order to attain its testicular toxicity. All stages of spermatocyte development and some stages of spermatid development are affected by 2-ME, but it seems to be more selective in destroying early- and late-stage pachytene primary spermatocytes. 2-ME is also embryotoxic and teratogenic in several species (Hanly et al., 1984). 2-ME (also known as methyl cellosolve) when applied dermally can produce a decline in epididymal sperm and testicular spermatid counts in rats (Feuston et al., 1989). Ethanol also causes delayed testicular development and may affect the Sertoli cell and/or the Leydig cell (Anderson et al., 1989). Trifluoroethanol and trifluoroacetaldehyde produce specific damage to pachytene and dividing spermatocytes and round spermatids in rats (Lloyd et al., 1988). Ethane dimethane sulfonate (EDS) effectively eradicates Leydig cells and endogenous testosterone (cf. Bremner, et al.,

Metabolites of cephalosporin reportedly cause testicular toxicity in rats (Comereski et al., 1987). Testicular degeneration from analogs of cephalosporin is most likely to occur with cefbuperazone, cefamandole, and cefoperazone. Cyclosporine can also inhibit testosterone biosynthesis in the rat testes (Rajfer et al., 1987). Amiodarone and its desethyl metabolite can be detected in high concentrations in the testes and semen, but their effects on spermatogenesis or sperm motility are not known (Holt et al., 1984).

Ovary Like the testes, the ovary has the metabolic capability to biotransform certain exogenous substrates. Furthermore, the process of ovarian steroidogenesis, like that of the testes and the adrenal cortex (cf. Colby, 1988), is susceptible to different agents that interfere with the biosynthesis of estrogens (see Table 20-6). Less is known about how chemicals or drugs interfere with ovarian metabolism. The ovary has not been studied as extensively because of its more difficult and complex hormonal relationships. Nevertheless, several chemotherapeutic agents can inhibit ovarian function (Table 20-8). Recently, Faustman et al. (1989) have studied the toxicity of direct-acting alkylating agents on rodent embryos. Their findings failed to reveal any specific structure/activity patterns among various alkylating agents. Like the testes, mixed-function oxidases and various cytochrome systems are found in the ovary. Primordial oocyte toxicity as well as toxicity at other sites can be affected by certain chemicals or drugs (Haney, 1985).

Prednisone	Busulfan

Table 20-8 Chemotherapeutic Agents and Ovarian Dysfunction

DNA Repair

Alkylating Agents Depending on the species, there are varying degrees of capacity for spermatogenic cells to repair DNA damage due to environmental toxicants (Lee, 1983). It is well known that ultraviolet and x-rays can damage DNA molecules; lethal mutation (i.e., cell deaths) and mutation resulting from transformed cells can also occur. Spermatogenic cells can be used to study unscheduled DNA synthesis (Dixon and Lee, 1980). Unscheduled DNA repair in spermatogenic cells is dose- and time-dependent. Spermiogenic cells are less able to repair DNA damage resulting from alkylating agents. This DNA repair system provides a protective mechanism from certain toxicants; it is also a sensitive index of chromosome damage.

Drug-induced unscheduled DNA synthesis in mammalian oocytes reveals that female gametes possess an excision repair capacity (Pedersen and Brandriff, 1980). Unlike mature sperm, the mature oocyte maintains a DNA repair ability. However, this ability decreases at the time of meiotic maturation.

Lead Different occupations can result in varying degrees of chromosomal aberration (Table 20-9). In particular, lead toxicity can induce a variety of chromatid and chromosome breaks. Lead is one of the earliest substances associated with deleterious effects on the reproductive system (Thomas and Brogan, 1983). Lead poisoning has been associated with reduced fertility, miscarriages, and stillbirth since antiquity (Lancranjan et al., 1975). Lead salts are among the oldest known spermicidal agents; lead has long been known to be an abortifacient *(cf.* Hildebrand et al., 1973). Lead exposure results in a general suppression of the hypothalamic-pituitary-testicular axis in rats (Klein et al., 1994) and possibly in men occupationally exposed to this heavy metal (Rodamilans et al., 1988) (Table 20-10).

EXPOSED SUBJECTS	TYPE OF ABERRATION
Positive findings	
Lead oxide factory workers	Chromatid and chromosome breaks
Chemical factory workers	Chromatid gaps, breaks
Zinc plant workers	Gaps, fragments, rings, exchanges, dicentrics
Miscellaneous workers, metal grinders, scrap workers	Gaps, breaks, hyperploidy, minimal abnormalities
Battery plant workers and lead foundry workers	Gaps, breaks, fragments
Lead oxide factory workers	Chromatid and chromosomal aberrations
Battery molters, tin workers	Dicentrics, rings, fragments
Ceramic, lead, and battery workers	Breaks, fragments
Smelter workers	Gaps, chromatid and chromosome aberrations
Battery plant workers	Chromatid and chromosome aberrations
Negative findings	
Policemen

Table 20-10 Some Actions of Lead on the Male Reproductive System

TARGETS FOR CHEMICAL TOXICITY

CNS

There are several sites of interference by chemicals upon the mammalian reproductive system (Fig. 20-9). Drugs and chemicals can act directly on the CNS, particularly the hypothalamus and the adenohypophysis (cf. Cooper et al., 1998). A number of drugs (e.g., tranquilizers, sedatives, etc.) can modify the CNS, leading to alterations in the secretion of hypothalamic-releasing hormones and/or gonadotropins. Synthetic steroids (namely 19-nortestosterones) are very effective in

suppressing gonadotropin secretion and hence block ovulation.

Gonads

The gonads are also targets for a host of drugs and chemicals (Table 20-11) (Chapman, 1983; Thomas and Keenan, 1986). The majority of these agents are representatives of major chemical classes of cancer chemotherapeutic agents, particularly the alkylating agents. A number of endocrine agents are of value in the treatment of certain cancers. Antiestrogens (e.g., tamoxifen), aromatase inhibitors (e.g., aminoglutethimide), GnRH agonists and antagonists, and antiandrogens (e.g., flutamide) can interfere with the endocrine system (cf., Lonning and Lien, 1993). Procarbazine, an antineoplastic drug, causes severe damage to the acrosomal plasma membrane and the nucleus of the sperm head in hamsters (Singh et al., 1989). Alkylating agents are effective against rapidly dividing cells. Not surprisingly, the division of germ cells is also affected, leading to arrest of spermatogenesis.

Table 20-11 Drugs That Are Gonadotoxic in Humans

Different cell populations of the mammalian testis exhibit somewhat different thresholds of sensitivity to different toxicants (Fig. 20-5). Thus, the germ cells are most sensitive to chemical insult (i.e., spermatogenesis). The Sertoli cells possess a somewhat intermediate sensitivity to chemical inhibition; Leydig cells are quite resistant to environmental toxicants. Cell-specific testicular toxicants have been employed to evaluate the distribution of creatine in the rete testis (Moore et al., 1992). Creatine is associated with cells of the seminiferous epithelium: elevated urinary excretion of creatine may provide a noninvasive marker for testicular toxicity in vivo.

Sertoli Cells (See also "Biotranformation of Exogenous Chemicals—Testes," above.) Dibromochloropropane (DBCP), a fungicide, causes infertility in a number of species, including humans. DBCP causes sterility, but it may do so by acting through the Sertoli cell. DBCP may also inhibit sperm carbohydrate metabolism at the NADH dehydrogenase step in the mitochondrial electron transport chain (Greenwell et al., 1987). Despite DBCP's propensity to cause degeneration of the seminiferous tubules, toxicokinetic studies fail to reveal any preferential uptake by the testes (Shemi et al., 1987). DBCP gonadotoxicity appears to be gender-specific, since only testicular injury has been reported; it does not cause comparable adverse effects in the female rat (Shaked et al., 1988). Analogs of DBCP cause testicular necrosis as well as DNA damage in the rat (Soderlund, et al., 1988).

The production of lactate and pyruvate are indicators of Sertoli cell function (Williams and Foster, 1988). Either dinitrobenzene (DNB) or mono-(2-ethylhexyl)phthalate (MEHP) can affect lactate (and pyruvate) production by rat Sertoli cell cultures. The Sertoli cell appears to be a prime target for the toxic actions of DNB (Blackburn, et al., 1988). Chapin et al. (1988) have also indicated that MEHP adversely affects the mitochondria of the Sertoli cell in vitro. Likewise, dinitrotoluene (DNT) has a locus of toxic action that is the Sertoli cell (Bloch et al., 1988). Dinitrobenzene initially damages Sertoli cells with a subsequent degeneration and exfoliation of germ cells.

Steroidogenesis Steroid biosynthesis can occur in several endocrine organs including the adrenal cortex, ovary, and the testes. Other peripheral tissues and the CNS contain enzymatic systems also capable of steroid synthesis. Pregnenolone is the common precursor of all steroid hormones produced by the adrenal cortex (e.g., mineratocorticoids and glucocorticoids), the ovary (e.g., estrogens and progesterone), and the testes (e.g., androgens). Specific subpopulations of cells in the mammalian gonad are capable of synthesizing steroids. In the ovary, the granulosa cells secrete estrogens in response to FSH. The thecal cells of the ovary secrete progesterone (as does the corpus luteum) (see Fig. 20-7). In the testes, the Leydig cell (or the interstitial cell) in response to LH (or ICSH) secretes androgens (e.g., testosterone and dihydro-testosterone).

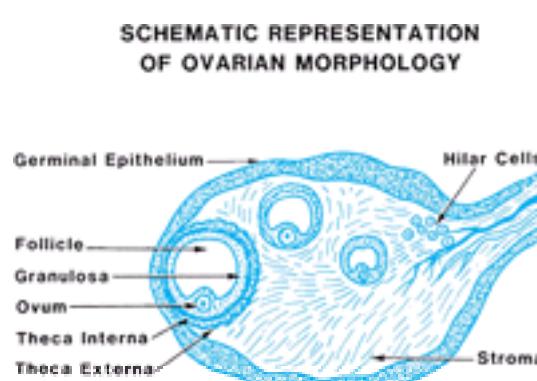
SCHEMATIC REPRESENTATION
OF OVARIAN MORPHOLOGY


Figure 20-7. Schematic representation of ovarian morphology.

Several drugs, hormones, and chemicals can affect steroidogenesis (see Table 20-7) by interfering or inhibiting specific enzymes (see also "Biotransformaton of Exogenous Chemicals," above). Also, anti-LH peptides can affect Leydig cell steroidogenesis. LHRH analogs (e.g., buserelin) can interfere with both ovarian and testicular function (Donaubauer et al., 1987).

The liver and the kidney contain enzyme systems that affect the biological half-life of steroids and other hormones. Hence, xenobiotics that interfere with excretory processes might be expected to alter the endocrine system. For example, a number of hepatic steroid hydroxylases can be induced by either organophosphates or organochlorine pesticides. Such hydroxylation reactions can be expected to render the endogenous steroid more polar and hence more readily excreted by the kidney.

EVALUATING REPRODUCTIVE CAPACITY

A number of hormone assays are available to assess endocrine function (Thomas and Thomas, 2001). The endocrine system of the female is more complex and dynamic than that of the male. Hence, evaluating reproductive function in the female is more difficult. Immediate distinctions must also be made between the pregnant and the nonpregnant female. Regardless of gender, both behavioral and physiologic factors must be considered in evaluating reproductive toxicity. The physiologic events involved in reproduction involve inherent time factors that are species-specific. Often, evaluating the potential of a chemical or drug to affect the reproductive system is costly and time-consuming. Furthermore, many of the endpoints used to evaluate the reproductive system are not always reliable and have limitations (Table 20-12).

ENDPOINT	LIMITATIONS	VALUE
Fertility	Insensitive	Integrates all reproductive functions
Testicular histology	Subjective; not quantitative	Information on target cell
Testis weights	Less sensitive than sperm counts; affected by edema	Rapid quantitative

Table 20-12 Advantages and Limitations of Standard Reproductive Procedures

The fact that such a wide variety of chemicals and drugs can perturb the reproductive system adds another dimension of difficulty in attempting to evaluate reproductive toxicity. Not only is there considerable diversity in chemical configuration of the toxicant, but sites and mechanisms of action can be very different. It is obvious that several classes of therapeutic agents can affect both the male and the female reproductive systems.

TESTING MALE REPRODUCTIVE CAPACITY

General Considerations

A host of tests have been used or proposed for evaluating the male reproductive system (Table 20-13). Several cellular sites or processes are vulnerable to chemical and/or drug insult. Perturbation of many of the endocrine or biochemical events associated with the male reproductive system seldom occurs after a single exposure to a toxicant(s). Rather, multiple exposure extended over some length of time are most likely required to detect male reproductive toxicity. Most of the tests are invasive and hence limited to animals and not generally acceptable for use in humans. Indeed, in humans, the noninvasive approaches involve sperm counts, blood gonadotrophin levels, and a nonbarren marriage. Testicular biopsy can be used in selected circumstances to evaluate spermatogenesis (i.e., infertility/sterility), but this procedure is obviously invasive. Azoospermia can be caused by certain chemical agents, genetic disorders (e.g., Klinefelter's syndrome), infections (e.g., mumps), irradiation, and hormonal defects. Dietary deficiencies are well known to cause spermatogenic arrest (Table 20-14). Similarly, lead can produce infertility, sterility, and varying abnormalities in sperm function and morphology (Table 20-10). Pogach et al., (1989) have reported that cisplatin causes Sertoli cell dysfunction in rodents. These changes in Sertoli cell function appear to be responsible for cisplatin-induced impairment in spermatogenesis. Other heavy metals such as cobalt, iron, cadmium, mercury, molybdenum, and silver can adversely affect spermatogenesis and accessory sex organ function. Dietary zinc deficiency can produce sterility (Prasad et al., 1967). Likewise, chemically induced zinc depletion (e.g., phthalates) can produce testicular damage, as evidenced by sterile seminiferous tubules (Thomas et al., 1982). In experimental animals, zinc prevents cadmium carcinogenicity in the rat testes (Koizumi and Waalkes, 1989). The major preventive effect of zinc against cadmium-induced testicular tumors may be due to its ability to reduce the cytotoxicity of cadmium in interstitial cells. Different heavy metals seem to exert their toxic effects upon different subpopulations of testicular cells (Table 20-15). Mechanisms of heavy metal toxicity vary and include not only different cell sensitivities but also direct versus indirect actions. Furthermore, it appears that primary damage to one cell type may secondarily affect other cell types in the testes.

Table 20-13 Potentially Useful Tests of Male Reproductive Toxicity for Laboratory Animals and/or Humans[13]

DEFICIENCY	SPECIES
Manganese	Rats and rabbits
Vitamin A	Mice, rats, and guinea pigs
Vitamin B (pyridoxine)	Rats
Vitamine E	Rats, hamsters, and guinea pigs
Zinc	Mice, rats, dogs, and sheep

Table 20-14 Dietary Deficiency(s) and Spermatogenic Arrest

Table 20-15 Summary of Cellular Site(s) of Action of Excess Heavy Metals on the Male Reproductive System

The sensitivity of the various parameters used to evaluate the male reproductive system varies considerably. There are advantages as well as limitations to a number of standard reproductive procedures. Testicular weight is a rapid quantitative index, but this measurement is less sensitive than sperm counts and is affected by water

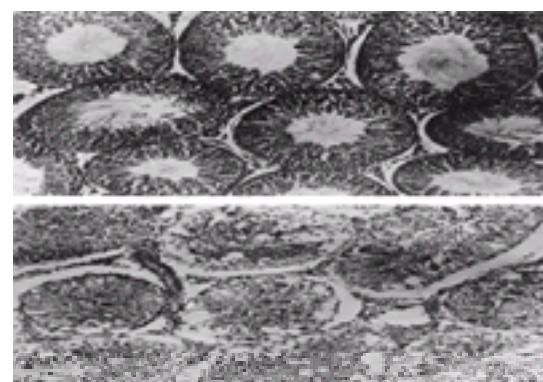
imbibition (edema). In normal males, the number of sperm produced per day per testis is largely determined by testicular size. In many mammals, testis size is correlated to daily sperm production. Fertility as an index is quite insensitive, although it does incorporate all reproductive functions. Fertility profiles using serial mating studies to assess the biological status of sperm cells have been a useful test for both dominant lethal mutations (Epstein et al., 1972) and male reproductive capacity (Lee and Dixon, 1972). Testicular histology provides information on target cell morphology, although it too is subjective and not particularly quantitative. Histologic evaluation of the seminiferous tubules can establish cellular integrity and provide information about the process of spermatogenesis (Fig. 20-10). Good tissue fixation is essential for detecting the more subtle changes in the seminiferous epithelium (cf. Creasy, 1997). It is more difficult to detect morphologic changes in Leydig cells and to some extent Sertoli cells. Leydig cell function is better determined by evaluating androgen levels (or gonadotropins) or, in the case of Sertoli cells, by the measurement of androgen-binding protein (ABP).


Figure 20-10. Histology section of rat testes.

Above: Normal H&E section revealing morphologic integrity of seminiferous tubules. Below: Chemically induced testicular damage resulting in vacuolation of seminiferous tubules. Note partially sterile tubules. (From Thomas and Thomas, 1994, with permission.)

In order to undertake a meaningful histologic evaluation of the testes, it is necessary to understand the spermatogenic cycle and to identify its various stages. The use of seminiferous tubule staging is very important to the evaluation of testicular injury (Creasy, 1997). If damage is detected, it must be characterized. For example, Sertoli cell damage is frequently recognized by inter- or intracellular vacuoles or by swelling of the basal Sertoli cell cytoplasm. Morphologic changes in the Leydig cell may be more difficult to detect. Degeneration and necrosis of germ cells can be recognized by the normal criteria of nuclear pyknosis and cytoplasmic eosinophilia. Some quantitative assessment of the histology of the testes includes measuring tubular diameter and cell counts of spermatocytes or round spermatids.

Thus, there are essentially two approaches to establish-ing whether or not a chemical is able to exert an adverse effect on spermatogenesis: (1) evaluation of testicular morphology (i.e., pathology) and (2) functional evaluation of spermatogenesis (Sharpe, 1998). Included in the assessment are the detection of abnormalities in spermatogenesis/testicular morphology, stage-dependent germ cell degeneration, and impairment of normal sperm release.

Flow Cytometry

Flow cytometric analyses of the testes can be used to evaluate specific cell populations (Selden et al., 1989). This technique has the advantage of being able to assess simultaneously multiple characteristics on a cell-to-cell basis, with the results being rapidly correlated for each cell type or property. Cell size, cell shape, cytoplasmic granularity and pigmentation, along with measurements of surface antigens, lectin binding, DNA/RNA, and chromatin structure are among some of the intrinsic and extrinsic parameters that can be evaluated. The toxic effects of thiotepa on mouse spermatogenesis have been determined using dual-parameter flow cytometry. The dual parameters of DNA stainability versus RNA content provide excellent resolution of testicular cell types (Evenson et al., 1986). Flow cytometry has also been used to study the effects of methyl-benzimidazol-2-yl-carbamate (MBC) on mouse germ cells. MBC exposure results in an altered ratio of testicular cell types, abnormal sperm head morphology, and altered sperm chromatin structure (Evenson et al., 1987).

Oxidative damage to spermatogenic cells has also been associated with reproductive dysfunction in laboratory animals, and this too can provide an index for assessing risk. Angioli et al., (1987) have proposed an in vitro spermatogenic cell model for assessing reproductive toxicity; it involves the ability of bleomycin to reduce oxidative changes in male germ cell populations.

Penetration of zona-free hamster eggs by human sperm has also been suggested as a useful chemical test to assess male fertility. Recently, this assay has also been recommended as a prognostic indicator in in vitro fertilization programs (Nahhas and Blumenfeld, 1989).

Sex Accessory Organs

The epididymis and the sex accessory organs can also be used to evaluate the status of male reproductive processes. While the epididymis has an important physiologic role in the male reproductive tract, it is less useful as a parameter for assessing gonadotoxins. Its histologic integrity may be examined, but the most meaningful determinations are the number of sperm stored within the cauda epididymis and a measure of sperm motility and morphology. Epididymal sperm may be extruded onto a glass slide and viewed under the microscope for motility and abnormalities. Sex accessory organs, usually the prostate (e.g., ventral lobes in the rodent) and the seminal vesicles (empty), provide a rapid and quantitative measure of the male reproductive processes that are androgen-dependent. Chemical indicators in sex accessory glands such as fructose and citric acid have also been used to evaluate male sex hormone function (cf. Mann and Lutwak-Mann, 1981).

Semen Analyses

Semen analysis can be used as an index of testicular and posttesticular organ function. Semen can be collected from a number of experimental and domestic animals using an artificial vagina. Electroejaculatory techniques and chemically induced ejaculations have also been employed to produce semen samples, particularly in animal husbandry. In humans, several trace elements—including Ca, Cd, Co, Cr, Cu, Fe, Mg, Mn, Mo, Ni, Pb, Rb, Se, Vd and Zn—can be detected in seminal plasma (Abou-Shakra et al., 1989).

Both quantitative and qualitative characteristics of more than one ejaculate must be evaluated to ensure that conclusions concerning testicular function are valid. Since semen represents contributions from accessory sex glands as well as the testes and epididymides, only the total number of sperm in an ejaculate is a reliable estimate of sperm production. The number of sperm introduced into the pelvic urethra during emission and the volume of fluid from the accessory sex glands are independent. The potential sources of error in measuring ejaculate volume, concentration, and the seminal characteristics necessary to calculate total sperm per ejaculate must be considered (Amann, 1981).

There have been recent advances in the automation of semen analysis. Semiautomated measures of sperm motility may be categorized as indirect or direct methods. Indirect methods of sperm analysis estimate mean swimming speed of cells by measuring properties of the whole sperm suspension. Spectrometry or turbidimetric methods record changes in optical density. Direct methods involve visual assessment of individual sperm cells and stem from early efforts to quantitate sperm swimming speed. Such direct measurements may include photographic methods like timed-exposure photography, multiple-exposure photography, and cinematography. Computer-aided sperm motion analysis (CASMA) may be applied to morphology, physiology, motility, or flagellar analysis. CASMA allows visualization of both digitized static and dynamic sperm images. Semen analysis and fertility assessment should recognize statistical power and experimental design for toxicologic studies (Williams et al., 1990).

Sperm Counts and Motility

Several factors affect the number of sperm in an ejaculate, including age, testicular size, frequency, degree of sexual arousal, and seasons (particularly in domestic animals) (cf. Thomas, 1996). Although ejaculatory frequency or the interval since the last ejaculation alters the total number of sperm per ejaculate, ejaculation frequency does not influence daily sperm production. However, because of epididymal storage, frequent ejaculation is necessary if the number of sperm counted in

ejaculated semen is to reflect sperm production accurately. If only one or two ejaculates are collected weekly, a 50 percent reduction in sperm production probably would remain undetected. Ejaculates should be collected daily (or every other day) over a period of time. The analysis of isolated ejaculate or even several ejaculates collected at irregular intervals cannot estimate sperm production or output. The first several ejaculates in each series contain more sperm than subsequent ejaculates because the number of sperm available for ejaculation is being reduced.

In experimental animals (e.g., rodents), epididymal sperm may be extruded, diluted with saline in a hemocytometer, and counted. Sperm motility may also be assessed. Sperm morphology may be evaluated using either wet preparations or properly prepared stained smears, which require an appropriate classification scheme (Wyrobek, 1983; Wyrobek et al., 1983). Chromosomal analyses can be used in the laboratory or the clinic to diagnose certain genetic diseases.

Androgens and Their Receptors

The androgen receptor (AR) is a member of the steroid/nuclear receptor superfamily, all members of which share a basic and functional homology. AR action is highly specific in spite of the homology between AR and other steroid receptors. The AR is composed of three functional domains. The two predominant naturally occurring ligands of the AR are testosterone and dihydrotestosterone. AR exists as a phosphoprotein in different cell types (cf. MacLean et al., 1997).

Androgen receptors for testosterone and dihydrotestosterone (DHT) have also been used to evaluate the effects of various gonadotoxins. A number of divalent metal ions (Zn, Hg, Cu, Cd, etc.) can inhibit androgen-receptor binding in rodent prostate glands (Donovan et al., 1980). In addition to heavy metals interfering with androgen binding, DDT and *p,p*'-DDE are potent androgen receptor antagonists and can affect male reproduction (Kelce et al., 1995). The major metabolite of DDT, namely, *p,p*'-DDE, inhibits androgen binding to the androgen receptor as well as androgen-induced transcriptional activity. Hydroxyflutamide and *p,p*'-DDE were equally effective in inhibiting androgen-induced transcriptional activity.

Hormonally active androgens promote reproductive and anabolic (myotropic) functions. Both reproductive and anabolic effects of androgens are mediated by their interaction with AR (cf. Roy et al., 1999). Hormonally active androgens are C-19 steroids with an oxo-functional group at the C-3 position and a hydroxy group at 17b. Androgen target cells (e.g., prostate gland, seminal vesicles) contain steroid-modifying enzymes that can activate, inactivate, and alter the receptor specificity of androgens. For example, steroid 5a-reductase converts testosterone to 5a-dihydrotestosterone, which is a more potent androgenic ligand. Many factors can affect androgenic actions (Table 20-16).

Table 20-16 Factors Affecting Androgen Effectiveness

Other Secretory Biomarkers

Efforts have been made to identify so-called testicular marker enzymes as indicators of normal or abnormal cellular differentiation in the gonad (Hodgen, 1977; Shen and Lee, 1977; Chapin et al., 1982). At least eight enzymes—hyaluronidase (H), lactate dehydrogenase isoenzyme-X (LDH-X), and the dehydrogenases of sorbitol (SDH), a-glycerophosphate (GPDH), glucose-6-phosphate (G6PDH), malate (MDH), glyceraldehyde-3-phosphate (G3PDH), and isocitrate (ICDH)—have been studied with regard to their usefulness as predictors of gonadal toxicity. Several genes are expressed exclusively in male germ cells (cf. Heckert and Griswold, 1993).

A number of secretory products of the Sertoli cell hold some potential for evaluating male reproductive function. Of the several secretory products of the Sertoli cell (e.g., transferrin, ceruloplasmin, tissue plasminogen activator, sulfated glycoproteins), androgen-binding protein (ABP) has perhaps received the most attention as a potential indicator for detecting gonadal injury. Sertoli cell ABP and testicular transferrin may be affected by similar regulatory agents (e.g., FSH, insulin) (Skinner et al., 1989). Leydig cell cultures can also be considered as a potential indicator to evaluate endocrine function of the gonad (Brun et al., 1991). Pig Leydig cell culture can be used to discriminate between specific and nonspecific inhibitors of steroidogenesis. Leydig cells, like Sertoli cells, secrete a number of proteins, peptides, and other substances [e.g., b-endorphin, corticotropin-releasing factor (CRF)] (Eskeland et al., 1989). The testes contain various neuropeptides and growth factors. These include LHRH, TRH, POMC, oxytocin, vasopressin and still other peptide precursors (cf. Shioda et al., 1994; Spiteri-Grech and Nieschlag, 1993). Many of these factors are involved in the autocrine or paracrine regulation of the testes (Table 20-2). Other than the inhibitory actions of DBCP on Sertoli cell ABP secretions, neither this cell and its secretions nor the Leydig cell has been used in reproductive toxicology evaluation.

TESTING FEMALE REPRODUCTIVE CAPACITY

General Considerations

The evaluation of mammalian reproductive processes is far more complex in the female than in the male. Female reproductive processes involve oogenesis, ovulation, the development of sexual receptivity, coitus, gamete and zygote transport, fertilization, and implantation of the concepters. All these processes or events offer potential opportunities for chemical or drug interference.

Evaluation of the female reproductive tract for toxicologic perturbations not surprisingly may overlap with testing methods for assessing teratogenicity and mutagenicity. Indeed, reproductive endpoints that indicate dysfunction in the female (Table 20-17), including perinatal parameters, often overlap with developmental toxicity endpoints (Table 20-18). The neonate is particularly sensitive to a variety of drugs and chemicals (Thomas, 1989).

Table 20-17 Potentially Useful Tests of Female Reproductive Toxicity

Table 20-18 Developmental Toxicity Endpoints

Gross pathology (e.g., gravimetric responses—ovary, uterus, etc.) and histopathology are important to reproductivity and should be evaluated (Ettlin and Dixon, 1985). Both light microscopy and electron (transmission and scanning) microscopy may be useful in assessing ovarian and pituitary ultrastructure. As in the male (Table 20-13), there are a number of useful tests to evaluate the female reproductive system (Table 20-17). These tests can be performed on a wide variety of endpoints, at different anatomic sites, and can include biochemical, hormonal, or morphologic parameters.

Oogenesis/Folliculogenesis

Methods to assess directly the effects of test compounds on oogenesis and/or folliculogenesis include histologic determination of oocytes and/or follicle number (Dobson et al., 1978). Chemical effects on oogenesis can be measured indirectly by determining the fertility of the offspring (McLachlan et al., 1981; Kimmel et al., 1995; Davis and Heindel, 1998). Other indirect measures of ovarian toxicity in animals include assessment of age at vaginal opening, onset of reproductive senescence, and total reproductive capacity (Gellert, 1978; Khan-Dawood and Satyaswaroop, 1995).

Morphologic tests can quantify and assess primordial germ cell number, stem cell migration, oogonial proliferation, and urogenital ridge development. In vitro techniques can be used to evaluate primordial germ cell proliferation, migration, ovarian differentiation, and folliculogenesis (Ways et al., 1980; Thompson, 1981).

Serial oocyte counts can monitor oocyte and/or follicle destruction in experimental animals (Pedersen and Peters, 1968). This approach is a reliable means of quantifying the effects of chemicals on oocytes and follicles.

Follicular growth may be assayed in experimental animals using (^{3}H)-thymidine uptake, ovarian response to gonadotropins, and follicular kinetics (Hillier et al., 1980). These approaches identify both direct and indirect effects on follicular growth and identify drugs and other environmental chemicals that are ovotoxic (Mattison and Nightingale, 1980).

Estrogens and Their Receptors

The rat, mouse, and human estrogen receptor (ER) exists as two subtypes, ERa and ERb, which differ in the C-terminal ligand-binding domain and in the N-terminal transactivation domain (Kuiper et al., 1998). Estrogen influences the growth, differentiation, and functioning of several target organs. Such organs include the mammary gland, uterus, vagina, ovary, and several male reproductive system organs (e.g., testes, prostate gland, etc.). Estrogens affect osteogenesis and the CNS and seem to play a role in the cardiovascular system's homeostasis. Estrogens migrate in and out of cells but are retained with high affinity and specificity in certain target tissues by an intranuclear binding protein called the estrogen receptor (ER). The newly discovered ERb is an important sex hormone receptor not only in the female, but also in the male. It has been suggested that a possible physiologic ligand for ERb in the male is 5a-androstane-3b,17b-diol. This testosterone metabolite binds more firmly to ERb than to ERa. ERa and ERb are differentially expressed along the length of the male reproductive tract. ER are expressed in the Sertoli cell, the Leydig cell, and the epididymis and accessory sex organs. ERb is expressed in Sertoli cells and in most germ cells. The presence of aromatase activity in these two cells suggests that estrogens may be involved in the modulation of spermatogenesis. ERb is expressed in the rodent and human testes (van Pelt et al., 1999). ERa is localized in the nuclei of Leydig cells in fetal and adult rodent testes.

The biological activity of estrogens (and progesterone) is manifest through high-affinity receptors located in the nuclei of specific target cells (Vegeto et al., 1996). The receptors for estrogen (and progesterone) are members of a large superfamily of nuclear proteins. Nuclear hormone receptors are single polypeptides organized into discrete functional domains (i.e., regions A through F).

It is understood that the activation of steroid hormone receptors (e.g., estrogen) regulates the transcriptional activity of specific genes, hence mediating classic or genomic actions of steroid hormones. However, not all steroid effects can be explained by such a classic model of steroid-target cell interaction. Instead, signal-generating steroid receptors on the cell surface have been referred to as nonclassic, nongenomic steroid effects (Revelli et al., 1998). There are several cell types within the reproductive system wherein estrogens exert early physiologic effects that are too rapid to be mediated by the sequence of genomic activation. Signal transduction mechanisms involving nongenomic steroid effects are particularly evident in spermatozoa. Most nongenomic actions of steroids seem to involve Ca^{2+} as a second messenger. It is possible that nongenomic and genomic actions may synergize, resulting in both rapid onset and long-lasting or persistent actions.

Serum levels of estrogen or estrogenic effects on target tissues are indicators of normal follicular function. Tissue and organ responses include time of vaginal opening in immature rats, uterine weight, endometrial morphology, and/or serum levels of FSH and LH. Granulosa cell culture techniques provide direct screens of the ability of chemicals to inhibit cell proliferation and/or estrogen production (Zeleznik et al., 1979). The biosynthesis of estradiol and its metabolism to estrone and estriol by the ovary constitutes another indicator of the reproductive process. The peripheral catabolism of these steroids is principally a function of the liver.

Nuclear and cytoplasmic estrogen/progesterone may provide important toxicologic applications. Estradiol and progesterone receptors are especially important since chemicals (e.g., DDT and other organochlorine pesticides) compete for these receptors and perhaps alter their molecular conformation (Thomas, 1975).

Ovulation/Fertilization/Implantation

Ovulation differs among various mammalian species. Some animals ovulate spontaneously upon copulation (e.g., the rabbit), whereas other species (e.g., humans and subhuman primates) have a hormonally dependent cycle. Several steroidal and nonsteroidal agents can interfere with this neuroendocrine process of ovulation. In the estrus cycle of rodents, ovulation occurs at intervals of 4 to 5 days. Ovulation occurs during estrus and can be readily detected by cornification of vaginal epithelium. The rat's estrus cycle can be divided into four stages and can be recognized by changes in vaginal cytology: proestrus, estrus, metestrus, and diestrus.

The processes of fertilization and implantation can be affected by both chemicals and drugs. The formation, maturation, and union of germ cells compose a complex physiologic event that is sensitive to foreign substances. Fertilization can also be achieved in vitro with sperm and ova extradited from a variety of different mammalian species including humans.

Reproductive performance is best assessed by pregnancy, and this represents a successful index for evaluating endocrine toxicity (or lack thereof). The mating study using rats is a fundamental procedure that determines total reproductive capacity.

REPRODUCTIVE TESTS AND REGULATORY REQUIREMENTS

General Considerations

The history of reproductive guidelines has recently been reviewed (Collins et al., 1998). Over the years several attempts have been made to standardize testing methods. Testing procedures to simulate human exposure have taken two different paths. One is based on the premise that specific injury from a chemical/drug can

be more readily established by administering it only during certain periods of gestation. The second path was devised for compounds likely to involve chronic exposure and for which there may be a concentration factor when administered during several generations. Over the years, many efforts have been undertaken to harmonize testing guidelines (Christian, 1992; 2001.)

Guidelines

Testing guidelines for evaluating reproductive and developmental toxicity in females are outlined in Table 20-19 (Collins et al., 1998) (see also Chap. 10, "Developmental Toxicology"). It may be seen that there is reasonable harmonization between the various regulatory agencies. This condensed table (Table 20-19) does not reveal the protocol for mating procedures, F1 mating, second mating, and other experimental design conditions, but they too are similar among the various regulatory agencies. The reproductive study guidelines of the U.S. Food and Drug Administration (FDA) harmonize with those of the Environmental Protection Agency (EPA) and the [OECD (Organization for Economic Cooperation and Development)]. Some of the guidelines of the [ICH (International Conference on Harmonization)] are blank because these guidelines are intended to be generic (Collins et al., 1998). While guidelines are reviewed periodically to keep abreast of changing science and technology, the FDA's *Redbook II* has reduced the number of generations from three to two. The number of litters/generations has been decreased from two to one. Monitoring of estrous cycle, time of vaginal opening, and time of preputial separation are new requirements. The amount of histopathology, particularly of the pups, has been increased (Collins et al., 1998).

	U.S. FDA (1993)	U.S. EPA (1996)	OECD (1996)	ICH (U.S. FDA 1994)
Number of generations	Two, or less/generation	Two	Two	Not specified
Animal species	Rodent	Rat preferred	Rat preferred	Not specified
Age of animals	5–9 weeks	5–9 weeks	6–9 weeks	
Number of animals	20 ea.	At least 20 pregnant	At least 20 pregnant	Sufficient to allow meaningful interpretation
Dose levels	Minimum three dose levels	Minimum three dose levels	Minimum three dose levels	Minimum three dose levels
Route of administration	Oral (preferred) diet, drinking water, gavage	Oral (preferred) diet, drinking water, gavage	Oral (preferred) diet, drinking water, gavage	Determined by intended human usage
Dosing schedule	8–11 weeks before mating, throughout mating and pregnancy	10 weeks before mating, dosing continued during mating and pregnancy	10 weeks before mating, dosing continued during mating and pregnancy	Treat males and females before mating, during mating and through implantation. Other treatment regimens required.

Table 20-19 Comparison of Reproductive Guidelines

Reproduction (multigenerational) study test guidelines have also undergone some revisions (Collins et al., 1998). The FDA prefers that either the rat or the rabbit be used, with the choice of species based on pharmacokinetic differences. The EPA, OECD, and ICH recommend the most relevant species, but again the rat or the rabbit is often preferred. At least three dose levels are recommended. All adults must undergo necropsy with examination of the uterus and placenta.

The minimal reproductive study recommended consists of two generations, with one litter per generation (Collins et al., 1999). The guideline contains optional procedures for inclusion of additional litters per generation, additional generations, a test for teratogenic and developmental toxicity effects, optional neurotoxicity screening, and optional immunotoxicity screening.

Endpoints—Females

Endpoints in studies of female reproductive toxicity include the following:

- Female fertility index
  [(number of pregnancies/number of matings) × 100]
- Gestation index
  [(number of litters—live pups/number of pregnancies) × 100]
- Live-born index
  [(number of pups born alive/total number of pups born) × 100]
- Weaning index
  [(number of pups alive at day 21/number of pups alive and kept on day 4) × 100]
- Sex ratio and percentage by sex
- Viability index
  [(number of pups alive on day 7/number of pups alive and kept on day 4) × 100]

Endpoints—Males

The endpoints of male reproductive toxicity include the following:

- Evaluation of testicular spermatid numbers
- Sperm evaluation for motility, morphology and numbers

Sperm motility can be assessed by microscopic techniques or with a computer-assisted sperm analysis (CASA) system (Seed et al., 1996). Sperm (minimum 200 per sample) from the cauda epididymis or proximal vas deferens should be examined as a fixed wet preparation and classified as either normal or abnormal (Clegg et al., 2001). Total sperm counts in the cauda epididymis can be assessed (Robb et al., 1978).

Both the FDA and the EPA have established study protocols to assess the reproductive risks of chemicals and drugs. The FDA imposes guidelines for drugs that includes three different protocols (namely segments) on development, fertility, and general reproductive performance:

Segment I: Fertility and Reproduction Function in Males and Females

Segment II: Developmental Toxicology and Teratology

Segment III: Perinatal and Postnatal Studies

Segment I studies are initial studies often leading to additional protocols such as developmental protocols. By using pregnant animals (e.g., segment III) that are treated for the last third of their period of gestation, including lactation and weaning, assessment can be made about the effects of chemical and/or drug exposure on late fetal development, particularly lactation and offspring survival.

The National Toxicology Program (NTP) adopted the Fertility Assessment by Continuous Breeding (FACB) protocol in the early 1980s. The FACB protocol was introduced by McLachlan et al. (1981) and was designed to reduce the time for reproductive toxicity testing yet still provide data comparable with those obtained from other testing systems. FACB tests take no longer than the improved and shortened EPA test designs. The FACB protocol uses more animals per group and in general increases the statistical power of the assay. Morrissey et al. (1988) have evaluated the effectiveness of continuous breeding reproduction studies. This subtle modification of increasing the statistical power of the assay is important, since fertility is an especially important indicator of reproductive toxicity and is one of the least sensitive indicators in the assessment of the reproductive system (Schwetz et al., 1980). Experimental design for toxicologic studies, particularly in studies involving semen analysis and fertility assessment, must recognize statistical power (Williams et al., 1990).

Reproductive toxicity studies extending over multiple generations are scientifically and logistically difficult to manage, interpret, and finance (Johnson, 1986). While

the FDA segment tests are collectively very meaningful in assessing reproductive toxicity (or safety), none of these batteries of tests can replace the other, and the multigeneration evaluation has considerable scientific merit for justifying their expense. However, current multigeneration protocols could be revised in order to improve on the toxicologic information collected. FDA reproductive testing guidelines require preclinical animal testing for each new drug depending on how women might be exposed to the drug itself. The FDA further categorizes drugs on five different levels, depending on potential risk (e.g., category A, no evidence of human development toxicity, to category D or X, demonstrated birth defects) (cf. Frankos, 1985).

It is evident that a number of test systems are available to assess the degree of change in the reproductive system. Some such tests employ many animals and follow their reproductive histories for more than one generation, whereas others employ cell systems that are perhaps representative of a molecular approach to determining mechanisms of toxicologic action.

HUMAN RISK FACTORS AFFECTING FERTILITY

General Considerations

Most humans are exposed to a vast number of chemicals that may be hazardous to their reproductive capacity (Faber and Hughes, 1995). Many chemicals have been identified as reproductive hazards in laboratory studies (Clegg et al., 1986; 2001; Working, 1988). Although the extrapolation of data from laboratory animals to humans is inexact, a number of these chemicals have also been shown to exert detrimental effects on human reproductive performance. The list includes drugs, especially steroid hormones and chemotherapeutic agents; metals and trace elements; pesticides; food additives and contaminants; industrial chemicals; and consumer products.

Fertility in humans, like that in experimental animals, is susceptible to toxic effects from environmental and/or industrial chemicals. Infertility is a problem of increasing concern in several industrialized countries. Levine (1983) has suggested methods for detecting occupational causes of male infertility. The decrease in sperm quality purportedly having occurred over the past 50 years (Carlsen et al., 1992) has been refuted as being due to the lower reference standards (cf. Bromwich et al., 1994). Furthermore, a comparison of the production of spermatozoa from the testes of different species reveals that the output of sperm in humans is approximately four times less than that in other mammals in terms of the number of sperm produced per gram of tissue (Amann and Howard, 1980).

Male

It has also been suggested that the human male is more vulnerable to environmental and occupational toxins than other mammals (Overstreet, 1984; Overstreet et al., 1988). Reproductive hazards and reproductive risks have led to the formulation of protection policies in certain occupations (Perrolle, 1993; Sattler, 1992; Thomas and Barsano, 1994). The somewhat fragile nature of the male reproductive system to occupational exposure to the fungicide DBCP was reaffirmed when Whorton et al. (1977) described its injurious effects on the testes. Fortunately, recovery from severe oligospermia after DBCP exposure has been reported by Lantz et al. (1981). Levine et al. (1983), however, have indicated that reproductive histories are superior to sperm counts in assessing male infertility caused by DBCP.

It has been extremely difficult to directly correlate human exposure to occupational chemicals with alterations in the reproductive system. A particularly complicating factor in this lack of correlation is that the normal reproductive processes seldom operate at a physiologic optimum. For example, as many as 15 percent of all married couples in the United States are defined as being clinically infertile (MacLeod, 1971), whereas another 25 percent of the women exhibit impaired fecundity (Mosher, 1981). At least 30 percent of early human conceptions and up to 15 percent of recognized pregnancies are terminated by spontaneous abortion (cf. Haney, 1985). Of the 15 percent of spontaneous abortions that terminate recognized pregnancies, about 25 percent involve abnormalities related to genetic etiologies and another 7 percent are caused by so-called environmental agents. By far, most of these abortions are due to unknown factors, and this constitutes about 7 percent of the cases of spontaneous abortions.

It is noteworthy that chronic illness may have a profound affect on gonadal function (Turner and Wass, 1997). Several systemic illnesses can reduce spermatogenesis, including thyrotoxicosis, hypothyroidism, renal failure, mumps, and Crohn's disease. A large number of nonhormonal diseases can likewise decrease serum testosterone as well as gonadotrophins. Aging, nutritional deficiencies, and obesity can affect fertility. Thus, a host of both endocrine and nonendocrine diseases can affect male fertility.

Female

Many factors can affect the normalcy of the female reproductive system, as evidenced by variations in the menstrual process. Hence, physiologic, sociologic, and psychological factors have been linked with menstrual disorders. Factors that are known to affect menstruation yet are for the most part completely unrelated to occupational settings include age, body weight extremes, liver disease, thyroid dysfunction, intrauterine contraceptive devices, stress, exercise, and marital status. It is, therefore, obvious that a number of factors can affect menstruation and that these factors do not even include such things as therapeutic drugs (Selevan et al., 1985), so-called recreational drugs, or potentially toxic substances present in occupational environments. Even the choice of control populations in studies involving the adverse effects on the reproductive system can affect the risk estimates.

EXTRAPOLATION OF ANIMAL DATA TO HUMANS

The exclusive use of animal experimental results to predict outcomes in humans still represents an uncertainty. This uncertainty can be somewhat relieved if findings from multiple species are known, particularly subhuman primates, and there are epidemiologic studies that help substantiate laboratory experiments. While there are many general similarities among mammals with respect to their response to drugs and/or chemicals, there are nevertheless some notable differences. Many of these species differences can be attributed to toxicokinetics, especially biotransformation. Greater predictability can be seen in results from well-validated animal models. Clegg et al. (2001), Buiatti et al. (1984), and Paul (1988) have reviewed several factors that are important in assessing risk to the male reproductive system. It is considerably easier to extrapolate controlled drug studies in animals to exact therapeutic regimens in humans than it is to simulate a chemical's exposure in an animal to a presumed environmental exposure in humans. Occupational exposures are inexact, and environmental levels are even more difficult to document (cf. Lemasters and Selevan, 1984). Exposures usually involve mixtures of chemicals, and individuals may not be aware of all the chemicals with which they come into contact. Thus, the effect of individual chemicals is difficult to assess, and cause-and-effect relationships are nearly impossible to establish.

Ulbrich and Palmer (1995) have undertaken a large survey of medicinal products in an effort to match human (male) and several experimental animals with respect to reproductive endpoints (e.g., spermatogenesis, sperm counts, sperm motility, etc.). The survey included a wide range of medicinal products, both hormonal and nonhormonal formulations. Sperm analysis results were comparable to results obtained by histopathology and/or organ weight changes following drug administration. Validation of sperm analyses is problematic but provides a realistic alternative to histopathology and organ weight when the latter are impractical.

EPIDEMIOLOGIC STUDIES

Epidemiology is increasingly important in establishing cause-and-effect relationships (Scialli and Lemasters, 1995). Epidemiology and risk assessment are inextricably related. Reproductive surveillance programs are important underpinnings for monitoring endocrine processes. By closely monitoring worker exposures to industrial/environmental toxicants, safer conditions will be established.

If exposure to a chemical has occurred in a human population or if concern surrounds the use of a certain chemical, epidemiologic studies may be used to identify effects on reproduction. Sheikh (1987) has pointed out factors that are important in selecting control populations for studying adverse reproductive effects on occupational environments. The design of epidemiologic studies may involve either retrospective or prospective gathering of data. Statistical aspects to be considered in epidemiologic studies include power, sample size, significance level, and magnitude of effect.

TOXIC RESPONSES OF THE ENDOCRINE SYSTEM

Charles C. Capen

INTRODUCTION

Endocrine glands are collections of specialized cells that synthesize, store, and release their secretions directly into the bloodstream. They are sensing and signaling devices located in the extracellular fluid compartment and are capable of responding to changes in the internal and external environments to coordinate a multiplicity of activities that maintain homeostasis.

Endocrine cells that produce polypeptide hormones have a well-developed rough endoplasmic reticulum that assembles hormone and a prominent Golgi apparatus for packaging hormone into granules for intracellular storage and transport. Secretory granules are unique to polypeptide hormone- and catecholamine-secreting endocrine cells and provide a mechanism for intracellular storage of substantial amounts of preformed active hormone. When the cell receives a signal for hormone secretion, secretory granules are directed to the periphery of the endocrine cell, probably by the contraction of microfilaments.

Steroid hormone-secreting cells are characterized by prominent cytoplasmic lipid bodies that contain cholesterol and other precursor molecules. The lipid bodies are in close proximity to an extensive tubular network of smooth endoplasmic reticulum and large mitochondria which contain hydroxylase and dehydrogenase enzyme systems. These enzyme systems function to attach various side chains to the basic steroid nucleus. Steroid hormone-producing cells lack secretory granules and do not store significant amounts of preformed hormone. They are dependent on continued biosynthesis to maintain the normal secretory rate for a particular hormone.

Many diseases of the endocrine system are characterized by dramatic functional disturbances and characteristic clinicopathologic alterations affecting one or several body systems. The affected animal or human patient may have clinical signs that primarily involve the skin (hair loss caused by hypothyroidism), nervous system (seizures caused by hyperinsulinism), urinary system (polyuria caused by diabetes mellitus, diabetes insipidus, and hyperadrenocorticism), or skeletal system (fractures induced by hyperparathyroidism).

The literature suggests that chemically induced lesions of the endocrine organs are most commonly encountered in the adrenal glands, followed in descending order by the thyroid, pancreas, pituitary, and parathyroid glands. In the adrenal glands, chemically induced lesions are most frequently found in the zona fasciculata/zona reticularis and to a lesser extent in either the zona glomerulosa or medulla. In a recent survey, conducted by the Pharmaceutical Manufacturers Association, of tumor types developing in carcinogenicity studies, endocrine tumors developed frequently in rats, with the thyroid gland third in frequency (behind the liver and mammary gland), followed by the pituitary gland (fourth), and adrenal gland (fifth). Selected examples of commonly encountered toxic endpoints involving endocrine organs in laboratory animals are discussed in this chapter. Mechanistic data is included whenever possible to aid in the interpretation of findings in animal toxicology studies and to determine their significance in risk assessment.

PITUITARY GLAND

Normal Structure and Function

The pituitary gland (hypophysis) is divided into two major compartments: (1) the adenohypophysis (anterior lobe), composed of the pars distalis, pars tuberalis, and pars intermedia, and (2) the neurohypophyseal system, which includes the pars nervosa (posterior lobe), infundibular stalk, and hypothalamic nuclei (supraoptic and paraventricular) containing the neurosecretory neurons, which synthesize and package the neurohypophyseal hormones into secretory granules. The pars intermedia forms the thin cellular zone between the adenohypophysis and neurohypophysis. The pituitary gland lies within the sella turcica of the sphenoid bone. The gland receives its blood supply via the posterior and anterior hypophyseal arteries, which originate from the internal carotid arteries. Arteriolar branches penetrate the pituitary stalk near the median eminence, lose their muscular coat, and form a capillary plexus. These vessels drain into the hypophyseal portal veins, which supply the adenohypophysis. The hypothalamic-hypophyseal portal system functionally is important as it transports the hypothalamic releasing- and release-inhibiting hormones directly to the adenohypophysis, where they interact with their specific populations of trophic hormone-producing cells.

The adenohypophysis in many animal species completely surrounds the pars nervosa of the neurohypophyseal system, in contrast to its position in human beings, where it is situated on the anterior surface. The pars distalis is the largest portion and is composed of the multiple populations of endocrine cells that secrete the pituitary trophic hormones. The secretory cells are surrounded by abundant capillaries derived from the hypothalamic-hypophyseal portal system. The pars tuberalis consists of dorsal projections of supportive cells along the infundibular stalk. It functions primarily as a scaffold for the capillary network of the hypophyseal portal system during its course from the median eminence to the pars distalis. The pars intermedia is located between the pars distalis and pars nervosa and lines the residual lumen of Rathke's pouch. It contains two populations of endocrine cells in certain species. One of these cell types (B cells) in the dog synthesizes and secretes adrenocorticotropic hormone (ACTH).

A specific population of endocrine cells is present in the pars distalis (and in the pars intermedia of dogs for ACTH) that synthesizes, processes, and secretes each of the pituitary trophic hormones. Secretory cells in the adenohypophysis formerly were classified either as acidophils, basophils, or chromophobes based on the reactions of their secretory granules with pH-dependent histochemical stains. Based upon contemporary specific immunocytochemical procedures, acidophils can be further subclassified functionally into somatotrophs that secrete growth hormone (GH; somatotrophin) and luteotrophs that secrete luteotropic hormone (LTH; prolactin). Their granules contain simple protein hormones. Basophils include both gonadotrophs, which secrete luteinizing hormone (LH) and follicle-stimulating hormone (FSH), and thyrotrophs, which secrete thyrotropic hormone [thyroid-stimulating hormone (TSH)]. Chromophobes are pituitary cells that, by light microscopy, do not have stainable cytoplasmic secretory granules. They include the pituitary cells involved with the synthesis of ACTH and melanocyte-stimulating hormone (MSH) in some species, nonsecretory follicular (stellate) cells, degranulated chromophils (acidophils and basophils) in the actively synthesizing phase of the secretory cycle, and undifferentiated stem cells of the adenohypophysis.

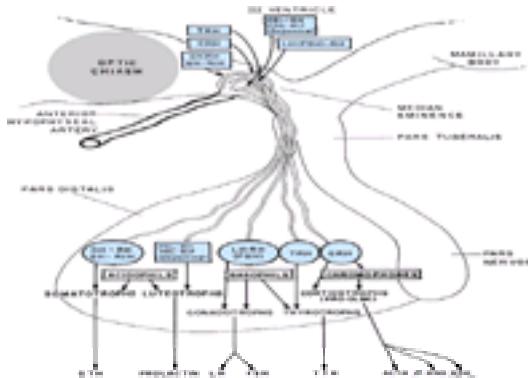
Each type of endocrine cell in the adenohypophysis is under the control of a specific releasing hormone from the hypothalamus (Fig. 21-1). These releasing hormones are small peptides that are synthesized and secreted by neurons of the hypothalamus. They are transported by short axonal processes to the median eminence, where they are released into capillaries and are conveyed by the hypophyseal portal system to specific trophic hormone-secreting cells in the adenohypophysis. Each hormone stimulates the rapid release of preformed secretory granules containing a specific trophic hormone. Specific releasing hormones have been identified for TSH, FSH and LH, ACTH, and GH. Prolactin (PRL) secretion is stimulated by a number of factors, the most important of which appears to be thyrotropin-releasing hormone (TRH). Dopamine serves as the major prolactin-inhibitory factor and suppresses prolactin secretion and also inhibits cell division and DNA synthesis of luteotrophs. Dopamine also suppresses ACTH production by corticotrophs in the pars intermedia of some species. Another hypothalamic release-inhibiting hormone is somatostatin (somatotropin-release inhibiting hormone, SRIH). This tetradecapeptide inhibits the secretion of both growth hormone and TSH. Control of pituitary trophic hormone secretion also is affected by negative feedback by the circulating concentration of target organ (thyroid, adrenal cortex, and gonad) hormones.


Figure 21-1. Control of trophic hormone secretion from the adenohypophysis by hypothalamic releasing hormones (RH) and release-inhibiting hormones (RIH).

The releasing and release-inhibiting hormones are synthesized by neurons in the hypothalamus, transported by axonal processes, and released into capillary plexus in the median eminence. They are transported to the adenohypophysis by the hypothalamic-hypophyseal portal system, where they interact with specific populations of trophic hormone–secreting cells to govern the rate of release of preformed hormones, such as growth hormone (GH), somatotropic hormone (STH), luteotropic hormone (LTH), luteinizing hormone (LH), follicle-stimulating hormone (FSH), thyrotropic hormone (TTH), adrenocorticotropic hormone (ACTH), and melanocyte-stimulating hormone (MSH). There are RIHs for those trophic hormones (e.g., prolactin and growth hormone) that do not directly influence the activity of target cells and result in production of a final endocrine product (hormone) that could exert negative feedback control.

The neurohypophysis is subdivided into three anatomic parts. The pars nervosa (posterior lobe of the human pituitary) represents the distal component of the neurohypophyseal system. The infundibular stalk joins the pars nervosa to the overlying hypothalamus and is composed of long axonal processes from neurosecretory neurons in the hypothalamus. It is made up of numerous capillaries, supported by modified glial cells (pituicytes), which are termination sites for the nonmyelinated axonal processes of neurosecretory neurons. The neurohypophyseal hormones (i.e., oxytocin and antidiuretic hormone) are synthesized in the cell body of hypothalamic neurons, packaged into secretory granules, transported by long axonal processes, and released into the bloodstream in the pars nervosa.

Antidiuretic hormone (ADH or vasopressin) and oxytocin are nonapeptides synthesized by neurons situated either in the supraoptic (primarily ADH) or paraventricular (primarily oxytocin) nuclei of the hypothalamus. ADH and its corresponding neurophysin are synthesized as part of a common larger biosynthetic precursor molecule, termed propressophysin. The hormones are packaged with a corresponding binding protein (i.e., neurophysin) into membrane-limited neurosecretory granules and transported by axons to the pars nervosa for release into the circulation. As the biosynthetic precursor molecules travel along the axons in secretion granules from the neurosecretory neurons, the precursors are cleaved into the active hormones and their respective neurophysins. These secretory products can be detected immunocytochemically. In Brattleboro rats with hereditary hypothalamic diabetes insipidus, nerve cells in the hypothalamus that normally produce ADH and neurophysin-I are negative immunocytochemically for both proteins whereas neurosecretory stain positive for cells that produce vasopressin and neurophysin-II are positive.

In addition to the specific trophic hormone-secreting cells, a population of supporting cells is also present in the adenohypophysis. These cells are referred to as stellate (follicular) cells and can be stained selectively with antibodies to S-100 protein. The stellate cells typically have elongate processes and prominent cytoplasmic filaments. These cells appear to provide a phagocytic or supportive function in addition to producing a colloid-like material that accumulates in follicles.

Mechanisms of Toxicity

Pituitary tumors can be induced readily by sustained uncompensated hormonal derangements leading to increased synthesis and secretion of pituitary hormones. The absence of negative feedback inhibition of pituitary cells leads to unrestrained proliferation (hyperplasia initially, neoplasia later). This effect can be potentiated by the concurrent administration of ionizing radiation or chemical carcinogens.

In the pituitary-thyroid axis, thyroxine (T_4) and triiodothyronine (T_3) normally regulate the pituitary secretion of TSH by a classic negative feedback control system. Surgical removal or radiation-induced ablation of the thyroid or interference with the production of thyroid hormones by the use of specific chemical inhibitors of thyroid hormone synthesis leads to a stimulation of TSH synthesis and secretion with elevated blood levels. The thyrotrophic cells in the adenohypophysis undergo prominent hypertrophy. Subsequently, hyperplasia of the thyrotrophs occurs concurrently with hypertrophy as a consequence of the lack of normal negative feedback control. In rodents foci of hyperplasia may progress to the formation of adenomas in the pituitary gland. The role of gonadectomy in pituitary tumor induction has been studied most intensively in mice. The pituitary tumors induced by gonadectomy in mice are markedly strain-dependent and may contain FSH, LH, or both.

The administration of estrogens is a reproducible method for inducing pituitary tumors in certain experimental animals. The effect of exogenous estrogen on the rat pituitary includes stimulation of prolactin secretion and the induction of prolactin-secreting tumors. The administration of estrogens in susceptible strains results in elevated serum prolactin levels, increased numbers of prolactin cells within the pituitary, enhanced incorporation of tritiated thymidine within the gland, and increased mitotic activity. The pituitary of the ovariectomized F344 female rat is more responsive to the tumorigenic effect of diethylstilbestrol than the intact female; however, there is considerable variation in the induction of pituitary tumors by estrogens in different rat strains. For example, F344 and Holtzman rats respond to an initial estrogen stimulus by increasing the rate of DNA synthesis in the pituitary within 2 to 4 days. The rate of DNA synthesis declines after 7 to 10 days of treatment to unstimulated levels in the Holtzman strain but remains elevated in F344 rats.

Sarkar and coworkers (1982) have reported that estrogen-induced pituitary adenomas derived from prolactin-secreting cells are associated with loss of hypothalamic dopaminergic neurons, which normally inhibit the function of prolactin-secreting cells. Prolactin-producing tumors, when transplanted subcutaneously, also were associated with degenerative changes in hypothalamic dopaminergic neurons. The tumorigenic action of estrogen may not be due exclusively to its effect on the hypothalamus, since estrogen can produce prolactinomas in pituitaries grafted beneath the renal capsule. The effects of estrogens on prolactin cells have been studied in hypophysectomized rats bearing transplanted pituitaries beneath the kidney capsule. The studies of El Etreby and coworkers (1988) using this model have shown that dopamine agonists, including lisuride and bromocriptine, antagonize the direct stimulatory effects of estrogens on the prolactin cells. These dopamine agonists may act directly on dopaminergic receptors within the transplanted pituitaries.

Other agents, including caffeine, have been implicated in the development of pituitary adenomas in rats. The administration of Λ-methylnitrosourea also is associated with the development of pituitary adenomas in Wistar rats. The neuroleptic agent sulpiride has been reported to cause the release of prolactin from the anterior pituitary in the rat and to stimulate DNA replication. The administration of clomiphene prevents the stimulation of DNA synthesis produced by sulpiride, but does not affect prolactin release from the gland. These findings suggest that the intracellular prolactin content of the pituitary plays a role in the regulation of DNA synthesis through a mechanism mediated by estrogens.

Morphologic Alterations and Proliferative Lesions of Pituitary Cells

Jameson et al. (1992) reported that the administration of salmon calcitonin for 1 year to Sprague-Dawley and Fisher 344 rats was associated with an increased incidence of focal hyperplasia and adenomas in the pituitary. The association of calcitonin treatment and pituitary tumors was dose-dependent and was more pronounced with salmon calcitonin than with porcine calcitonin. Using both immunohistochemical analysis and measurements of serum hormone levels, they provided evidence that prolonged administration of calcitonin resulted in pituitary tumors that produced the common a-subunit of the glycoprotein hormones [luteinizing hormone (LH), follicle-stimulating hormone (FSH) and thyroid-stimulating hormones (TSH)], a type of tumor that has been reported to compose a significant fraction of pituitary tumors in humans. Immunohistochemistry and in situ hybridization demonstrated that most pituitary tumors associated with the chronic administration of high doses of calcitonin expressed a glycoprotein hormone a-subunit, whereas expression of the a-subunit was identified infrequently in hyperplastic lesions of control rats.

Serum levels of each of the major pituitary hormones were measured in both sexes of Sprague-Dawley and Fisher rats administered calcitonin. There were no significant alterations in the circulating levels of growth hormone, prolactin, or ACTH and the tumors were negative by immunohistochemical and in situ hybridization assessment for these hormones. Serum LH and FSH levels were unaffected by the treatment with calcitonin; however, TSH levels were elevated 2.1-fold after

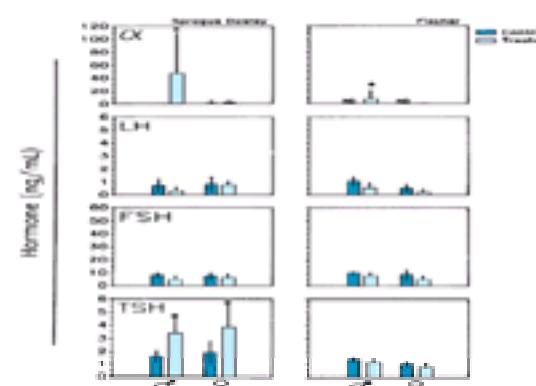
calcitonin treatment in Sprague-Dawley but not Fischer rats of both sexes (Fig. 21-2). Interestingly, thyroid weights were decreased by 43 percent in calcitonin-treated male rats and there was atrophy of thyroid follicular cells in some treated rats, suggesting that the immunoreactivity detected by the TSH assay was not biologically active. After treatment with calcitonin, serum a-subunit levels were increased by at least 20-fold in Sprague-Dawley males and 4-fold in male Fischer rats (Fig. 21-3 and Fig. 21-4). There was a good correlation between histopathologic evidence of a-subunit–producing pituitary tumors and elevated serum levels. In each of the calcitonin-treated rats that had adenomas, the tumors were positive for a-subunit by immunohistochemistry and in situ hybridization for expression of a-subunit mRNA.


Figure 21-2. Serum glycoprotein hormone levels in rats treated chronically with salmon calcitonin.

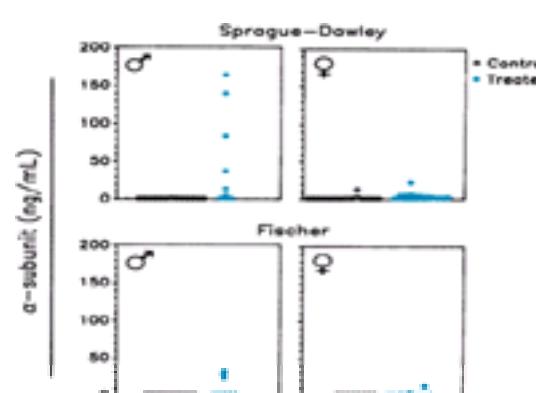
Sprague-Dawley (*left panels*) or Fischer rats (*right panels*) were treated for 52 weeks with vehicle (*dark blue bars*) or calcitonin (80 IU/kg/day) (*light blue bars*). Results are the mean ± SD; *p <0.05. (From Jameson et al., 1992, with permission.)


Figure 21-3. Serum a-subunit levels in individual male rats treated chronically with calcitonin.

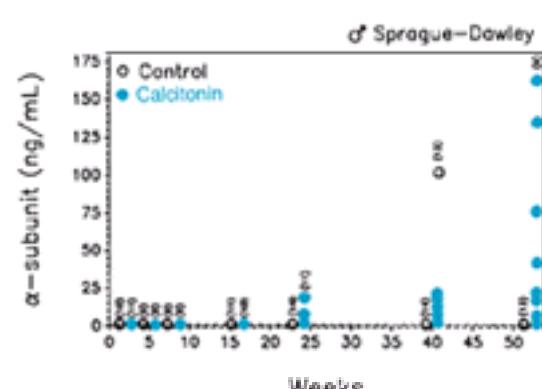
The serum levels for individual animals are denoted. o = vehicle; · = calcitonin-treated. (From Jameson et al., 1992, with permission.)


Figure 21-4. Time course for the increase in serum a-subunit levels in male Sprague-Dawley rats.

Symbols in the undetectable range represent values for more than one animal. The number of animals in each group is shown in parenthesis. o = control; · = calcitonin-treated. (From Jameson et al., 1992, with permission.)

Serum levels of a-subunit were elevated in male Sprague-Dawley rats after 2, 5, 8, 16, 24, 40, and 52 weeks to determine the time course for hormone elevation. Elevated levels of a-subunit were detected as early as 24 weeks in rats treated with calcitonin and the majority of animals had increased a-subunit levels by 40 weeks of treatment (Fig. 21-4), suggesting that pituitary tumors developed only after several months of exposure to calcitonin. Levels of a-subunit in vehicle-treated rats were below the detection limits of the assay at each time point.

The studies reported by Jameson et al. (1992) did not determine whether the effects of calcitonin on the pituitary were direct or indirect. Calcitonin is known to be produced in large amounts in the posterior hypothalamus and median eminence where it may normally exert an effect on the hypothalamus-pituitary axis. Calcitonin receptors have been identified in the hypothalamus and lower numbers of receptors are found in the pituitary gland. A striking feature of the calcitonin-induced pituitary tumors and elevated serum a-subunit levels was the predilection for male compared with female rats. The basis for the sex- and species-specific effects of calcitonin was not determined. The relevance of the effects of calcitonin in the rat pituitary gland to human pathophysiology is uncertain at present. However, neither the treatment of patients with calcitonin nor patients with the multiple endocrine neoplasia syndrome II with medullary thyroid cancer and elevated serum calcitonin levels have resulted in the development of pituitary tumors. The doses of calcitonin used in rats were from 25- to 50-fold greater on a per-weight basis than doses administered to patients. In addition, several strains of rats are known to be highly predisposed to develop pituitary tumors compared to humans.

The high frequency of spontaneous pituitary adenomas in laboratory rats is a well-recognized phenomenon which must be considered in any long-term toxicological study. The incidence of pituitary tumors is determined by many factors including strain, age, sex, reproductive status, and diet. Studies from the National Toxicology Program (NTP) historical database of 2-year-old F344 rats have shown that the incidence of pituitary adenomas was 21.7 and 44 percent for males and females, respectively. Corresponding figures for carcinomas arising in the adenohypophysis were 2.4 and 3.5 percent for males and females, respectively. Numerous hypotheses have been invoked to explain the high incidence of pituitary adenomas in certain inbred rat strains. Both hereditary factors and the levels of circulating sex steroids have been suggested as important etiological mechanisms. The hypothalamus has also been incriminated in the development of these tumors. Age-related hypothalamic changes may result in diminished activity of dopamine, the major prolactin-inhibitory factor.

Numerous studies have demonstrated the striking degree of strain variation in the incidence of pituitary tumors in rats, which has been reported to range from 10 to more than 90 percent. Particularly high incidences of pituitary adenomas have been reported in Wistar, WAG/Rij, Osborne-Mendel, Long-Evans, Amsterdam, and Columbia-Sherman rats. In the BN/Bi strain, pituitary adenomas have been found in 26 percent of females and 14 percent of males. Adenomas were identified in 95 percent of females and 96 percent of males in the WAG/Rij strain while (WAG/Rij 3 BN) F $_1$ rats had incidences of 83 percent for females and 64 percent for males. Rapid body growth rates and high levels of conversion of feed to body mass in early life or high protein intake in early adult life predispose any strain of rat to the development of pituitary adenomas. In rats fed a low protein diet (less than 12.7 percent crude protein) the overall tumor incidence, the numbers of multifocal tumors,

and the degree of cellular atypia within tumors are significantly lower than in rats fed a standard diet.

"Cystoid degeneration" has been used to describe foci of parenchymal cell loss in the adenohypophysis. Foci of cystoid degeneration (50 to 150 mm in diameter) have margins composed of normal secretory cells of the pars distalis. Cystoid degeneration also may occur in hyperplastic foci and in neoplasms of the pituitary. The frequency of cystoid degeneration is increased by feeding diets containing diethylstilbestrol to female C3H HeN (MTV+) mice.

The separation between focal hyperplasia, adenoma, and carcinoma utilizing histopathologic techniques is difficult in the pituitary gland. However, criteria for their separation have been established and should be applied in a consistent manner in the evaluation of proliferative lesions of the pituitary gland. For the specific trophic hormone–secreting cells of the adenohypophysis, there appears to be a continuous spectrum of proliferative lesions between diffuse or focal hyperplasia and adenomas derived from a specific population of secretory cells. It appears to be a common feature of endocrine glands that prolonged stimulation of a population of secretory cells predisposes to the subsequent development of a higher than expected incidence of focal hyperplasia and tumors. Long-continued stimulation may lead to the development of clones of cells within the hyperplastic foci that grow more rapidly than the rest and are more susceptible to neoplastic transformation when exposed to the right combination of promoting carcinogens.

Focal ("nodular") hyperplasia in the adenohypophysis appears as multiple small areas that are well demarcated but not encapsulated from adjacent normal cells. Cells in areas of focal hyperplasia closely resemble the cells of origin; however, the cytoplasmic area may be slightly enlarged and the nucleus more hyperchromatic than in the normal cells. Adenomas usually are solitary nodules that are larger than the often multiple areas of focal hyperplasia. They are sharply demarcated from the adjacent normal pituitary glandular parenchyma and there often is a thin, partial to complete, fibrous capsule. The adjacent parenchyma is compressed to varying degrees depending on the size of the adenoma. Cells composing an adenoma closely resemble the cells of origin morphologically and in their architectural pattern of arrangement.

Carcinomas usually are larger than adenomas in the pituitary and usually result in a macroscopically detectable enlargement. Histopathologic features that are suggestive of malignancy include extensive intraglandular invasion, invasion into adjacent structures (e.g., dura mater, sphenoid bone), formation of tumor cell thrombi within vessels, and particularly the establishment of metastases at distant sites. The growth of neoplastic cells subendothelially in highly vascular benign tumors of the pituitary should not be mistaken for vascular invasion. Malignant cells often are more pleomorphic than normal, but nuclear and cellular pleomorphism are not a consistent criterion to distinguish adenoma from carcinoma in the adenohypophysis of rodents.

The vast majority of pituitary adenomas in humans and rodents have been described as chromophobic in type by light microscopy; however, many of these tumors have been found to stain for prolactin by immunohistochemistry. Of the prolactin-producing tumors, most are sparsely granulated with low levels of prolactin immunoreactivity by immunohistochemistry and having small numbers of secretory granules by electron microscopy. Diffuse hyperplasia of the prolactin cells has been observed adjacent to some adenomas. The development of tumors and hyperplasia of prolactin-secreting cells often is accompanied by increasing serum levels of prolactin. Occasionally, prolactin cells within adenomas may be admixed with FSH/LH-, TSH-, or ACTH-positive cells in the rat pituitary.

ADRENAL CORTEX

Introduction

The adrenal cortex of animals is prone to develop degenerative and proliferative lesions, the etiology of which may be either spontaneous in nature or experimentally induced. Therefore, testing of xenobiotic chemicals using various laboratory animal species is a valid means of assessing the toxic potential for humans exposed to various xenobiotic chemicals. The choice of test animal species also is critical, as a number of studies have demonstrated that there often is a variable species susceptibility to chemical toxicity. This suggests that interspecies differences in metabolism plays a role in the development of adrenal cortical toxicity and in the inhibition of steroidogenesis. The age of the test animal, to a lesser degree, can be a factor in the development of chemically induced adrenal cortical lesions.

Normal Structure and Function

The adrenal (suprarenal) glands in mammals are flattened bilobed organs located in close proximity to the kidneys. The adrenal glands receive arterial blood from branches of the aorta or from the phrenic, renal, and lumbar arteries resulting in a subcapsular sinusoidal vascular plexus that drains through the cortex into the medulla. The ratio of cortex:medulla is approximately 2:1 in healthy laboratory-reared animals.

The cortex is histologically characterized by defined regions or zones. The cortical zones consist of the zona glomerulosa (multiformis), zona fasciculata, and zona reticularis. The zones are not always clearly delineated, as in the normal rat adrenal cortex. The mineralocorticoid-producing zona glomerulosa (multiformis) (approximately 15 percent of the cortex) contains cells aligned in a sigmoid pattern in relationship to the capsule. Degeneration of this zone or an interference in the ability to produce mineralocorticoids (namely, aldosterone) results in a life-threatening retention of potassium and hypovolemic shock associated with the excessive urinary loss of sodium, chloride, and water. The largest part of the cortex is the zona fasciculata comprising >70 percent of the cortical width. Cells in this zone are arranged in long anastomosing columns separated by vascular sinusoids and are responsible for the secretion of glucocorticoid hormones (e.g., corticosterone or cortisol). The innermost portion of the cortex is the zona reticularis (>15 percent of the cortex), which secretes minute quantities of adrenal sex hormones.

The adrenal cortical cells contain large cytoplasmic lipid droplets consisting of cholesterol and other steroid hormone precursors. The lipid droplets are in close proximity to the smooth endoplasmic reticulum and large mitochondria, which contain the specific hydroxylase and dehydrogenase enzyme systems required to synthesize the different steroid hormones. Unlike polypeptidehormone-secreting cells, there are no secretory granules in the cytoplasm, since there is direct secretion without significant storage of preformed steroid hormones.

Steroid hormone-producing cells of the adrenal cortex synthesizes a major parent steroid with one to four additional carbon atoms added to the basic 17-carbon steroid nucleus. Since steroid hormones are not stored in any significant amount, a continued rate of synthesis is required to maintain a normal secretory rate. Once in the circulation, cortisol or corticosterone are bound reversibly to plasma proteins (such as transcortin, albumin). Under normal conditions 10 percent of the glucocorticoids are in a free unbound state.

Adrenal steroids are synthesized from cholesterol by specific enzyme-catalyzed reactions and involve a complex shuttling of steroid intermediates between mitochondria and endoplasmic reticulum. The specificity of mitochondrial hydroxylation reactions in terms of precursor acted upon and the position of the substrate which is hydroxylated is confined to a specific cytochrome P450. The common biosynthetic pathway from cholesterol is the formation of pregnenolone, the basic precursor for the three major classes of adrenal steroids. Pregnenolone is formed after two hydroxylation reactions at the carbon 20 and 22 positions of cholesterol and a subsequent cleavage between these two carbon atoms. In the zona fasciculata, pregnenolone is first converted to progesterone by two microsomal enzymes. Three subsequent hydroxylation reactions occur involving, in order, carbon atoms at the 17, 21, and 11 positions. The resulting steroid is cortisol, which is the major glucocorticoid in teleosts, hamsters, dogs, nonhuman primates, and humans. Corticosterone is the major glucocorticoid produced in amphibians, reptiles, birds, rats, mice, and rabbits. It is produced in a manner similar to the production of cortisol, except that pro-gesterone does not undergo 17a-hydroxylation and proceeds directly to 21-hydroxylation and 11b-hydroxylation.

In the zona glomerulosa, pregnenolone is converted to aldosterone by a series of enzyme-catalyzed reactions similar to those involved in cortisol formation; however, the cells of this zone lack the 17a-hydroxylase and thus cannot produce 17a-hydroxyprogesterone, which is required to produce cortisol. Therefore, the initial hydroxylation product is corticosterone. Some of the corticosterone is acted on by 18-hydroxylase to form 18-hydroxycorticosterone, which in turn interacts with 18-hydroxysteroid dehydrogenase to form aldosterone. Since 18-hydroxysteroid dehydrogenase is found only in the zona glomerulosa, it is not surprising that only this zone has the capacity to produce aldosterone. In addition to the aforementioned steroid hormones, cells in the zona reticularis also produces small amounts of sex steroids including progesterone, estrogens, and androgens.

The mineralocorticoids (e.g., aldosterone) are the major steroids secreted from the zona glomerulosa under the control of the renin–angiotensin II system. The mineralocorticoids have their effects on ion transport by epithelial cells, particularly renal cells, resulting in conservation of sodium (chloride and water) and loss of potassium. In the distal convoluted tubule of the mammalian nephron, a cation exchange exists that promotes the resorption of sodium from the glomerular filtrate and the secretion of potassium into the lumen.

Under conditions of decreased blood flow or volume, the enzyme renin is released into the circulation at an increased rate by cells of the juxtaglomerular apparatus of the kidney. Renin release has also been associated with potassium loading or sodium depletion. Renin in the peripheral circulation acts to cleave a plasma globulin

precursor (angiotensinogen produced by the liver) to angiotensin I. An angiotensin converting enzyme (ACE), subsequently hydrolyzes angiotensin I to angiotensin II, which acts as a trophic hormone to stimulate the synthesis and secretion of aldo-sterone. Under normal conditions negative feedback control to inhibit further renin release is exerted by the elevated levels of angiotensin (principally angiotensin II) as well as the expanded extracellular fluid volume resulting from the increased electrolyte (sodium and chloride) and water reabsorption by the kidney.

The principal control for the production of glucocorticoids by the zona fasciculata and zona reticularis is exerted by adrenocorticotropin (ACTH), a polypeptide hormone produced by corticotrophs in the adenohypophysis of the pituitary gland. ACTH release is largely controlled by the hypothalamus through the secretion of corticotropin-releasing hormone (CRH). An increase in ACTH production results in an increase in circulating levels of glucocorticoids and under certain conditions also can result in weak stimulation of aldosterone secretion. Negative feedback control normally occurs when the elevated blood levels of cortisol act either on the hypothalamus, anterior pituitary, or both to cause a suppression of ACTH secretion.

Mechanisms of Toxicity

The reason the adrenal cortex is predisposed to the toxic effects of xenobiotic chemicals appears to be related to at least two factors. *First,* adrenal cortical cells of most animal species contain large stores of lipids used primarily as substrate for steroidogenesis. Many adrenal cortical toxic compounds are lipophilic and therefore can accumulate in these lipid-rich cells. *Second,* adrenal cortical cells have enzymes capable of metabolizing of xenobiotic chemicals, including enzymes of the cytochrome P450 family. Many of these enzymes function in the biosynthesis of endogenous steroids and are localized in membranes of the endoplasmic reticulum or mitochondria. A number of toxic xenobiotic chemicals serve as pseudosubstrates for these enzymes and can be metabolized to reactive toxic compounds. These reactive compounds result in direct toxic effects by covalent interactions with cellular macromolecules or through oxygen activation with the generation of free radicals.

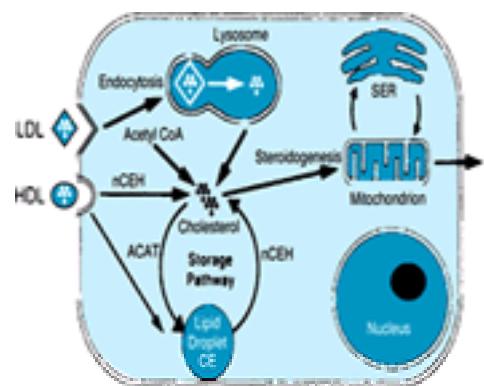
Classes of chemicals known to be toxic for the adrenal cortex include short-chain (three- or four-carbon) aliphatic compounds, lipidosis-inducers, and amphiphilic compounds. A variety of other compounds also may affect the medulla. The most potent aliphatic compounds are of three-carbon length with electronegative groups at both ends. These compounds frequently produce necrosis, particularly in the zonae fasciculata and reticularis. Examples include acrylonitrile, 3-aminopropionitrile, 3-bromopropionitrile, 1-butanethiol, and 1,4-butanedithiol. By comparison, lipidosis-inducers can cause the accumulations, often coalescing, of neutral fats, which may be of sufficient quantity to cause a reduction or loss of organellar function and eventual cell destruction. Cholesterol is the precursor substrate required to synthesize steroid hormones. Steroidogenic cells obtain cholesterol exogenously from serum lipoproteins and endogenously from de novo synthesis via the acetyl coenzyme A pathway (Fig. 21-5). The adrenal cortical cells and OI cells in the rat preferentially utilize serum high-density lipoproteins (HDLs) for their primary source of cholesterol and resort to de novo synthesis if HDL does not meet the demand of steroidogenesis. This is in contrast to Leydig cells of the testis, which preferentially utilizes de novo synthesis of cholesterol and uses an exogenous source only when intracellular synthesis does not meet the demand and the cholesterol pool has been depleted (Payne et al., 1985).


Figure 21-5. Cholesterol metabolism and steroid biosynthesis in adrenocortical and ovarian interstitial cells.

Cholesterol is the substrate for steroid biosynthesis. Conversion of cholesterol to pregnenolone occurs in the mitochondria, and oxidative reactions catalyzed by P450 enzymes occur in the smooth endoplasmic reticulum and mitochondria. Sources of cholesterol include lipoprotein uptake from serum (LDL and HDL), de novo synthesis from acetate via the acetyl coenzyme A pathway, and hydrolysis of cholesteryl ester (CE) by neutral CE hydrolase (nCEH). The storage pool in the form of lipid droplets is derived principally from the conversion of free cholesterol to CE catalyzed by acyl coenzyme A: cholesterol acyltransferase (ACAT). Direct uptake of CE from serum to the storage pool is minimal in the rat. (From Latendresse et al., 1993, with permission.)

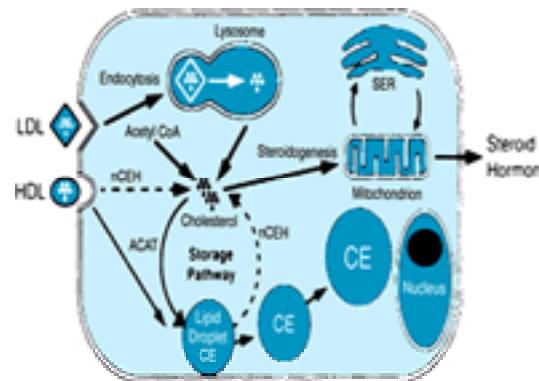
The zonae reticularis and fasciculata appear to be the principal targets of xenobiotic chemicals in the adrenal cortex. Examples of the compounds causing lipidosis include aminoglutethimide, amphenone, and anilines. Tricresyl phosphate (TCP) and other triaryl phosphates cause a defect in cholesterol metabolism by blocking both the uptake from serum and storage pathways. An inhibition of cytosolic neutral cholesteryl ester hydroxylase (nCEH) by triaryl phosphate (97 percent inhibition compared to controls) results in the progressive accumulation of cholesteryl ester in the form of lipid droplets in the cytoplasm of adrenal cortical and ovarian interstitial (OI) cells (Fig. 21-6) but not in testicular Leydig cells of rats (Latendresse et al., 1993). Acyl coenzyme A: cholesterol acyl transferase (ACAT), an enzyme that esterifies cholesterol to make cholesteryl ester, was depressed only 27 percent (compared to controls) resulting in elevated intracellular storage of cholesterol in the form of lipid droplets (Fig. 21-7).


Figure 21-6. Pathogenesis of cholesteryl lipidosis in adrenocortical cells and ovarian interstitial cells.

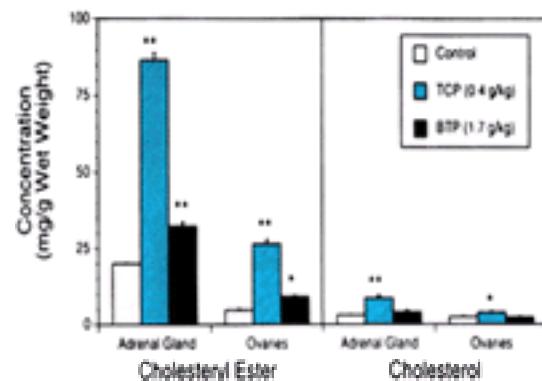
The defect in cholesterol metabolism occurs in the uptake from serum and storage pathways. An inhibition of neutral cholesteryl ester hydrolase (nCEH) by a xenobiotic chemical results in the accumulation of CE in the form of lipid droplets in the cytoplasm. Acyl coenzyme A:cholesterol acyltransferase (ACAT) (catalyzes the formation of CE from cholesterol) activity remains near normal levels. (From Latendresse et al., 1993, with permission.)


Figure 21-7. The effects of tricresyl phosphate (TCP) and butylated triphenyl phosphate (BTH) on concentration of cholesteryl ester (CE) and cholesterol in adrenal gland and ovary of rats.

Mean ± SEM (n = 8–9)mg/g wet weight of adrenal gland and ovary. ***Different (p £ 0.01, p £ 0.05, respectively) from control. (From Latendresse et al., 1993, with permission.)

Biologically active cationic amphiphilic compounds produce a generalized phospholipidosis that involves primarily the zonae reticularis and fasciculata and produce microscopic phospholipid-rich inclusions. These compounds affect the functional integrity of lysosomes, which appear ultrastructurally to be enlarged and filled with membranous lamellae or myelin figures. Examples of compounds known to induce phospholipidosis include chloroquine, triparanol, and chlorphentermine.

Another class of compounds that affect the adrenal cortex are hormones, particularly natural and synthetic steroids. The administration of exogenous steroid hormones such as corticosteroids may cause functional inactivity and trophic atrophy following prolonged use. Other steroid hormones such as natural and synthetic estrogens and androgens have been reported to cause proliferative lesions in the adrenal cortex of laboratory animals.

In addition, there is a miscellaneous group of chemicals that affect hydroxylation and other functions of mitochondrial and microsomal fractions (e.g., smooth endoplasmic reticulum) in the adrenal cortex. Examples of these compounds include o,p'-DDD and a-(1,4-dioxido-3-methylquinoxalin-2-yl)- N-methylnitrone (DMNM). Other compounds in this miscellaneous category cause their effects by means of cytochrome P450 metabolism and the production of toxic metabolites. A classic example is the activation of carbon tetrachloride, resulting in lipid peroxidation and covalent binding to cellular macromolecules of the adrenal cortex.

Many of the chemicals that cause morphologic changes in the adrenal glands also affect cortical function. Chemically induced changes in adrenal function result either from blockage of the action of adrenocorticoids at peripheral sites or by inhibition of synthesis and/or secretion of hormone. In the first mechanism, many antisteroidal compounds (antagonists) act by competing with or binding to steroid hormone–receptor sites; thereby, either reducing the number of available receptor sites or by altering their binding affinity. Cortexolone (11a-deoxycortisol) an antiglucocorticoid and spironolactone, an antimineralocorticoid, are two examples of peripherally acting adrenal cortical hormone antagonists.

Xenobiotic chemicals affecting adrenal function often do so by altering steroidogenesis and result in histologic and ultrastructural changes in adrenal cortical cells. For example, chemicals causing increased lipid droplets often inhibit the utilization of steroid precursors, including the conversion of cholesterol to pregnenolone. Chemicals that affect the fine structure of mitochondria and smooth endoplasmic reticulum often impair the activity of 11a-, 17a-, and 21-hydroxylases, respectively, and are associated with lesions primarily in the zonae reticularis and fasciculata. Atrophy of the zona glomerulosa may reflect specific inhibition of aldosterone synthesis or secretion, either directly (e.g., inhibition of 18a-hydroxylation) or indirectly (e.g., suppression of the renin–angiotensin system II) by chemicals such as spironolactone and captopril.

It is well documented that synthetic and naturally occurring corticosteroids are potent teratogens in laboratory animals. The principal induced defect is cleft lip or palate; however, there is a paucity of information on the direct effect of xenobiotic chemicals on the development of the adrenal cortex. For example, adrenal aplasia occurred in 7.6 of 9.8 percent of white Danish rabbits when thalidomide was given to their dams.

Pathologic Alterations and Proliferative Lesions in Cortical Cells

Macroscopic lesions of chemically affected adrenal glands are characterized either by enlargement or reduction in size that often is bilateral. Cortical hypertrophy due to impaired steroidogenesis or hyperplasia due to long-term stimulation often is present when the adrenal cortex is increased in size. Small adrenal glands often are indicative of degenerative changes or trophic atrophy of the adrenal cortex. Midsagittal longitudinal sections of adrenal glands under the above conditions will reveal either a disproportionately wider cortex relative to the medulla or vice versa, resulting in an abnormal cortical:medullary ratio. Nodular lesions that distort and enlarge one or both adrenal glands suggest that a neoplasm is present. A single well-demarcated nodular lesion suggests a cortical adenoma, whereas widespread incorporation of the entire adrenal gland by a proliferative mass is suggestive of cortical carcinoma, especially if there is evidence of local invasion into periadrenal connective tissues or into adjacent blood vessels and the kidney.

Nonneoplastic lesions of the adrenal cortex induced by xenobiotic chemicals are characterized by changes ranging from acute progressive degeneration to reparative processes such as multifocal hyperplasia. Early degenerative lesions characterized by enlarged cortical cells filled with cytoplasmic vacuoles (often lipid) may result in a diffuse hypertrophy of the cortex. A lesion of this type has been observed in rats treated with an antibacterial compound a-(1,4-dioxido-3-methylquinoxalin-2-yl)- N-methylntrone (DMNM). This type of vacuolar degeneration is a reflection of impaired steroidogenesis resulting in an accumulation of steriod precursors. More destructive lesions such as hemorrhage and/or necrosis are associated with an inflammatory response in the cortex. If the zona glomerulosa remains functional there will be no life-threatening electrolyte disturbances and no signs of hypoadrenocorticism (Addison's disease). While many chemical agents that affect the adrenal cortex initially involve the zona reticularis and inner zona fasciculata, certain chemicals such as DMNM can cause a progressive degeneration of the entire adrenal cortex. Occasionally, a chemical's effect is limited to a specific zone of the adrenal cortex and may be species-specific.

Ultrastructural alterations of adrenal cortical cells associated with chemical injury are quite diverse in nature. The zonae reticularis and fasciculata typically are most severely affected, although eventually the lesions involve the zona glomerulosa. These lesions may be classified as follows: endothelial damage (e.g., acrylonitrile), mitochondrial damage (e.g., DMNM, o,p'-DDD, amphenone), endoplasmic reticulum disruption (e.g., triparanol), lipid aggregation (e.g., aniline), lysosomal phospholipid aggregation (e.g., chlorphentermine), and secondary effects due to embolization by medullary cells (e.g., acrylonitrile). Mitochondrial damage with vacuolization and accompanying changes in the endoplasmic reticulum and autophagocytic responses appear to be among the most common ultrastructural changes observed following chemical injury in the adrenal cortex. Since mitochondria and smooth endoplasmic reticulum form an intimate subcellular organellar network in cortical cells with important hydroxylases and dehydrogenase enzymes, it is not surprising that many chemical agents altering the ultrastructural morphology of cortical cells inhibit steroidogenesis.

Chemically induced proliferative lesions of the adrenal cortex are less frequently reported and include hyperplasia, adenoma, and carcinoma. Unlike the diffuse cortical hyperplasia/hypertrophy associated with excess ACTH stimulation, chemically induced hyperplasia usually is nodular in type, often multiple in distribution, and composed of increased numbers of normal or vacuolated cortical cells.

A variety of different chemicals are associated with an increased incidence of adrenal cortical neoplasia. Most of the reported tumors tend to be benign (adenomas) although an occasional tumor may be malignant (carcinomas). The zonae reticularis and fasciculata are more prone to develop tumors following chemical injury whereas the zona glomerulosa is spared unless invaded by an expanding tumor in the adjacent zones of the cortex. The tumorigenic agents of the adrenal cortex have a diverse chemical nature and use.

Spontaneous proliferative lesions may be found in all zones of the adrenal cortex but in adult rats are found most frequently in the zona fasciculata. Spontaneous nodular hyperplasia of the adrenal cortex is common in the rabbit, golden hamster, rat, mouse, dog, cat, horse, and baboon. Naturally occurring adrenal cortical tumors are found infrequently in domestic animals except adult dogs and castrated male goats. However, cortical adenomas and (to a lesser extent) cortical carcinomas have been reported in moderately high incidence in certain strains of laboratory hamsters (e.g., BIO 4.24 and BIO 45.5 strains) and rat (e.g., Osborne

Mendel, WAG/Rij, BUF, and BN/Bi strains). The incidence often increases markedly in rats over 18 months of age. Adrenal cortical neoplasms in mice are uncommon but the incidence may be increased by gonadectomy.

ADRENAL MEDULLA

Normal Structure and Function

The medulla constitutes approximately 10 percent of the volume of the adrenal gland. In the normal rodent adrenal gland and in most other laboratory animal species, the medulla is sharply demarcated from the surrounding cortex. The bulk of the medulla is composed of chromaffin cells, which are the sites of synthesis and storage of the catecholamine hormones. In the rat and mouse, norepinephrine and epinephrine are stored in separate cell types that can be distinguished ultrastructurally after fixation in glutaraldehyde and postfixation in osmium tetroxide. The norepinephrine-containing core of the secretory granules appears electron-dense and is surrounded by a wide submembranous space, whereas epinephrine-containing granules are less dense; they have a finely granular core and a narrow space beneath the limiting membrane. Granules of varying densities may be found in the same cell types in the adrenal medulla of immature rats. Human adrenal medullary cells may contain both norepinephrine and epinephrine within a single chromaffin cell.

The adrenal medulla contains variable numbers of ganglion cells in addition to chromaffin cells. A third cell type has been described in the medulla and designated the small granule–containing (SGC) cell or small intensely fluorescent (SIF) cell. These cells morphologically appear intermediate between chromaffin cells and ganglion cells, and may function as interneurons. The adrenal medullary cells also contain serotonin and histamine, but it has not been determined if these products are synthesized in situ or taken up from the circulation. A number of neuropeptides also are present in rat chromaffin cells, including enkephalins, neurotensin, and neuropeptide Y.

In the catecholamine biosynthetic pathway, tyrosine is acted on by tyrosine hydroxylase to produce dopa, which is converted to dopamine by dopa decarboxylase. Dopamine in turn, is acted on by dopamine beta-hydroxylase to form norepinephrine, which is converted to epinephrine by phenylethanolamine- Λ-methyltransferase (PNMT). Tyrosine hydroxylase and PNMT are the principal rate-limiting steps in catecholamine synthesis. The conversion of tyrosine into dopa and dopamine occurs within the cytosol of chromaffin cells. Dopamine then enters the chromaffin granule, where it is converted to norepinephrine. Norepinephrine leaves the granule and is converted into epinephrine in the cytosol, and epinephrine reenters and is stored in the chromaffin granule. In contrast to the synthesis of catecholamines, which occurs in the cytosol, neuropeptides and chromogranin-A proteins are synthesized in the granular endoplasmic reticulum and are packaged into granules in the Golgi apparatus.

Innervation plays an important role in regulating the functions of chromaffin cells. During adult life, stresses such as insulin-induced hypoglycemia or reserpine-induced depletion of catecholamines produces a reflex increase in splanchnic nerve discharge, resulting both in catecholamine secretion and transsynaptic induction of catecholamine biosynthetic enzymes, including tyrosine hydroxylase. These effects become apparent during the first week of life, following an increase in the number of nerve terminals in the adrenal medulla. Other environmental influences including growth factors, extracellular matrix, and a variety of hormonal signals that generate cyclic AMP also may regulate the function of chromaffin cells.

Mechanisms of Toxicity

Proliferative lesions of the medulla, particularly in the rat, have been reported to develop as a result of a variety of different mechanisms. Warren and coworkers (1966) studied over 700 pairs of rats with parabiosis and found that more than 50 percent of male irradiated rats developed adrenal medullary tumors. A relationship exists between adenohypophyseal (anterior pituitary) hormones and the development of adrenal medullary proliferative lesions. For example, the long-term administration of growth hormone is associated with an increased incidence of pheochromocytomas as well as the development of tumors at other sites. Prolactin-secreting pituitary tumors, which occur commonly in many rat strains, also play a role in the development of proliferative medullary lesions. In addition, several neuroleptic compounds that increase prolactin secretion by inhibiting dopamine production have been associated with an increased incidence of proliferative lesions of medullary cells in chronic toxicity studies in rats.

Both nicotine and reserpine have been implicated in the development of adrenal medullary proliferative lesions in rats. Both agents act by a shared mechanism, since nicotine directly stimulates nicotinic acetylcholine receptors whereas reserpine causes a reflex increase in the activity of cholinergic nerve endings in the adrenal. A short dosing regimen of reserpine administration in vivo stimulates proliferation of chromaffin cells in the adult rat, and the mechanism may involve a reflex increase in neurogenic stimulation via the splanchnic nerve. Several other drugs have been reported to increase the incidence of adrenal medullary proliferative lesions. These include zomepirac sodium (a nonsteroidal anti-inflammatory drug), isoretinoin (a retinoid), and nafarelin (LHRH analog), atenolol (beta-adrenergic blocker), terazosin (alpha-adrenergic blocker), ribavirin (antiviral), and pamidronate (bisphosphonate) (Davies and Monro, 1995).

Lynch et al. (1996) have reported that nutritional factors have an important modulating effect on the spontaneous incidence of adrenal medullary proliferative lesions in rats. Several sugars and sugar alcohols have produced adrenal medullary tumors at high dosages (concentrations of 10 to 20 percent in the diet), including xylitol, sorbitol, lacitol, and lactose. Although the exact mechanism involved is not completely understood, an important role for calcium has been suggested. High doses of slowly absorbed sugars and starches increase the intestinal absorption and urinary excretion of calcium. Hypercalcemia is known to increase catecholamine synthesis in response to stress, and low-calcium diets will reduce the incidence of adrenal medullary tumors in xylitol-treated rats. Other compounds that may act by a similar mechanism of altered calcium homeostasis include the retinoids (which will produce hypercalcemia) and conditions such as progressive nephrocalcinosis in aging male rats treated with nonsteroidal anti-inflammatory agents.

Roe and Bar (1985) have suggested that environmental and dietary factors may be more important than genetic factors as determinants of the incidence of adrenal medullary proliferative lesions in rats. The incidence of adrenal medullary lesions can be reduced by lowering the carbohydrate content of the diet. Several of the agents that increase the incidence of adrenal medullary lesions, including sugar alcohols, increase absorption of calcium from the gut. Calcium ions as well as cyclic nucleotides and prostaglandins may act as mediators capable of stimulating both hormonal secretion and cellular proliferation.

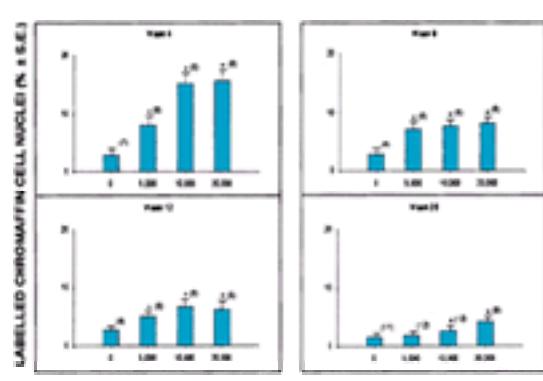
Tischler et al. (1999) recently presented data that vitamin D is the most potent in vivo stimulus yet identified for chromaffin cell proliferation in the adrenal medulla. Vitamin D_3 (5000; 10,000; or 20,000 IU/kg/day in corn oil) resulted in a four- to fivefold increase in bromodeoxyuridine (BrdU) labeling at week 4 that diminished to a twofold increase by week 26 (Fig. 21-8). An initial preponderance of epinephrine-labeled (PNMT-positive cells) subsequently gave way to norepinephrine-labeled cells. By week 26, a total of 89 percent of rats receiving the two highest doses of vitamin D_3 had focal medullary proliferative lesions (BrdU-labeled focal hyperplasia, or "hot spots") and pheochromocytomas in contrast to absence of proliferative lesions in controls. This increase in medullary cell proliferation was associated with a significant increase in circulating levels of both calcium and phosphorus after vitamin D administration (Fig. 21-9). The nuclei of hyperplastic chromaffin cells labeled by BrdU but were phenylethanolamine-Λ-methyl transferase-negative indicating they most likely were norepinephrine-producing cells of the rat medulla (Fig. 21-10). The proliferative lesions usually were multicentric, bilateral, and peripheral in location in the medulla; nearly all were PNMT negative, and they appeared to represent a morphologic continuum rather than separate entities. Earlier studies reported by the same research group had demonstrated that the vitamin D_3 (20,000; 40,000 IU/kg/day) increase in chromaffin cell proliferation was observed as early as 1 week and had declined by 4 weeks. These findings support the hypothesis that altered calcium homeostasis is involved in the pathogenesis of pheochromocytomas in rodents, most likely via effects on increasing chromaffin cell proliferation (Fig. 21-11). Vitamin D_3, calcitriol (active metabolite of D_3), lactose, and xylitol all failed to stimulate directly the proliferation of rat chromaffin cells in vitro.


Figure 21-8. Effects of vitamin D$_3$ on percent of chromaffin cells labeled with BrdU during weeks 4, 8, 12, and 26 of dietary supplementation.

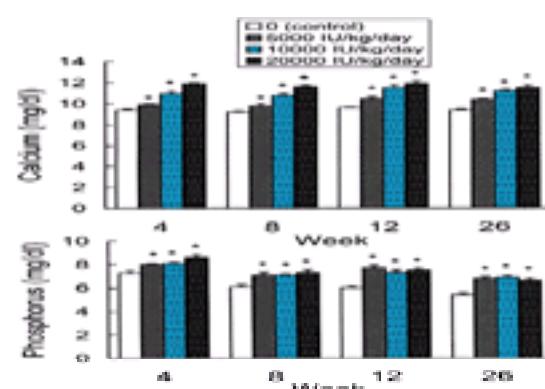
Asterisks indicate statistically significant increases over corn oil controls. Numbers in parentheses indicate numbers of rats scored for each point. Premature deaths or euthanasia caused loss of three animals from the group receiving 20,000 IU/kg/day, two from the group receiving 10,000 IU/kg/day, and one control. Histologic examination of these animals' adrenal glands showed no detectable abnormalities. One extra animal at the start of the experiment was assigned to the control group at week 1. At least 2500 chromaffin cells were scored for each rat. (From Tischler et al., 1999, with permission.)


Figure 21-9. Effects of vitamin D$_3$ on serum calcium and phosphorus levels at weeks 4, 8, 12, and 26.

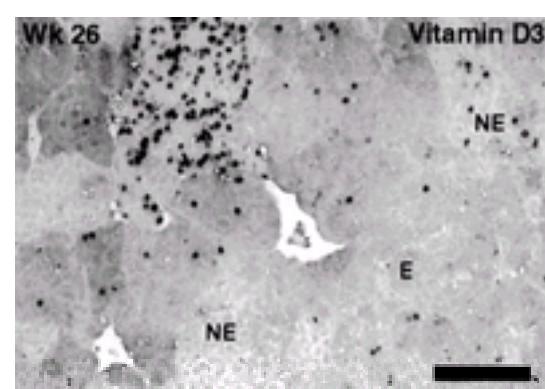
Sustained perturbation of both Ca^{2+} and PO$_4$ concentrations persisted throughout the time course. (From Tischler et al., 1999, with permission.)


Figure 21-10. Photomicrographs of adrenal medullary sections stained for BrdU (dark nuclei) and PNMT (dark cytoplasm) to compare BrdU labeling of epinephrine (E) and norepinephrine (NE) cells.

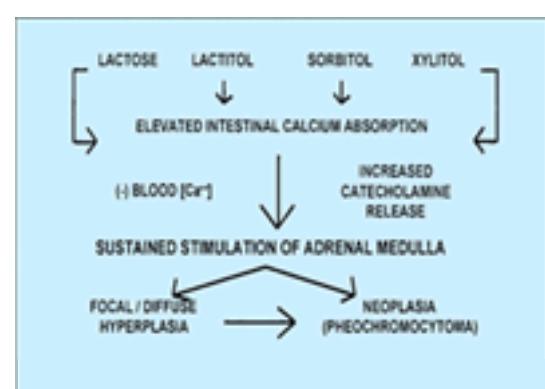
Vitamin D$_3$ (20,000 IU/kg/day) caused a dramatic increase in BrdU labeling of predominantly E cells at week 4. The response was greatly reduced at week 26 and there was no longer an E-cell predominance. A representative hyperplasic nodule in the vitamin D$_3$–stimulated adrenal medulla at week 26 (*top left*) is densely labeled with BrdU and is PNMT-negative (bar = 100 mm). (From Tischler et al., 1999, with permission.)


Figure 21-11. Pathogenesis of adrenal medullary proliferative lesions associated with ingestion of polyols resulting in elevation of the blood calcium concentration. (Modified from Lynch et al., 1996, with permission.)

In summary, three dietary factors have been suggested to lead to an increased incidence of adrenal medullary proliferative lesions in chronic toxicity studies in rats (Roe and Bar, 1985). These are (1) excessive intake of food associated with feeding ad libitum; (2) excessive intake of calcium and phosphorus, since commercial diets contain two to three times more calcium and phosphorus than needed by young rats; and (3) excessive intake of other food components (e.g., vitamin D and poorly absorbable carbohydrates), which increase calcium absorption.

Pathologic Alterations and Proliferative Lesions in Medullary Cells

The adrenal medulla undergoes a series of proliferative changes ranging from diffuse hyperplasia to benign and malignant neoplasia. The latter neoplasms have the capacity to invade locally and to metastasize to distant sites. Diffuse hyperplasia is characterized by symmetrical expansion of the medulla with maintenance of the usual sharp demarcation between the cortex and the medulla. The medullary cell cords often are widened, but the ratio of norepinephrine to epinephrine cells is similar to that of normal glands. Focal hyperplastic lesions are often juxtacortical but may occur within any area of the medulla. The small nodules of hyperplasia in general are not associated with compression of the adjacent medulla; however, the larger foci may be associated with limited medullary compression. The foci of adrenal medullary hyperplasia are typically composed of small cells with round to ovoid nuclei and scanty cytoplasm. At the ultrastructural level, the cells composing these focal areas of hyperplasia contain small numbers of dense core secretory granules resembling the granules of SIF or SGC cells.

Larger benign adrenal medullary proliferative lesions are designated as pheochromocytomas. These lesions may be composed of relatively small cells similar to those found in smaller hyperplastic foci or larger chromaffin cells or a mixture of small and large cells. According to some authors, the lack of a positive chromaffin reaction in these focal proliferative lesions precludes the diagnosis of pheochromocytoma; however, the chromaffin reaction is quite insensitive and catecholamines (particularly norepinephrine) can be demonstrated in these proliferative lesions by biochemical extraction studies and by the formaldehyde- or glyoxylic-acid-induced fluorescence methods. Even in some of the larger medullary lesions, the chromaffin reaction is equivocal but catecholamines can be demonstrated both biochemically and histochemically. Malignant pheochromocytomas invade the adrenal capsule and often grow in the periadrenal connective tissues with or without distant metastases.

Proliferative lesions occur with high frequency in many strains of laboratory rats. The incidence of these lesions varies with strain, age, sex, diet, and exposure to drugs, and a variety of environmental agents. Studies from the NTP historical data base of 2-year-old F344 rats have reported that the incidence of pheochromocytomas was 17.0 percent and 3.1 percent for males and females, respectively. Malignant pheochromocytomas were detected in 1 percent of males and 0.5 percent of females. In addition to F344 rats, other strains with a high incidence of pheochromocytomas include Wistar, NEDH (New England Deaconess Hospital), Long-Evans, and Sprague-Dawley. Pheochromocytomas are considerably less common in Osborne-Mendel, Charles River, Holtzman, and WAG/Rij rats. Most studies have revealed a higher incidence in males than in females (Fig. 21-12 and Fig. 21-13). Crossbreeding of animals with high and low frequencies of adrenal medullary proliferative lesions results in F $_1$ animals with an intermediate tumor frequency. Pheochromocytomas are less common in the mouse than in most strains of rats.

There is a conspicuous relationship between increasing age and the frequency, size, and bilateral occurrence of adrenal medullary proliferative lesions in the rat. In the Long-Evans strain, medullary nodules have been found in less than 1 percent of animals under twelve months of age. The frequency increases to almost 20 percent in 2-year-old animals and to 40 percent in animals between 2 and 3 years of age. The mean tumor size increases progressively with age, as does the frequency of bilateral and multicentric occurrence.

A variety of techniques may be used for the demonstration of catecholamines in tissue sections. The chromaffin reaction is the oxidation of catecholamines by potassium dichromate solutions and results in the formation of a brown-to-yellow pigment in medullary tissue. The chromaffin reaction as traditionally performed possesses a low level of sensitivity and should not be used for the definitive demonstration of the presence of catecholamines in tissues. Similarly, both the argentaffin and argyrophil reactions, which have been used extensively in the past for the demonstration of chromaffin cells, also possess low sensitivity and specificity. Fluorescence techniques using formaldehyde or glyoxylic acid represent the methods of choice for the demonstration of catecholamines at the cellular level. These aldehydes form highly fluorescent derivatives with catecholamines, which can be visualized by ultraviolet microscopy. Immunohistochemistry provides an alternative approach for the localization of catecholamines in chromaffin cells and other cell types. Antibodies are available that permit epinephrine- and norepinephrine-containing cells to be distinguished in routinely fixed and embedded tissue samples. Several of the important enzymes involved in the biosynthesis of catecholamine hormones also may be demonstrated by immunohistochemical procedures. Antibodies to chromogranin-A can be used for the demonstration of this unique protein in chromaffin cells.

Pheochromocytomas in rats and human beings are both composed of chromaffin cells with variable numbers of hormone-containing secretory granules (Fig. 21-14). The incidence is high in many strains of rats by comparison to human patients, where pheochromocytomas are uncommon except in patients with inherited clinical syndromes of multiple endocrine neoplasia (MEN). These tumors in rats usually do not secrete excess amounts of catecholamines, whereas human pheochromocytomas episodically secrete increased amounts of catecholamines leading to hypertension and other clinical disturbances. There appears to be a striking species difference in the response of medullary chromaffin cells to mitogenic stimuli with rats being very sensitive compared to humans (Fig. 21-14).

RESPONSE OF AM TO MITOGENIC STIMULI	SENSITIVE	RESISTANT

Figure 21-14. Characteristics of pheochromocytomas in rats compared to humans. (Modified from Lynch et al., 1996, with permission.)

Tischler and Riseberg (1993) reported that adult rat chromaffin cells had a marked increase (from not more than 10 to 40 percent) in bromodeoxyuridine (BrdU)–labeled nuclei in vitro following the addition of the following mitogens: nerve growth factor (NGF), fibroblast growth factor (FGF), forskolin, and phorbol myristate (PMA), whereas human chromaffin cells had a minimal (< 0.1 percent) response to the same mitogens (Fig. 21-15). This striking difference in sensitivity to mitogenic stimuli may explain the lower frequency of adrenal medullary proliferative lesions in humans compared to many rat strains (Tischler and Riseberg, 1993). The mouse adrenal medulla, which, as in humans, has a low spontaneous incidence of proliferative lesions of chromaffin cells, also failed to respond to a variety of mitogenic stimuli (Fig. 21-15). These findings and others suggest that chromaffin cells of the rat represent an inappropriate model to assess the potential effects of xenobiotic chemicals on chromaffin cells of the human adrenal medulla (Lynch et al., 1996).

THYROID GLAND (FOLLICULAR CELLS)

Species Differences in Thyroid Hormone Economy

Long-term perturbations of the pituitary-thyroid axis by various xenobiotics or physiologic alterations (e.g., iodine deficiency, partial thyroidectomy, and natural goitrogens in food) are more likely to predispose the laboratory rat to a higher incidence of proliferative lesions [e.g., hyperplasia and benign tumors (adenomas) of follicular cells] in response to chronic TSH stimulation than in the human thyroid (Capen and Martin, 1989; Curran and DeGroot, 1991). This is particularly true in the male rat which has higher circulating levels of TSH than in females. The greater sensitivity of the rodent thyroid to derangement by drugs, chemicals, and physiologic perturbations also is related to the shorter plasma half-life of thyroxine T_4 in rats than in humans due to the considerable differences in the transport proteins for thyroid hormones between these species (Döhler et al., 1979).

The plasma T_4 half-life in rats is considerably shorter (12 to 24 h) than in humans (5 to 9 days). In human beings and monkeys circulating T_4 is bound primarily to thyroxine-binding globulin (TBG), but this high-affinity binding protein is not present in rodents, birds, amphibians, or fish (Table 21-1).

Table 21-1 Thyroxine (T_4) Binding to Serum Proteins in Selected Vertebrate Species

The binding affinity of TBG for T_4 is approximately a thousand times higher than for prealbumin. The percent of unbound active T_4 is lower in species with high levels of TBG than in animals in which T_4 binding is limited to albumin and prealbumin. Therefore, a rat without a functional thyroid requires about 10 times more T_4 (20 mg/kg body weight) for full substitution than an adult human (2.2 mg/kg body weight). Triiodothyronine (T_3) is transported bound to TBG and albumin and transthyretin in the human being, monkey, and dog but only to albumin in the mouse, rat, and chicken (Table 21-2). In general, T_3 is bound less avidly to transport proteins than T_4, resulting in a faster turnover and shorter plasma half-life in most species. These differences in plasma half-life of thyroid hormones and binding to transport proteins between rats and human beings may be one factor in the greater sensitivity of the rat thyroid to developing hyperplastic and/or neoplastic nodules in response to chronic TSH stimulation.

Table 21-2 Triiodothyronine (T_3) Binding to Serum Proteins in Selected Vertebrate Species

Thyroid-stimulating hormone levels are higher in male than female rats and castration decreases both the baseline serum TSH and response to thyrotropin-releasing hormone (TRH) injection. Follicular cell height often is higher in male than in female rats in response to the greater circulating TSH levels. The administration of exogenous testosterone to castrated male rats restores the TSH level to that of intact rats. Malignant thyroid tumors (carcinomas or "cancer") develop at a higher incidence following irradiation in males than females (2:1) and castration of irradiated male rats decreases the incidence to that of intact irradiated female rats. Testosterone replacement to castrated male rats restores the incidence of irradiation-induced thyroid carcinomas in proportion to the dose of testosterone and, similarly, serum TSH levels increase proportionally to the dose of replacement hormone. Likewise, higher incidence of follicular cell hyperplasia and neoplasia has been reported in males compared to female rats following the administration of a wide variety of drugs and chemicals in chronic toxicity/carcinogenicity testing.

There also are marked species differences in the sensitivity of the functionally important peroxidase enzyme to inhibition by xenobiotics. Thioamides (e.g., sulfonamides) and other chemicals can selectively inhibit the thyroperoxidase and significantly interfere with the iodination of tyrosyl residues incorporated in the thyroglobulin molecule, thereby disrupting the orderly synthesis of T_4 and T_3. A number of studies have shown that the long-term administration of sulfonamides results in the development of thyroid nodules frequently in the sensitive species (such as the rat, dog, and mouse) but not in species resistant (e.g., monkey, guinea pig, chicken, and human beings) to the inhibition of peroxidase in follicular cells.

Mechanisms of Thyroid Tumorigenesis

Numerous studies have reported that chronic treatment of rodents with goitrogenic compounds results in the development of follicular cell adenomas. Thiouracil and

its derivatives have this effect in rats (Napalkov, 1976) and mice (Morris, 1955). This phenomenon also has been observed in rats that consumed brassica seeds (Kennedy and Purves, 1941), erythrosine (FD&C Red No. 3) (Capen and Martin, 1989; Borzelleca et al., 1987), sulfonamides (Swarm et al., 1973), and many other compounds (Hill et al., 1989; Paynter et al., 1988). The pathogenetic mechanism of this phenomenon has been understood for some time (Furth, 1954) and are widely accepted by the scientific community. These goitrogenic agents either directly interfere with thyroid hormone synthesis or secretion in the thyroid gland, increase thyroid hormone catabolism and subsequent excretion into the bile, or disrupt the peripheral conversion of thyroxine (T$_4$) to triiodothyronine (T$_3$). The ensuing decrease in circulating thyroid hormone levels results in a compensatory increased secretion of pituitary thyroid stimulating hormone (TSH). The receptor-mediated TSH stimulation of the thyroid gland leads to proliferative changes of follicular cells that include hypertrophy, hyperplasia, and ultimately, neoplasia in rodents.

Excessive secretion of TSH alone (i.e., in the absence of any chemical exposure) also has been reported to produce a high incidence of thyroid tumors in rodents (Ohshima and Ward, 1984, 1986). This has been observed in rats fed an iodine-deficient diet (Axelrod and Leblond, 1955) and in mice that received TSH-secreting pituitary tumor transplants (Furth, 1954). The pathogenetic mechanism of thyroid follicular cell tumor development in rodents involves a sustained excessive stimulation of the thyroid gland by TSH. In addition, iodine deficiency is a potent promoter of the development of thyroid tumors in rodents induced by intravenous injection of N-methyl-N-nitrosurea (Fig. 21-16) (Ohshima and Ward, 1984). The subsequent parts of thyroid section discuss specific mechanisms by which xenobiotic chemicals disrupt thyroid hormone synthesis and secretion, induce hepatic microsomal enzymes that enhance thyroid hormone catabolism or inhibit enzymes involved in monodeiodination in peripheral tissues that result in perturbations of thyroid hormone economy which in rodents predisposes to the development of follicular cell tumors in chronic studies.

Figure 21-16. Data demonstrating the potent promoting effects of iodine deficiency (ID) in rats administered a single intravenous dose of a known initiator [N = nitrosomethylurea (NMU)] of thyroid neoplasms. (From Ohshima and Ward, 1984, with permission.)

Chemicals that Directly Inhibit Thyroid Hormone Synthesis

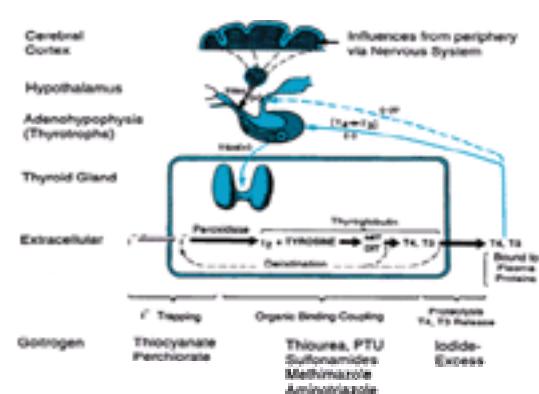
Blockage of Iodine Uptake The biosynthesis of thyroid hormones is unique among endocrine glands because the final assembly of the hormones occurs extracellularly within the follicular lumen. Essential raw materials, such as iodide, are trapped efficiently at the basilar aspect of follicular cells from interfollicular capillaries, transported rapidly against a concentration gradient to the lumen, and oxidized by a thyroid peroxidase in microvillar membranes to reactive iodine (I$_2$) (Fig. 21-17). The mechanism of active transport of iodide has been shown to be associated with a sodium-iodide (Na$^+$-I$^-$) symporter (NIS) present in the basolateral membrane of thyroid follicular cells. Transport of iodide ion across the thyroid cell membrane is linked to the transport of Na$^+$. The ion gradient generated by the Na$^+$, K$^+$-ATPase appears to be the driving force for the active cotransport of iodide. The transporter protein is present in the basolateral membrane of thyroid follicular cells (thyrocytes) and is a large protein containing 643 amino acids with 13 transmembrane domains.


Figure 21-17. Mechanism of action of goitrogenic chemicals on thyroid hormone synthesis and secretion. (From Capen and Martin, 1989, with permission.)

Immunohistochemical staining using a polyclonal antibody against the human NIS fusion protein (hNIS) revealed that expression of the protein is heterogenous in the normal human thyroid and detected only in occasional thyrocytes of a follicle (Jhiang et al., 1998). The hNIS-positive thyrocytes usually were detected in small follicles composed of cuboidal to columnar cells but rarely were detected in large follicles composed of flattened thyrocytes. The heterogeneity of hNIS expression among thyroid follicles is consistent with the finding that iodide concentrating ability also varies between follicles in the thyroid gland (Spitzweg et al., 2000).

Other tissues such as the salivary gland, gastric mucosa, choroid plexus, ciliary body of the eye, and lactating mammary gland also have the capacity to actively transport iodide, albeit at a much lower level than the thyroid. In the salivary glands the hNIS protein was detected in ductal cells but not in acinar cells. Only the thyroid follicular cells accumulate iodide in a TSH-dependent manner. The NIS gene is complex (15 exons, 14 introns) and its expression in the thyroid is up-regulated by TSH. The functionally active iodine transport system in the thyroid gland has important clinical applications in the evaluation, diagnosis, and treatment of several thyroid disorders, including cancer. The NIS and active transport of iodide can be selectively inhibited by competitive anion inhibitors, thereby effectively blocking the ability of the gland to iodinate tyrosine residues in thyroglobulin and synthesize thyroid hormones.

The initial step in the biosynthesis of thyroid hormones is the uptake of iodide from the circulation and transport against a gradient across follicular cells to the lumen of the follicle. A number of anions act as competitive inhibitors of iodide transport in the thyroid, including perchlorate (ClO$_4^-$), thiocyanate (SCN$^-$), and pertechnetate (Fig. 21-17). Thiocyanate is a potent inhibitor of iodide transport and is a competitive substrate for the thyroid peroxidase, but it does not appear to be concentrated in the thyroid. Blockage of the iodide trapping mechanism has a disruptive effect on the thyroid-pituitary axis, similar to iodine deficiency. The blood levels of T$_4$ and T$_3$ decrease, resulting in a compensatory increase in the secretion of TSH by the pituitary gland. The hypertrophy and hyperplasia of follicular cells following sustained exposure results in an increased thyroid weight and the development of goiter.

Inhibition of Thyroid Peroxidase Resulting in an Organification Defect A wide variety of chemicals, drugs, and other xenobiotics affect the second step in thyroid hormone biosynthesis (Fig. 21-17). The stepwise binding of iodide to the tyrosyl residues in thyroglobulin requires oxidation of inorganic iodide (I^2) to molecular (reactive) iodine (I$_2$) by the thyroid peroxidase present in the luminal aspect (microvillar membranes) of follicular cells and adjacent colloid. Classes of chemicals that inhibit the organification of thyroglobulin include (1) the thionamides (such as thiourea, thiouracil, propylthiouracil, methimazole, carbimazole, and goitrin); (2) aniline derivatives and related compounds (e.g., sulfonamides, paraaminobenzoic acid, paraaminosalicylic acid, and amphenone); (3) substituted phenols (such as resorcinol, phloroglucinol, and 2,4-dihydroxybenzoic acid); and (4) miscellaneous inhibitors [e.g., aminotriazole, tricyanoaminopropene, antipyrine, and its iodinated derivative (iodopyrine)] (Fig. 21-18).

Figure 21-18. Chemicals disrupting thyroid function (decreased synthesis of thyroid hormones) by inhibiting thyroperoxidase.

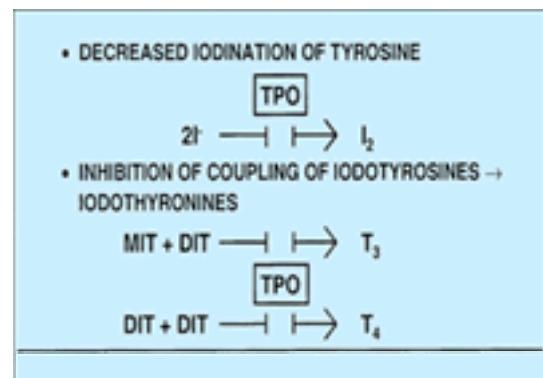
Many of these chemicals exert their action by inhibiting the thyroid peroxidase, which results in a disruption both of the iodination of tyrosyl residues in thyroglobulin and also the coupling reaction of iodotyrosines [e.g., monoiodothyronine (MIT) and di-iodothyronine (DIT)] to form iodothyronines (T_3 and T_4) (Fig. 21-19). Propylthiouracil (PTU) has been shown to affect each step in thyroid hormone synthesis beyond iodide transport in rats. The order of susceptibility to the inhibition by PTU is the coupling reaction (most susceptible), iodination of MIT to form DIT, and iodination of tyrosyl residues to form MIT (least susceptible). Thiourea differs from PTU and other thioamides in that it neither inhibits guaiacol oxidation (the standard assay for peroxidase) nor inactivates the thyroid peroxidase in the absence of iodine. Its ability to inhibit organic iodinations is due primarily to the reversible reduction of active I_2 to $2I^-$.


Figure 21-19. Mechanisms by which xenobiotic chemicals decrease thyroid hormone synthesis by inhibiting thyroperoxidase (TPO) in follicular cells.

The goitrogenic effects of sulfonamides have been known for more than fifty years, since the reports of the action of sulfaguanidine on the rat thyroid. Sulfamethoxazole and trimethroprim exert a potent goitrogenic effect in rats, resulting in marked decreases in circulating T_3 and T_4, a substantial compensatory increase in TSH, and increased thyroid weights due to follicular cell hyperplasia. The dog also is a species sensitive to the effects of sulfonamides, resulting in markedly decreased serum T_4 and T_3 levels, hyperplasia of thyrotrophic basophils in the pituitary gland, and increased thyroid weights.

By comparison, the thyroids of monkeys and human beings are resistant to the development of changes that sulfonamides produce in rodents (rats and mice) and the dog. Rhesus monkeys treated for 52 weeks with sulfamethoxazole (doses up to 300 mg/kg/day) with and without trimethroprim had no changes in thyroid weights and the thyroid histology was normal. Takayama and coworkers (1986) compared the effects of PTU and a goitrogenic sulfonamide (sulfamonomethoxine) on the activity of thyroid peroxidase in the rat and monkey using the guaiacol peroxidation assay. The concentration required for a 50 percent inhibition of the peroxidase enzyme was designated as the inhibition constant $_{5c}$ (IC_{50}). When the IC_{50} for PTU was set at 1 for rats it took 50 times the concentration of PTU to produce a comparable inhibition in the monkey. Sulfamonomethoxine was almost as potent as PTU in inhibiting the peroxidase in rats. However, it required about 500 times the concentration of sulfonamide to inhibit the peroxidase in the monkey compared to the rat. Studies such as these with sulfonamides demonstrate distinct species differences between rodents and primates in the response of the thyroid to chemical inhibition of hormone synthesis. It is not surprising that the sensitive species (e.g., rats, mice, and dogs) are much more likely to develop follicular cell hyperplasia and thyroid nodules after long-term exposure to sulfonamides than the resistant species (e.g., subhuman primates, human beings, guinea pigs, and chickens) (Fig. 21-20).

Figure 21-20. Variable species sensitivity of thyroperoxidase (TPO) inhibition by sulfonamides. (From Takayama et al., 1986, with permission.)

Recent evidence suggests that propylthiouracil (PTU) or feeding a low-iodine diet markedly increase thyroid follicular cell proliferation in rats by disrupting the movement of low-molecular-weight ions and molecules through gap junctions (Kolaja et al., 2000). Inhibition of gap-junction intercellular communication (GJIC) prior to induction of cell proliferation has been reported with several tumor promoters and in proliferative diseases. After 14 days of either PTU or a low iodine diet (plus 1 percent $KClO_4$ in water) serum T_3 and T_4 were decreased to undetectable levels, serum TSH was increased significantly and thyroid follicular cell proliferation was increased nearly threefold. This was accompanied by a 30 to 35 percent decrease in GJIC [determined by an ex vivo method with Lucifer yellow—a low-molecular-weight (457) fluorescent dye] and a twofold increase in apoptosis in both treat-ed groups. Therefore, inhibition of GJIC by PTU or a low-iodine diet may result in increased thyroid follicular cell proliferation, similar to other tissues, possibly by disrupting the passage of regulatory substance(s) through these highly permeable intercellular channels.

A contemporary example of a chemical acting as a thyroperoxidase inhibitor is sulfamethazine. This is a widely used antibacterial compound in food-producing animals with a current permissible tissue residue level of 100 ppb. Recently completed carcinogenicity studies at NCTR reported a significant increase of thyroid tumors in male Fischer 344 rats administered the high dose (2400 ppm) of sulfamethazine (McClain, 1995). The incidence of thyroid tumors was increased in both male and female $B_6C_3F_1$ mice after two years in the high-dose (4800 ppm) group but not in the lower-dose groups. Quantitative risk assessment based upon these new carcinogenicity findings, using low-dose linear extrapolation, yielded a 1×10^6 lifetime risk of 90 ppb in female rats and 40 ppb in male rats. A consideration of the ratio of intact drug to metabolites further reduced the tissue residue level to 0.4 ppb, which would be unachievable in practice (McClain, 1995).

A number of mechanistic studies have been performed in collaboration with Dr. McClain and others with the objective of developing a database that would support the

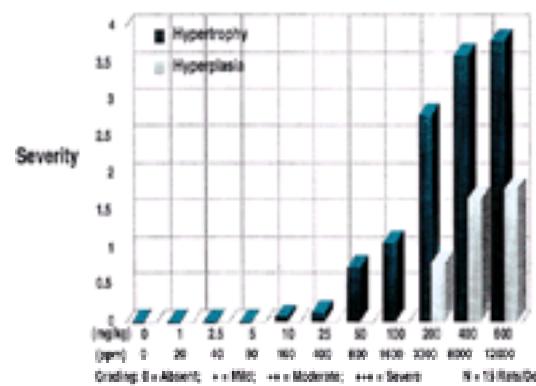
hypothesis that the thyroid tumors observed in rats and mice from chronic studies were secondary to hormonal imbalances following the administration of high doses of sulfamethazine. In a 4-week mechanistic study, the effects of 10 dose levels (0 > 12,000 ppm) of sulfamethazine, spanning the range that induced thyroid tumors in rodents, were evaluated on thyroid hormone economy in Sprague-Dawley rats. There was a characteristic log-dose response relationship in all parameters of thyroid function evaluated. There were no significant changes at the six lower doses (20 > 800 ppm) of sulfamethazine, followed by sharp relatively linear changes at the four higher dose levels (1600 > 12,000 ppm) in percent decrease of serum T_3 and T_4, increase in serum TSH, and increase in thyroid weight. A similar, nonlinear dose response was present in the morphologic changes of thyroid follicular cells following the feeding of varying levels of sulfamethazine. Follicular cell hypertrophy was observed at lower doses of sulfamethazine than hyperplasia, which was increased only at dose levels of 3300 ppm and above (Fig. 21-21).


Figure 21-21. Nonlinear dose-response in morphologic changes in thyroid follicular cells in response to 10 dose levels of sulfamethazine administered in the feed to male Sprague-Dawley rats. (From Capen, 1997, with permission.)

Other mode-of-action studies have demonstrated sulfameth-azine to be a potent inhibitor of thyroperoxidase in rodents with a IC $_{50}$ of 1.2×10^{-6} M. The morphologic effects on the thyroid were reversible after withdrawal of compound and addition of supplemental T_4 to the diet inhibited the development of the functional and morphologic changes in thyroid follicular cells (McClain, 1995). Hypophysectomized rats (with no TSH) administered sulfamethazine did not develop morphologic changes in the thyroid. Sulfamethazine did not increase thyroid cell proliferation in vitro in the absence of TSH and there was no effect on thyroid structure/function in cynomolgus monkeys administered sulfameth-azine. Nonhuman primates and human beings are known to be more resistant than rodents to the inhibition of thyroperoxidase.

Chemicals that Disrupt Thyroid Hormone Secretion

Blockage of Thyroid Hormone Release by Excess Iodide and Lithium Relatively few chemicals selectively inhibit the secretion of thyroid hormone from the thyroid gland (Fig. 21-17). An excess of iodine has been known for years to inhibit secretion of thyroid hormone and occasionally can result in goiter and subnormal function (hypothyroidism) in animals and human patients. High doses of iodide have been used therapeutically in the treatment of patients with Graves' disease and hyperthyroidism to lower circulating levels of thyroid hormones. Several mechanisms have been suggested for this effect of high iodide levels on thyroid hormone secretion, including a decrease in lysosomal protease activity (in human glands), inhibition of colloid droplet formation (in mice and rats), and inhibition of TSH-mediated increase in cAMP (in dog thyroid slices). Studies in my laboratory demonstrated that rats fed an iodide-excessive diet had a hypertrophy of the cytoplasmic area of follicular cells with an accumulation of numerous colloid droplets and lysosomal bodies (Collins and Capen, 1980). However, there was limited evidence ultrastructurally of the fusion of the membranes of these organelles and of the degradation of the colloid necessary for the release of active thyroid hormones (T_4 and T_3) from the thyroglobulin. Circulating levels of T_4, T_3, and rT_3 all would be decreased by an iodide-excess in rats.

Lithium also has been reported to have a striking inhibitory effect on thyroid hormone release (Fig. 21-17). The widespread use of lithium carbonate in the treatment of manic states occasionally results in the development of goiter with either euthyroidism or occasionally hypothyroidism in human patients. Lithium inhibits colloid droplet formation stimulated by cAMP in vitro and inhibits the release of thyroid hormones.

Xenobiotic-Induced Thyroid Pigmentation or Alterations in Colloid The antibiotic minocycline produces a striking black discoloration of the thyroid lobes in laboratory animals and humans with the formation of brown pigment granules within follicular cells. The pigment granules stain similarly to melanin and are best visualized on thyroid sections stained with the Fontana-Masson procedure. Electron-dense material first accumulates in lysosome-like granules and in the rough endoplasmic reticulum. The pigment appears to be a metabolic derivative of minocycline and the administration of the antibiotic at high dose to rats for extended periods may result in a disruption of thyroid function and the development of goiter. The release of T_4 from perfused thyroids of minocycline-treated rats was significantly decreased but the follicular cells retained the ability to phagocytose colloid in response to TSH and had numerous colloid droplets in their cytoplasm.

Other xenobiotics [or metabolite(s)] selectively localize in the thyroid colloid of rodents resulting in abnormal clumping and increased basophilia to the colloid. Brown to black pigment granules may be present in follicular cells, colloid, and macrophages in the interthyroidal tissues resulting in a macroscopic darkening of both thyroid lobes. The physiochemically altered colloid in the lumen of thyroid follicles appears to be less able than normal colloid either of reacting with organic iodine in a stepwise manner to result in the orderly synthesis of iodothyronines or being phagocytized by follicular cells and enzymatically processed to release active thyroid hormones into the circulation. Serum T_4 and T_3 are decreased, serum TSH levels are increased by an expanded population of pituitary thyrotrophs, and thyroid follicular cells undergo hypertrophy and hyperplasia. As would be expected, the incidence of thyroid follicular cell tumors in 2-year carcinogenicity studies is significantly increased at the higher dose levels, usually with a greater effect in males than females. Autoradiographic studies often demonstrate tritiated material to be preferentially localized in the colloid and not within follicular cells. Tissue distribution studies with ^{14}C-labeled compound may reveal preferential uptake and persistence in the thyroid gland compared to other tissues. However, thyroperoxidase activity is normal and the thyroid's ability to take up radioactive iodine often is increased compared to controls in response to the greater circulating levels of TSH. Similar thyroid changes and/or functional alterations usually do not occur in dogs, monkeys, or humans.

Hepatic Microsomal Enzyme Induction

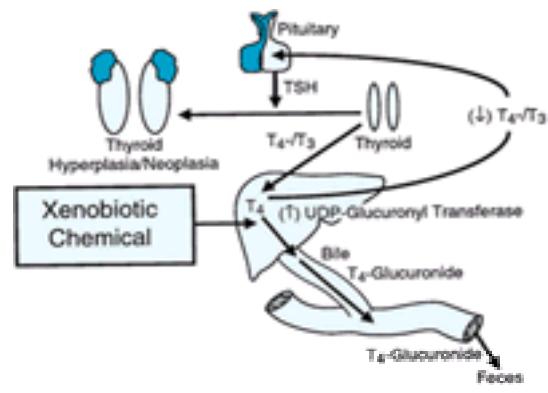
Hepatic microsomal enzymes play an important role in thyroid hormone economy because glucuronidation is the rate-limiting step in the biliary excretion of T_4 and sulfation primarily by phenol sulfotransferase for the excretion of T_3. Long-term exposure of rats to a wide variety of different chemicals may induce these enzyme pathways and result in chronic stimulation of the thyroid by disrupting the hypothalamic-pituitary-thyroid axis (Curran and DeGroot, 1991). The resulting chronic stimulation of the thyroid by increased circulating levels of TSH often results in a greater risk of developing tumors derived from follicular cells in 2-year or lifetime chronic toxicity/carcinogenicity studies with these compounds in rats (Fig. 21-22). Recent studies have suggested that glucuronidation and enhanced biliary excretion of T_3 may be the reason why serum TSH is increased in short-term (7 days) studies with some microsomal enzyme inducing chemicals (e.g., phenobarbital, pregnenolone-16a-carbonitrile) but is less affected with others (3-methylcholanthrene, PCB) (Hood and Klaassen, 2000). However, microsomal enzyme inducers are more effective in reducing serum T_4 than serum T_3 (Hood and Klaassen, 2000). Outer-ring deiodinase (ORD) activity, an enzyme involved in the peripheral conversion of T_4 (major secretory product of the thyroid) to T_3, was reduced (not increased as would be expected if this was the mechanism) following the administration of four well-characterized enzyme inducers in rats. Type I ORD was measured in thyroid, kidney, and liver whereas type II ORD was quantified in brown adipose tissue, pituitary gland, and brain.


Figure 21-22. Hepatic microsomal enzyme induction by the chronic administration of xenobiotic chemicals, leading to thyroid follicular cell hyperplasia and neoplasia.

Xenobiotics that induce liver microsomal enzymes and disrupt thyroid function in rats include CNS-acting drugs (e.g., phenobarbital, benzodiazepines); calcium channel blockers (e.g., nicardipine, bepridil); steroids (spironolactone); retinoids; chlorinated hydrocarbons (e.g., chlordane, DDT, TCDD), polyhalogenated biphenyls (PCB, PBB), among others. Most of the hepatic microsomal enzyme inducers have no apparent intrinsic carcinogenic activity and produce little or no mutagenicity or DNA damage. Their promoting effect on thyroid tumors usually is greater in rats than in mice, with males more often developing a higher incidence of tumors than females. In certain strains of mice these compounds alter liver cell turnover and promote the development of hepatic tumors from spontaneously initiated hepatocytes.

Phenobarbital has been studied extensively as the prototype for hepatic microsomal inducers that increase a spectrum of cytochrome P450 isoenzymes (McClain et al., 1988). McClain and associates (1989) reported that the activity of uridine diphosphate glucuronyltransferase (UDP-GT), the rate limiting enzyme in T_4 metabolism, is increased in purified hepatic microsomes of male rats when expressed as picomoles/min/mg microsomal protein (1.3-fold) or as total hepatic activity (threefold). This resulted in a significantly higher cumulative (4-h) biliary excretion of ^{125}I-labeled T_4 and bile flow than in controls.

Phenobarbital-treated rats develop a characteristic pattern of changes in circulating thyroid hormone levels (McClain et al., 1988, 1989). Plasma T_3 and T_4 are markedly decreased after 1 week and remain decreased for 4 weeks. By 8 weeks T_3 levels return to near normal due to compensation by the hypothalamic-pituitary-thyroid axis. Serum TSH values are elevated significantly throughout the first month but often decline after a new steady state is attained. Thyroid weights increase significantly after 2 to 4 weeks of phenobarbital, reach a maximum increase of 40 to 50 percent by 8 weeks, and remain elevated throughout the period of treatment.

McClain and coworkers (1988) in a series of experiments have shown that supplemental administration of thyroxine (at doses that returned the plasma level of TSH to the normal range) blocked the thyroid tumor-promoting effects of phenobarbital and that the promoting effects were directly proportional to the level of plasma TSH in rats. The sustained increase in circulating TSH levels results initially in hypertrophy of follicular cells, followed by hyperplasia, and ultimately places the rat thyroid at greater risk to develop an increased incidence of benign tumors.

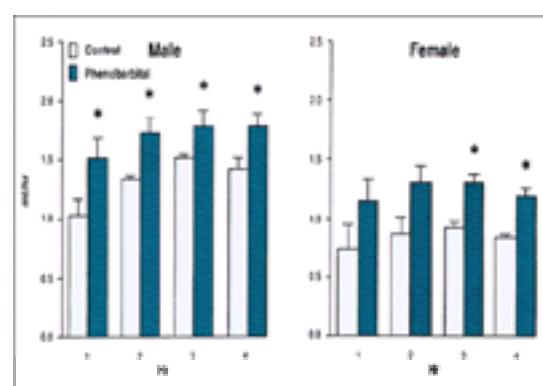
Phenobarbital has been reported to be a thyroid gland tumor promoter in a rat initiation-promotion model. Treatment with a nitrosamine followed by phenobarbital has been shown to increase serum TSH concentrations, thyroid gland weights, and the incidence of follicular cell tumors in the thyroid gland (McClain 1988; McClain et al., 1989). These effects could be decreased in a dose-related manner by simultaneous treatment with increasing doses of exogenous thyroxine. McClain et al. (1989) have demonstrated that rats treated with phenobarbital have a significantly higher cumulative biliary excretion of ^{125}I-labeled thyroxine than controls (Fig. 21-23). Most of the increase in biliary excretion was accounted for by an increase in T_4-glucuronide due to an increased metabolism of thyroxine in phenobarbital-treated rats. This is consistent with enzymatic activity measurements which result in increased hepatic T_4-UDP-glucuronyl transferase activity in phenobarbital-treated rats (Fig. 21-24). Results from these experiments are consistent with the hypothesis that the promotion of thyroid tumors in rats was not a direct effect of phenobarbital on the thyroid gland but rather an indirect effect mediated by TSH secretion from the pituitary secondary to the hepatic microsomal enzyme-induced increase of T_4 excretion in the bile.


Figure 21-23. Cumulative biliary excretion of ^{125}I-thyroxine (percentage of administered dose) in control and phenobarbital treated rats (100 mg/kg/day in the diet for 4 to 6 weeks).

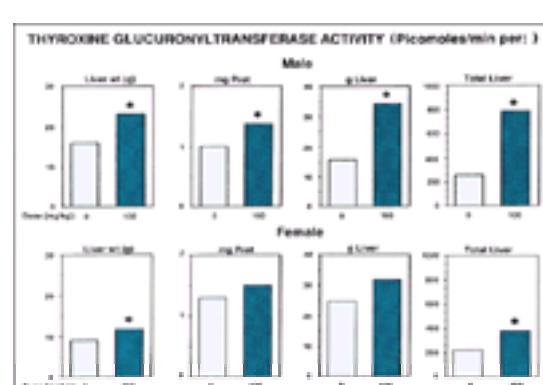
Phenobarbital treatment resulted in an increase in the cumulative excretion of thyroxine over a 4-h period. Thin-layer chromatography of bile samples indicated that most of the increase in biliary excretion was accounted for by an increase in the fraction corresponding to thyroxine-glucuronide. (From McClain, 1989, with permission.)


Figure 21-24. Hepatic thyroxine glucuronyltransferase activity in control and phenobarbital-treated rats (100 mg/kg/day in the diet for 4 weeks).

Glucuronyltransferase activity was measured in hepatic microsomes using thyroxine as a substrate. Phenobarbital treatment induced thyroxine-glucuronyltransferase in male and female rats; however, the effect in male rats was quantitatively larger. (From McClain, 1989, with permission.)

The activation of the thyroid gland during the treatment of rodents with substances that stimulate thyroxine catabolism is a well-known phenomenon and has been investigated extensively with phenobarbital and many other compounds (Curran and DeGroot, 1991). It occurs particularly with rodents, first because UDP-glucuronyl transferase can easily be induced in rodent species, and second because thyroxine metabolism takes place very rapidly in rats in the absence of thyroxine-binding globulin. In humans a lowering of the circulating T_4 level but no change in TSH and T_3 concentrations has been observed only with high doses of very powerful enzyme-inducing compounds, such as rifampicin with and without antipyrine.

Although phenobarbital is the only UDP-glucuronyl transferase (UDP-GT) inducer that has been investigated in detail to act as a thyroid tumor promoter, the effects of other well-known UDP-GT inducers on the disruption of serum T_4 TSH and thyroid gland have been investigated. For example, pregnenolone-16a-carbonitrile (PCN), 3-methylcholanthrene (3MC) and aroclor 1254 (PCB) induce hepatic microsomal UDP-GT activity towards T_4 (Barter and Klaassen, 1992a). These UDP-GT inducers reduce serum T_4 levels in both control as well as in thyroidectomized rats that are infused with T_4, indicating that reductions in serum T_4 levels are not due to a direct effect of the inducers on the thyroid gland (Barter and Klaassen, 1992, 1994). However, serum TSH levels and the thyroid response to reductions in serum T_4 levels by UDP-GT inducers is not always predictable. While PCN increased serum TSH and resulted in thyroid follicular cell hyperplasia similar to that observed with phenobarbital, 3MC and PCB in these short-duration experiments and at the dose levels used did not increase serum TSH levels or produce thyroid follicular cell hyperplasia (Liu et al., 1995; Hood et al., 1995). These findings support the overall hypothesis that UDP-GT inducers can adversely affect the thyroid gland by a secondary mechanism, but this applies only to those UDP-GT inducers that increase serum TSH in addition to reducing serum T_4.

Additional investigations by this research group demonstrated that hepatic microsomal enzyme inducing xenobiotic chemicals [e.g., phenobarbital and pregnenolone-16a-carbontrile (PCN)] increased serum TSH (0 > 75 percent) much less than the thyroperoxidase inhibitor propylthiouracil (PTU) (830 percent) (Hood et al., 1999). Phenobarbital and PCN administration increased thyroid weight approximately 80 percent compared to a 500 percent increase in PTU-treated rats. Thyroid follicular cell proliferation (determined by BrdU labeling) was increased 260, 330, and 850 percent in rats treated with phenobarbital, PCN, and PTU, respectively, for 7 days but the labeling index had returned to control levels by the 45th day of treatment. These findings demonstrate that certain hepatic microsomal enzyme-inducing chemicals that result in mild to modest elevations in serum TSH lead to dramatic increases in thyroid follicular cell proliferation that peak after 7 days of treatment and then rapidly return to control values. These findings are similar to those of Wynford-Thomas et al. (1982), who reported a maximal proliferative response (evaluated by mitotic index) after 7 days of treatment with aminotriazole (a thyroperoxidase inhibitor). The decline in thyroid follicular cell proliferation was suggested to be due to desensitization of the cells to the mitogenic actions of TSH (Wynford-Thomas et al., 1982a).

Hood et al. (1999) reported that moderate increases in serum TSH of between 10 and 20 ng/ml increased the number of proliferating thyroid follicular cells but had no effect on thyroid weight, emphasizing that small increases in serum TSH can be sufficient to stimulate proliferation. These important findings suggest that quantitation of follicular cell proliferation may be more useful than thyroid weights for assessing alterations in thyroid growth in rats administered xenobiotic chemicals that produce only small to moderate increases in serum TSH.

There is no convincing evidence that humans treated with drugs or exposed to chemicals that induce hepatic microsomal enzymes are at increased risk for the development of thyroid cancer (Curran and DeGroot, 1991). In a study on the effects of microsomal enzyme–inducing compounds on thyroid hormone metabolism in normal healthy adults, phenobarbital (100 mg daily for 14 days) did not affect the serum T_4, T_3, or TSH levels (Ohnhaus et al., 1981). A decrease in serum T_4 levels was observed after treatment with either a combination of phenobarbital plus rifampicin or a combination of phenobarbital plus antipyrine; however, these treatments had no effect on serum T_3 or TSH levels (Ohnhaus and Studer, 1983). Epidemiologic studies of patients treated with therapeutic doses of phenobarbital have report-ed no increase in risk for the development of thyroid neoplasia (Clemmesen et al., 1974; Clemmesen and Hualgrim-Jensen, 1977, 1978, 1981; White et al., 1979; Friedman, 1981; Shirts et al., 1986; Olsen et al., 1989). Highly sensitive assays for thyroid and pituitary hormones are readily available in a clinical setting to monitor circulating hormone levels in patients exposed to chemicals potentially disruptive of pituitary-thyroid axis homeostasis.

Likewise, there is no substantive evidence that humans treated with drugs or exposed to chemicals that induce hepatic microsomal enzymes are at increased risk for the development of liver cancer. This is best exemplified by the extensive epidemiologic information on the clinical use of phenobarbital. Phenobarbital has been used clinically as an anticonvulsant for more than eighty years. Relatively high microsomal enzyme-inducing doses have been used chronically, sometimes for lifetime exposures, to control seizure activity in human beings. A study of over 8000 patients admitted to a Danish epilepsy center from 1933 to 1962 revealed no evidence for an increased incidence of hepatic tumors in phenobarbital-treated humans when patients receiving thorotrast, a known human liver carcinogen, were excluded (Clemmesen and Hjalgrim-Jensen, 1978). A follow-up report on this patient population confirmed and extended this observation (Clemmesen and Hjalgrim-Jensen, 1981; Olsen et al., 1989). The results of two other smaller studies (2099 epileptics and 959 epileptics) also revealed no hepatic tumors in patients treated with phenobarbital (White et al., 1979).

Chemical Inhibition of 5'-Monodeiodinase

FD&C Red No. 3 (erythrosine) is an example of a well-characterized xenobiotic that results in perturbations of thyroid function in rodents and in long-term studies is associated with an increased incidence of benign thyroid tumors. Red No. 3 is a widely used color additive in foods, cosmetics, and pharmaceuticals. A chronic toxicity/carcinogenicity study revealed that male Sprague-Dawley rats fed a 4 percent dietary concentration of Red No. 3 beginning in utero and extending over their lifetime (30 months) developed a 22 percent incidence of thyroid adenomas derived from follicular cells compared to 1.5 percent in control rats and a historical incidence of 1.8 percent for this strain (Borzelleca et al., 1987; Capen, 1989) (Fig. 21-25). There was no significant increase in follicular cell adenomas in the lower-dose groups of male rats or an increase in malignant thyroid follicular cell tumors. Female rats fed similar amounts of the color did not develop a significant increase in either benign or malignant thyroid tumors. Feeding of the color at the high dose (4 percent) level provided male rats with 2464 mg/kg of Red No. 3 daily; by comparison human consumption in the United States is estimated to be 0.023 mg/kg/day.

Groups	Original Study					High-Dose Study	
	I_A	I_B	II	III	IV	I_C	V
Red No. 3 (%) (mg/kg/day)	0 −	0 −	0.1 (48)	0.5 (251)	1.0 (547)	0 −	4.0 (2464)
F.C. Adenoma (%)	0	0	0	2.8	1.5	1.5	21.8
F.C. Carcinoma (%)	0	0	4.5	1.5	4.4	2.3	4.4
Cystic follicular hyperplasia (%)	2.8	1.5	12	16.2	7.3	0	23.2
Diffuse or local F.C. hyperplasia (%)	1.4	0	7.5	7.4	26.1	5.3	87.0
Follicular cysts (%)	10	14.5	8.0	11.8	11.6	2.3	14.5

Figure 21-25. Thyroid lesions in male Sprague-Dawley rats fed varying doses of FD&C Red No. 3 beginning in utero and for a lifetime of 30 months. (From Borzelleca et al., 1987, with permission.)

The results of mechanistic studies with FD&C Red No. 3 have suggested that a primary (direct) action on the thyroid is unlikely to result from (1) failure of the color (^{14}C-labeled) to accumulate in the gland, (2) negative genotoxicity and mutagenicity assays, (3) lack of an oncogenic response in mice and gerbils, (4) a failure to promote thyroid tumor development at dietary concentrations of 1.0 percent or less in male and female rats (Capen, 1989), and (5) no increased tumor development in other organs. Investigations with radiolabeled compound have demonstrated that the color does not accumulate in the thyroid glands of rats following the feeding of either 0.5 percent or 4.0 percent FD&C Red No. 3 for 1 week prior to the oral dose of ^{14}C-labeled material.

Mechanistic investigations with FD&C Red No. 3 included, among others, a 60-day study of male Sprague-Dawley rats fed either 4 percent (high dose) or 0.25 percent (low dose) Red No. 3 compared to controls, whose food was without the color, in order to determine the effects of the color on thyroid hormone economy. The experimental design of the study was to sacrifice groups of rats (n = 20 rats/interval and dose) fed Red No. 3 and their control groups after 0, 3, 7, 10, 14, 21, 30, and 60 days.

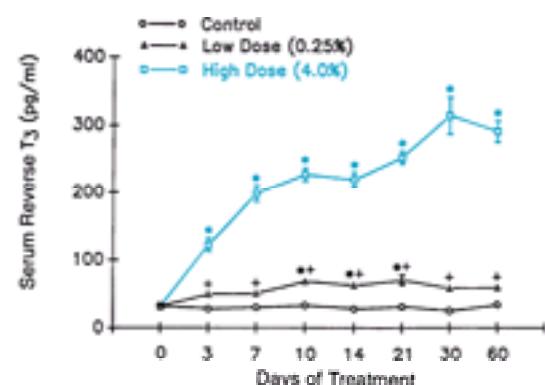
A consistent effect of Red No. 3 on thyroid hormone economy was the striking increase in serum reverse T_3 (Fig. 21-26). In the rats fed high doses, reverse T_3 was increased at all intervals compared to controls and this also held for rats killed at 10, 14, and 21 days in the low-dose group. The mechanisms responsible for the increased serum reverse T_3 appear to be, first, substrate (T_4) accumulation due to 5'-monodeiodinase inhibition with subsequent conversion to reverse T_3 rather than active T_3; and, second, reverse T_3 accumulation due to 5'-monodeiodinase inhibition resulting in an inability to degrade reverse T_3 further to diiodothyronine (T_2). Serum triiodothyronine (T_3) was decreased significantly at all intervals in rats of the high-dose group compared to interval controls (Fig. 21-27). The mechanism responsible for the reduced serum T_3 following feeding of Red No. 3 was decreased monodeiodination of T_4 due to an inhibition of the 5'-monodeiodinase by the color.


Figure 21-26. Rapid and significant increase in serum reverse triiodothyronine (rT_3) levels in Sprague-Dawley rats (N = 20 per group and interval) administered a high (4 percent) and low (0.25 percent) dose of FD&C Red No. 3.

The significant increase in rT3 was detected at the initial interval of 3 days and persisted during the 60-day experiment in the high-dose group. Serum TSH was increased significantly at all intervals in rats of the high-dose (4 percent) group compared to controls. Rats fed 0.25 percent Red No. 3 had increased serum TSH only at days 21, 30, and 60 (Fig. 21-28). The mechanism responsible for the increased serum TSH following ingestion of Red No. 3 was a compensatory response by the pituitary gland to the low circulating levels of T_3 that resulted from an inhibition of the 5'-monodeiodinase. Serum T_4 also was increased significantly at all intervals in rats fed 4 percent Red No. 3 compared to controls (Fig. 21-29). The mechanism responsible for the increased serum T_4 was, first, accumulation due to an inability to monodeiodinate T_4 to T_3 in the liver and kidney from the inhibition of 5'-monodeiodinase by the color; and, second, TSH stimulation of increased T_4 production by the thyroid gland.

[125]I-labeled T_4 metabolism was significantly altered in liver homogenates prepared from rats fed 4 percent FD&C Red No. 3. Degradation of labeled T_4 was decreased to approximately 40 percent of the values in control homogenates (Fig. 21-30). This was associated with a 75 percent decrease in percent generation of ^{125}I and an approximately 80 percent decrease in percent generation of ^{125}I-labeled T_3 from radiolabeled T_4 substrate. These mechanistic investigations suggested that the color results in a perturbation of thyroid hormone economy in rodents by inhibiting the 5'-monodeiodinase in the liver, resulting in long-term stimulation of follicular cells by TSH, which over their lifetime predisposed to an increased incidence of thyroid tumors (Capen and Martin, 1989; Borzelleca et al., 1987). The color tested negative in standard genotoxic and mutagenic assays, and it did not increase the incidence of tumors in other organs.

(Courtesy of the Certified Color Manufacturers Association, Inc., and the late Sidney H. Ingbar, M.D.)

Morphometric evaluation was performed on thyroid glands from all rats at each interval during the 60-day study. Four levels of exposure of rat thyroid to Red No. 3 were evaluated, with 25 measurements from each rat. The direct measurements included the diameter of thyroid follicles, area of follicular colloid, and height of follicular cells. Thyroid follicular diameter was decreased significantly in both low- and high-dose groups at 3, 7, 10, and 14 days compared to interval controls. The area of follicular colloid generally reflected the decrease in thyroid follicular diameter and was decreased significantly at days 3 and 10 in high-dose rats and days 7 and 10 in the low-dose group compared to interval controls. These reductions in thyroid follicular diameter and colloid area were consistent with morphologic changes expected in response to an increased serum TSH concentration.

Thyroid follicular height was increased significantly only after feeding FD&C Red No. 3 for 60 days in both the high- and low-dose groups compared to interval controls. The absence of morphometric evidence of follicular cell hypertrophy at the shorter intervals was consistent with the modest increase (15.8 percent) in thyroid gland:body weight ratio after this relatively short exposure to the color. The lack of follicular cell hypertrophy at the shorter intervals of feeding Red No. 3 in rats with severalfold elevations in serum TSH levels may be related, in part, to the high iodine content (58 percent of molecular weight) interfering with the receptor-mediated response of thyroid follicular cells to TSH. The thyroid responsiveness to TSH is known to vary inversely with iodine content (Ingbar, 1972; Lamas and Ingbar, 1978). Thyroid glands of rats fed FD&C Red No. 3 would be exposed to an increased iodine concentration primarily from sodium iodide contamination of the color and, to a lesser extent, from metabolism of the compound and release of iodide.

Secondary Mechanisms of Thyroid Tumorigenesis and Risk Assessment

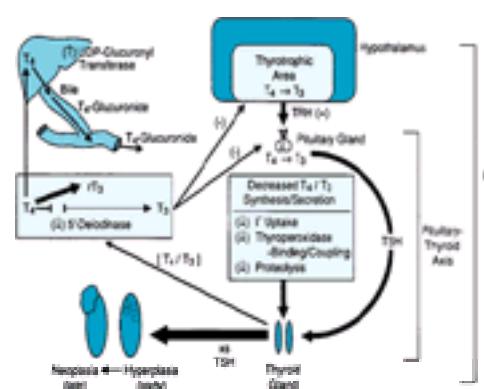
Understanding the mechanism of action of xenobiotics on the thyroid gland provides a rational basis for extrapolation findings from long-term rodent studies to the assessment of a particular compound's safety for humans. Many chemicals and drugs disrupt one or more steps in the synthesis and secretion of thyroid hormones, resulting in subnormal levels of T_4 and T_3, associated with a compensatory increased secretion of pituitary TSH (Fig. 21-31). When tested in highly sensitive species, such as rats and mice, early on these compounds resulted in follicular cell hypertrophy/hyperplasia and increased thyroid weights, and in long-term studies they produced an increased incidence of thyroid tumors by a secondary (indirect) mechanism associated with hormonal imbalances.


Figure 21-31. Multiple sites of disruption of the hypothalamic-pituitary-thyroid axis by xenobiotic chemicals.

Chemicals can exert direct effects by disrupting thyroid hormone synthesis or secretion and indirectly influence the thyroid through an inhibition of 5'-deiodinase or by inducing hepatic microsomal enzymes (e.g., T_4-UDP glucuronyltransferase). All of these mechanisms can lower circulating levels of thyroid hormones (T_4 and/or T_3), resulting in a release from negative-feedback inhibition and increased secretion of thyroid stimulating hormone (TSH) by the pituitary gland. The chronic hypersecretion of TSH predisposes the sensitive rodent thyroid gland to develop an increased incidence of focal hyperplastic and neoplastic lesions (adenomas) by a secondary (epigenetic) mechanism.

Review of the *Physicians' Desk Reference* (PDR) reveals a number of marketed drugs that result in a thyroid tumorigenic response when tested at high concentrations in rodents, primarily in rats. A broad spectrum of product classes are represented including antibiotics, calcium-channel blockers, antidepressants, hypolipidemic agents, among others (Fig. 21-32). Amiodarone (an antiarrhythmic drug) and iodinated glycerol (an expectorant) are highly iodinated molecules that disrupt thyroid hormone economy by mechanisms similar to the food color FD&C Red No. 3 (Fig. 21-33).

DRUG	PRODUCT CLASS	SPECIES
MINOCYCLINE	ANTIBIOTIC	R
OXAZEPAM	ANTIANXIETY	R
NICARDIPINE	Ca-CHANNEL BLOCKER	R
SERTRALINE	ANTIDEPRESSANT	R
SIMVASTATIN	HYPOLIPIDEMIC	R
SPIRONOLACTONE	DIURETIC	R
VIDARABINE	ANTIVIRAL	R

Figure 21-32. Examples of marketed drugs with a tumorigenic response in the thyroid gland of rats. (Modified from Davis and Monro, 1995, with

Figure 21-33. Marketed drugs with a thyroid tumorigenic response. (Modified from Davis and Monro, 1995, with permission.)

In the secondary mechanism of thyroid oncogenesis in rodents, the specific xenobiotic chemical or physiologic perturbation evokes another stimulus (e.g., chronic hypersecretion of TSH) that promotes the development of nodular proliferative lesions (initially hypertrophy, followed by hyperplasia, subsequently adenomas, infrequently carcinomas) derived from follicular cells. Thresholds for "no effect" on the thyroid gland can be established by determining the dose of xenobiotic that fails to elicit an elevation in the circulating level of TSH. Compounds acting by this indirect (secondary) mechanism with hormonal imbalances usually show little or no evidence for mutagenicity or for producing DNA damage.

In human patients who have marked changes in thyroid function and elevated TSH levels, as is common in areas with a high incidence of endemic goiter due to iodine deficiency, there is little if any increase in the incidence of thyroid cancer (Doniach, 1970; Curran and DeGroot, 1991). The relative resistance to the development of thyroid cancer in humans with elevated plasma TSH levels is in marked contrast to the response of the thyroid gland to chronic TSH stimulation in rats and mice. The human thyroid is much less sensitive to this pathogenetic phenomenon than rodents (McClain, 1989).

Human patients with congenital defects in thyroid hormone synthesis (dyshormonogenetic goiter) and markedly increased circulating TSH levels have been reported to have an increased incidence of thyroid carcinomas (Cooper et al., 1981; McGirr et al., 1959). Likewise, thyrotoxic patients with Graves' disease, in which follicular cells are autonomously stimulated by an immunoglobulin (long-acting thyroid stimulator, or LATS) also appear to be at greater risk of developing thyroid tumors (Pendergrast et al., 1961; Clements, 1954). Therefore, the literature suggests that prolonged stimulation of the human thyroid by TSH will induce neoplasia only in exceptional circumstances, possibly by acting together with some other metabolic or immunologic abnormality (Curran and DeGroot, 1991).

THYROID C CELLS

Normal Structure and Function

Calcitonin (CT) has been shown to be secreted by a second population of endocrine cells in the mammalian thyroid gland that are much less numerous than follicular cells. C cells (parafollicular or light cells) are distinct from follicular cells in the thyroid that secrete T_4 and T_3 (Kalina and Pearse, 1971). They are situated either within the follicular wall immediately beneath the basement membrane or between follicular cells and as small groups of cells between thyroid follicles. C cells do not border the follicular colloid directly and their secretory polarity is oriented toward the interfollicular capillaries. The distinctive feature of C cells, compared to thyroid follicular cells, is the presence of numerous small membrane-limited secretory granules in the cytoplasm. Immunocytochemical techniques have localized the calcitonin activity of C cells to these secretory granules (DeGrandi et al., 1971).

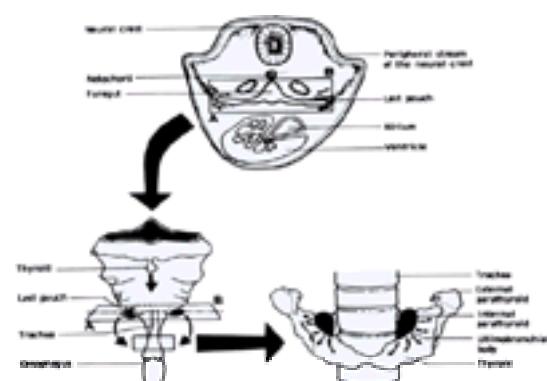
Calcitonin-secreting thyroid C cells have been shown to be derived embryologically from cells of the neural crest. Primordial cells from the neural crest migrate ventrally and become incorporated within the last (ultimobranchial) pharyngeal pouch (Fig. 21-34). They move caudally with the ultimobranchial body to the point of fusion with the midline thyroglossal duct primordia that gives rise to the thyroid gland. The ultimobranchial body fuses with and is incorporated into the thyroid near the hilum in mammals, and C cells subsequently are distributed throughout the gland. Although C cells are present throughout the thyroid gland of humans and most other mammals in postnatal life, they often remain more numerous near the hilum and point of fusion with the ultimobranchial body. Under certain conditions colloid-containing follicles lined by follicular cells also can differentiate from cells of ultimobranchial origin (Takayama et al., 1986).


Figure 21-34. Schematic representation of neural crest origin of calcitonin-secreting C cells.

Primordial cells arising from the neural crest migrate ventrally during embryonic life to become incorporated in the last (ultimobranchial) pharyngeal pouch. The ultimobranchial body fuses with primordia of the thyroid and distributes C cells to varying degrees throughout the mammalian thyroid gland. (From Foster, 1972, with permission.)

In contrast to the iodothyronines (T_4 and T_3) produced by follicular cells, calcitonin is a polypeptide hormone composed of 32 amino acid residues arranged in a straight chain (Copp, 1970). The concentration of calcium ion in plasma and extracellular fluids is the principal physiological stimulus for the secretion of CT by C cells. CT is secreted continuously under conditions of normocalcemia, but the rate of secretion of CT is increased greatly in response to elevations in blood calcium. C cells store substantial amounts of CT in their cytoplasm in the form of membrane-limited secretory granules. In response to hypercalcemia there is a rapid discharge of stored hormone from C cells into interfollicular capillaries. The hypercalcemic stimulus, if sustained, is followed by hypertrophy of C cells and an increased development of cytoplasmic organelles concerned with the synthesis and secretion of CT. Hyperplasia of C cells occurs in response to long-term hypercalcemia. When the blood calcium is lowered, the stimulus for CT secretion is diminished and numerous secretory granules accumulate in the cytoplasm of C cells.

Calcitonin exerts its function by interacting with target cells, primarily in bone and kidney. The action of calcitonin is antagonistic to that of parathyroid hormone on mobilizing calcium from bone but synergistic on decreasing the renal tubular reabsorption of phosphorus. The storage of large amounts of preformed hormone in C cells and rapid release in response to moderate elevations of blood calcium is a reflection of the physiologic role of calcitonin as an "emergency" hormone to protect against the development of hypercalcemia. Calcitonin and parathyroid hormone, acting in concert, provide a dual negative feedback control mechanism to maintain the life-sustaining concentration of calcium ion in extracellular fluids within narrow limits. Calcitonin secretion is increased in response to a high-calcium meal often before a significant rise in plasma calcium can be detected. Gastrin, pancreozymin, and glucagon are examples of gastrointestinal hormones whose secretion is

stimulated by an oral calcium load which, in turn, act as secretagogues for calcitonin release from the thyroid gland.

Mechanisms of Toxicity

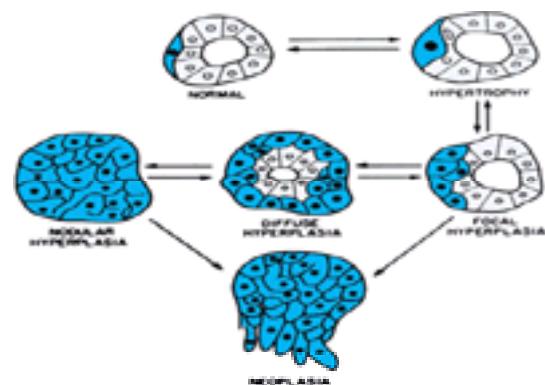
Nodular and/or diffuse hyperplasia of C cells occurs with advancing age in many strains of laboratory rats and in response to long-term hypercalcemia in certain animal species and human beings. Focal aggregation of C cells near the thyroid hilum are a normal anatomic finding in the thyroids of dogs and should not be over-interpreted as areas of C-cell hyperplasia. There is suggestive evidence that focal or diffuse hyperplasia precedes the development of C-cell neoplasms (DeLellis et al., 1977) (Fig. 21-35). Other studies (Triggs and Williams, 1977) have demonstrated significantly elevated circulating levels of immunoreactive calcitonin in rats with C-cell neoplasms compared to either young or old rats without C-cell tumors. Neither consistent changes in total blood calcium and phosphorus nor bone lesions have been reported in rats with calcitonin-secreting C-cell neoplasms.


Figure 21-35. Focal and nodular hyperplasia of C cells in the thyroid often precedes the development of C-cell neoplasms. (From DeLellis et al., 1977, with permission.)

Triggs and Williams (1977) reported that radiation (5 or 10 mCi ^{131}I) increased the incidence of C-cell (as well as follicular cell) thyroid tumors in Wistar rats but that high dietary calcium intake (2,000 mg/100 g) did not further incease the incidence of C cell tumors in irradiated rats. Further studies by Thurston and Williams (1982) found that irradiated rats receiving diets high in vitamin D that developed hypercalcemia had a higher incidence of C-cell tumors than rats fed diets adequate or deficient in vitamin D. Stoll et al. (1978) reported that the antithyroid drug thiamazole can result in proliferative lesions (hyperplasia and adenoma) in thyroid C cells as well as in follicular cells in rats.

Morphologic Alterations and Proliferative Lesions of Thyroid C Cells

C-cell proliferative lesions occur commonly in many rat strains but are uncommon in the mouse. Rat strains with high incidences of these lesions include WAG/Rij, Sprague-Dawley, Fisher, Wistar, Buffalo, and Osborne-Mendel. The incidence varies from 19 to 33 percent with no obvious sex differences. Burek (1978) reported that cross-breeding of high- (WAG/Rij) and low- (BN/Bi) incidence strains results in F $_1$ animals with intermediate tumor incidences. As with proliferative lesions of other endocrine organs, there is a correlation between the age of the animal and the presence of the entire spectrum of C-cell proliferative lesions. For example, Long-Evans rats under 1 year of age rarely have C-cell neoplasms in the thyroid. Rats that were between 12 and 24 months of age had a 10 percent incidence, whereas approximately 20 percent of 2- to 3-year-old rats had C-cell tumors. Similarly, the frequency of focal and diffuse C-cell hyperplasia increased progressively with age in this strain of rat. According to the NTP historical database of 2-year-old F344 rats, the incidence of C-cell neoplasms was 8.9 percent in males and 8.5 percent in females.

There are two types of C-cell hyperplasia: diffuse and focal (nodular) (Fig. 21-35). In diffuse hyperplasia, the numbers of C cells are increased throughout the thyroid lobe to a point where they may be more numerous than follicular cells. In contrast to the predominantly central distribution of C cells in thyroids from young rats, C cells in the more severe forms of hyperplasia extend to the extreme upper and lower poles as well as the peripheral regions of the lobes. Focal (nodular) hyperplasia of C cells often occurs concurrently with diffuse hyperplasia in the thyroid glands of rats. Follicular cells adjacent to the proliferating C cells often are compressed and atrophic with prominent supranuclear accumulations of lipofuscin. In the later stages, follicles with intense C-cell hyperplasia often assume irregular, twisted, and elongated configurations. Occasional colloid-filled thyroid follicles are entrapped among the proliferating C cells.

The histologic distinction between focal hyperplasia and adenoma of C cells is indistinct and somewhat arbitrary. The diagnosis of C-cell hyperplasia refers to a focal or diffuse increase of C cells between thyroid follicles and/or within the follicular basement membrane. The C cells appear normal with an abundant, lightly eosinophilic, granular cytoplasm and a round-to-oval nucleus with finely stippled chromatin. In focal C-cell hyperplasia the accumulations of proliferating C cells are of a lesser diameter than five average colloid-containing thyroid follicles, with minimal evidence of compression of adjacent follicles. Hyperplastic C cells within the follicular basement membrane may compress individual thyroid follicles.

The ultimobranchial body (last, usually fifth, pharyngeal pouch) that delivers the neural crest–derived C cells to the post-natal thyroid gland fuses with each thyroid lobe at the hilum during embryonic development and distributes C cells throughout each lobe to varying degrees in different species (Fig. 21-34). In the dog nodular aggregations of C cells frequently persist along the course of the major vessels to the thyroid; therefore, C-cell hyperplasia in dogs should be diagnosed only when there is a definite increase in C cells throughout each thyroid lobe compared to age-matched controls. Both thyroid lobes should be sectioned longitudinally in a consistent manner for microscopic evaluation. This will minimize the prominent regional differences of C cells in the thyroid glands of normal dogs that can result in the overinterpretation of these focal aggregations of C cells as a significant lesion. There are occasional ultimobranchial-derived, colloid-containing follicles within the focal accumulations of microscopically normal C cells along the course of vessels within the thyroid lobe or in the connective tissues of the thyroid hilum in dogs.

By comparison, C-cell adenomas are discrete, expansive masses of C cells larger than five average colloid-containing thyroid follicles. Adenomas either are well circumscribed or partially encapsulated from adjacent thyroid follicles that often are compressed to varying degrees. C cells composing an adenoma may be subdivided by fine connective tissue septae and capillaries into small neuroendocrine packets. Some C-cell adenomas are composed of larger pleomorphic cells with amphophilic cytoplasm, large nuclei with coarsely clumped chromatin, and prominent nucleoli; histologically, they resemble ganglion cells. Occasional amyloid deposits may be found both in nodular hyperplasia and in adenomas.

C-cell carcinomas often result in macroscopic enlargement of one or both thyroid lobes due to the extensive proliferation and infiltration of C cells. There is evidence of intrathyroidal and/or capsular invasion by the malignant C cells, often with areas of hemorrhage and necrosis within the neoplasm. The malignant C cells are more pleomorphic than those making up benign proliferative lesions. Immunoperoxidase reactions for calcitonin generally are more intense in diffuse or nodular hyperplasia, whereas in adenomas and carcinomas calcitonin immunoreactivity is much more variable between tumors and in different regions of a tumor. Hyperplastic C cells adjacent to adenomas and carcinomas usually are intensely positive for calcitonin. In addition to calcitonin, some of the tumor cells and adjacent hyperplastic C cells have positive staining for somatostatin or bombesin.

PARATHYROID GLAND

Introduction

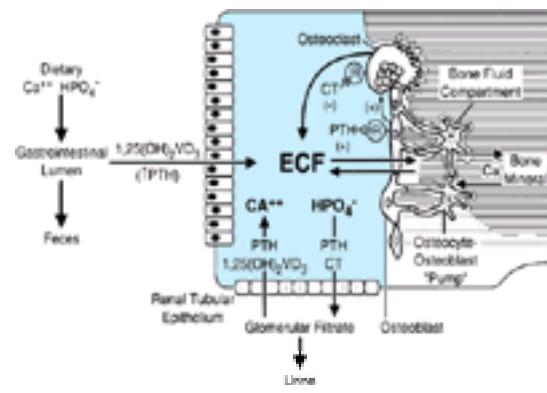
Calcium plays a key role as an essential structural component of the skeleton and also in many fundamental biological processes. These processes include neuromuscular excitability, membrane permeability, muscle contraction, enzyme activity, hormone release, and blood coagulation, among others. The precise control of calcium in extracellular fluids is vital to health. To maintain a constant concentration of calcium, despite marked variations in intake and excretion, endocrine control mechanisms have evolved that primarily consist of the interactions of three major hormones—parathyroid hormone (PTH), calcitonin (CT), and cholecalciferol (vitamin D) (Fig. 21-36).


Figure 21-36. Interrelationship of parathyroid hormone (PTH), calcitonin (CT), and 1,25-dihydroxycholecalciferol (1,25(OH) $_2$VD$_3$) in the regulation of calcium (Ca) and phosphorus in extracellular fluids.

Receptors for PTH are on osteoblasts and for CT on osteoclasts in bone. PTH and CT are antagonistic in their action on bone but synergistic in stimulating the renal excretion of phosphorous. Vitamin D exerts its action primarily on the intestine to enhance the absorption of both calcium and phosphorus.

Normal Structure and Function of Chief Cells

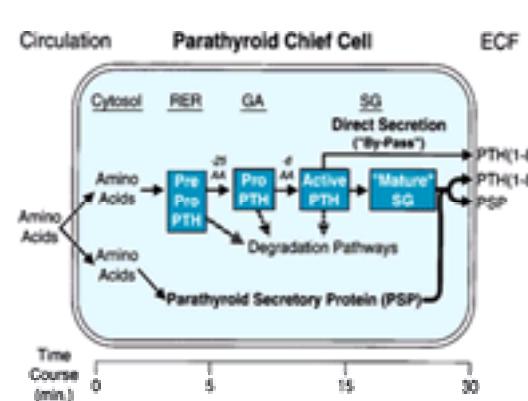
Biosynthesis of Parathyroid Hormone Parathyroid chief cells in humans and many animal species store relatively small amounts of preformed hormone, but they respond quickly to variations in the need for hormone by changing the rate of hormone synthesis. Parathyroid hormone, like many peptide hormones, is first synthesized as a larger biosynthetic precursor molecule that undergoes posttranslational processing in chief cells. Preproparathyroid hormone (preproPTH) is the initial translation product synthesized on ribosomes of the rough endoplasmic reticulum in chief cells. It is composed of 115 amino acids and contains a hydrophobic signal or leader sequence of 25 amino acid residues that facilitates the penetration and subsequent vectorial discharge of the nascent peptide into the cisternal space of the rough endoplasmic reticulum (Kronenberg et al., 1986) (Fig. 21-37). PreproPTH is rapidly converted within 1 min or less of its synthesis to proparathyroid hormone (ProPTH) by the proteolytic cleavage of 25 amino acids from the NH$_2$-terminal end of the molecule (Habener, 1981). The intermediate precursor, proPTH, is composed of 90 amino acids and moves within membranous channels of the rough endoplasmic reticulum to the Golgi apparatus (Fig. 21-37). Enzymes within membranes of the Golgi apparatus cleave a hexapeptide from the NH$_2$-terminal (biologically active) end of the molecule, forming active PTH. Active PTH is packaged into membrane-limited, macromolecular aggregates in the Golgi apparatus for subsequent storage in chief cells. Under certain conditions of increased demand (e.g., a low calcium ion concentration in the extracellular fluid compartment), PTH may be released directly from chief cells without being packaged into secretion granules by a process termed bypass secretion.


Figure 21-37. Biosynthesis of parathyroid hormone (PTH) and parathyroid secretory protein (PSP) by parathyroid chief cells.

Active PTH is synthesized as a larger biosynthetic precursor molecule (preproPTH) that undergoes rapid posttranslational processing to proPTH prior to secretion from chief cells as active PTH (amino acids 1 to 84).

Although the principal form of active PTH secreted from chief cells is a straight-chain peptide of 84 amino acids (molecular weight 9500), the molecule is rapidly cleaved into amino- and carboxy-terminal fragments in the peripheral circulation and especially in the liver. The purpose of this fragmentation is uncertain because the biologically active amino-terminal fragment is no more active than the entire PTH molecule (amino acids 1 to 84). The plasma half-life of the *N*-terminal fragment is considerably shorter than that of the biologically inactive carboxy-terminal fragment of parathyroid hormone. The C terminal and other portions of the PTH molecule are degraded primarily in the kidney and tend to accumulate with chronic renal disease.

Control of Parathyroid Hormone Secretion Secretory cells in the parathyroid gland store small amounts of preformed hormone but are capable of responding to minor fluctuations in calcium concentration by rapidly altering the rate of hormonal secretion and more slowly by altering the rate of hormonal synthesis. In contrast to most endocrine organs that are under complex controls involving both long and short feedback loops, the parathyroids have a unique feedback controlled by the concentration of calcium (and to a lesser extent magnesium) ion in serum. The concentration of blood phosphorus has no direct regulatory influence on the synthesis and secretion of PTH; however, several disease conditions with hyperphosphatemia in both animals and humans are associated clinically with secondary hyperparathyroidism. An elevated blood phosphorus level may lead indirectly to parathyroid stimulation by virtue of its ability to lower blood calcium, primarily by suppressing the 1a-hydroxylase in the kidney and decreasing the production of the active form of vitamin D [1,25-(OH) $_2$-cholecalciferol] thereby diminishing the rate of intestinal calcium absorption. Magnesium ion has an effect on parathyroid secretion rate similar to that of calcium, but its effect is not equipotent to that of calcium.

Serum Ca^{2+} binds to a recently identified Ca receptor on the chief cell, which permits the serum Ca $^{2+}$ to regulate chief cell function (Pollak et al., 1993). The receptor is present on the plasma membranes of parathyroid chief cells, renal epithelial cells, and other cells that respond to extracellular Ca $^{2+}$. Mutations in one or both of the Ca^{2+}-sensing receptor genes in humans results in familial hypocalciuric hypercalcemia or neonatal severe hypercalcemia, respectively. Interaction of serum Ca $^{2+}$ with its receptor on chief cells results in the formation of an inverse sigmoidal relationship between serum Ca $^{2+}$ and PTH concentrations (Cloutier et al., 1993; Silver, 1992).

The serum [Ca^{2+}] that results in half maximal PTH secretion is defined as the serum calcium "set point" and is stable for an individual animal. The sigmoidal relationship between serum [Ca^{2+}] and PTH secretion permits the chief cells to respond rapidly to a reduction in serum Ca $^{2+}$. The major inhibitors of PTH synthesis and secretion are increased serum [Ca^{2+}] and 1,25-dihydroxyvitamin D. Inhibition of PTH synthesis by 1,25-dihydroxyvitamin D completes an important endocrine feedback loop between the parathyroid chief cells and the renal epithelial cells since PTH stimulates renal production of 1,25-dihydroxyvitamin D.

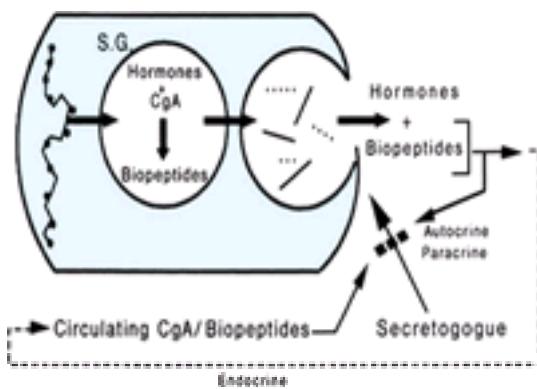
Chief cells synthesize and secrete another major protein termed parathyroid secretory protein (I), or chromogranin A. It is a higher-molecular-weight molecule (70 kDa) composed of from 430 to 448 amino acids that is stored and secreted together with PTH. A similar molecule has been found in secretory granules of a wide variety of peptide hormone–secreting cells and in neurotransmitter secretory vesicles. An internal region of the parathyroid secretory protein or chromogranin A molecule is identical in sequence to pancreastatin, a C terminal amidated peptide, which inhibits glucose-stimulated insulin secretion. This 49–amino acid proteolytic cleavage product (amino acids number 240 to 280) of parathyroid secretory protein has been reported to inhibit low calcium-stimulated secretion of parathyroid hormone and chromogranin A from parathyroid cells. These findings suggest that chromogranin A–derived peptides may act locally in an autocrine manner to inhibit the secretion of active hormone by endocrine cells, such as chief cells of the parathyroid gland (Barbosa et al., 1991; Cohn et al., 1993; Fasciotto et al., 1990) (Fig. 21-38).


Figure 21-38. Autocrine/paracrine action of chromogranin A (CgA)-derived peptides. PTH and CgA are coreleased from chief cells in response to a low calcium ion signal.

Pancreastatin (PST) is a 49–amino acid peptide derived from CgA that exerts local negative feedback on chief cells and decreases PTH secretion from chief cells. (Modified from Cohn et al., 1993, with permission.)

Xenobiotic Chemical-Induced Toxic Injury of Parathyroids

Ozone Inhalation of a single dose of ozone (0.75 ppm) for 4 to 8 h has been reported to produce light and electron microscopic changes in parathyroid glands (Atwal and Wilson, 1974). Subsequent studies have utilized longer (48-h) exposure to ozone in order to define the pathogenesis of the parathyroid lesions (Atwal et al., 1975; Atwal, 1979). Initially (1 to 5 days after ozone exposure), many chief cells undergo compensatory hypertrophy and hyperplasia with areas of capillary endothelial cell proliferation, interstitial edema, degeneration of vascular endothelium, formation of platelet thrombi, leukocyte infiltration of the walls of larger vessels in the gland, and disruption of basement membranes. Chief cells had prominent Golgi complexes and endoplasmic reticulum, aggregations of free ribosomes, and swelling of mitochondria (Atwal and Pemsingh, 1981).

Inactive chief cells with few secretory granules predominate in the parathyroids in the later stages of exposure to ozone. There was evidence of parathyroid atrophy from 12 to 20 days after ozone exposure, with mononuclear cell infiltration and necrosis of chief cells. The reduced cytoplasmic area contained vacuolated endoplasmic reticulum, a small Golgi apparatus, and numerous lysosomal bodies. Plasma membranes of adjacent chief cells were disrupted, resulting in coalescence of the cytoplasmic area. Fibroblasts with associated collagen bundles were prominent in the interstitium, and the basal lamina of the numerous capillaries often was duplicated.

The parathyroid lesions in ozone-exposed animals are similar to isoimmune parathyroiditis in other species (Lupulescu et al., 1968). Antibody against parathyroid tissue was localized near the periphery of chief cells by indirect immunofluorescence, especially 14 days following ozone injury (Atwal et al., 1975).

Aluminum Evidence for a direct effect of aluminum on the parathyroid was suggested from studies of patients with chronic renal failure treated by hemodialysis with aluminum-containing fluids or orally administered drugs containing aluminum. These patients often had normal or minimal elevations of immunoreactive parathyroid hormone (iPTH), little histologic evidence of osteitis fibrosa in bone, and a depressed response by the parathyroid gland to acute hypocalcemia (Bourdeau et al., 1987). Studies by Morrissey and coworkers (1983) have reported that an increase in aluminum concentration in vitro over a range of 0.5 to 2.0 mM in a low-calcium medium (0.5 mM) progressively inhibited the secretion of PTH. At 2.0 mM aluminum, PTH secretion was inhibited by 68 percent, while a high-calcium medium (2.0 mM) without aluminum maximally inhibited PTH secretion by only 39 percent. The inhibition of PTH secretion by aluminum does not appear to be related to an irreversible toxic effect because normal secretion was restored when parathyroid cells were returned to the 0.5 mM calcium medium without aluminum. The incorporation of [^{3}H] leucine into total cell protein, parathyroid secretory protein, proparathyroid hormone, or PTH was not affected by aluminum; however, the secretion of radiolabeled protein by dispersed parathyroid cells was inhibited by aluminum (Morrissey et al., 1983).

The molecular mechanism by which aluminum inhibits PTH secretion, reducing diglyceride levels in chief cells (Morrissey and Slatopolsky, 1986), appears to be similar to that of the calcium ion. Aluminum appears to decrease diglyceride synthesis, which is reflected in a corresponding decrease in synthesis of phosphatidylcholine and possible triglyceride; however, phosphatidylinositol synthesis was not affected by aluminum. The mechanism by which aluminum decreases diglycerides and maintains phosphatidylinositol synthesis in parathyroid cells is not known.

ʟ-Asparaginase Tettenborn and colleagues (1970) and Chisari et al. (1972) reported that rabbits administered ʟ-asparaginase develop severe hypocalcemia and tetany characterized by muscle tremors, opisthotonos, carpopedal spasms, paralysis, and coma. This drug was of interest in cancer chemotherapy because of the beneficial effects of guinea pig serum against lymphosarcoma in mice.

Parathyroid chief cells appeared to be selectively destroyed by ʟ-asparaginase (Young et al., 1973). Chief cells were predominately inactive and degranulated, with large autophagic vacuoles present in the cytoplasm of degenerating cells. Cytoplasmic organelles concerned with synthesis and packaging of secretory products were poorly developed in chief cells. Rabbits developed hyperphosphatemia, hypomagnesemia, hyperkalemia, and azotemia in addition to acute hypocalcemia. Rabbits with clinical hypocalcemic tetany did not recover spontaneously; however, administration of parathyroid extract prior to or during treatment with ʟ-asparaginase decreased the incidence of hypocalcemic tetany.

The development of hypocalcemia and tetany has not been observed in other experimental animals administered ʟ-asparaginase (Oettgen et al., 1970). However, this response may not be limited to the rabbit, because some human patients receiving the drug also have developed hypocalcemia (Jaffe et al., 1972). The ʟ-asparaginase-induced hypoparathyroidism in rabbits is a valuable model for investigating drug–endocrine cell interactions, somewhat analogous to the selective destruction of pancreatic beta cells by alloxan with production of experimental diabetes mellitus.

Proliferative Lesions of Parathyroid Chief Cells

Chief Cell Adenoma *Introduction* Parathyroid adenomas in adult-aged rats vary in size from microscopic to unilateral nodules several millimeters in diameter; they are located in the cervical region by the thyroids or infrequently in the thoracic cavity near the base of the heart. Parathyroid neoplasms in the precardiac mediastinum are derived from ectopic parathyroid tissue displaced into the thorax with the expanding thymus during embryonic development. Tumors of parathyroid chief cells do not appear to be a sequela of long-standing secondary hyperparathyroidism of either renal or nutritional origin. The unaffected parathyroid glands may be atrophic if the adenoma is functional, normal if the adenoma is nonfunctional, or enlarged if there is concomitant hyperplasia. In functional adenomas, the normal mechanism by which PTH secretion is regulated—changes in the concentration of blood calcium ion—is lost and hormone secretion is excessive in spite of an increased level of blood calcium.

Adenomas are solitary nodules that are sharply demarcated from adjacent parathyroid parenchyma. Because the adenoma compresses the rim of surrounding parathyroid to varying degrees depending upon its size, there may be a partial fibrous capsule, resulting either from compression of existing stroma or from proliferation of fibrous connective tissue.

Adenomas are usually nonfunctional (endocrinologically inactive) in adult-aged rats from chronic toxicity/carcinogenicity studies. Chief cells in nonfunctional adenomas are cuboidal or polyhedral and arranged either in a diffuse sheet, in lobules, or in acini with or without lumens. Chief cells from functional adenomas often are closely packed into small groups by fine connective tissue septa. The cytoplasmic area varies from normal size to an expanded area. There is a much lower density of cells in functional parathyroid adenoma compared to the adjacent rim with atrophic chief cells.

Larger parathyroid adenomas, such as those that are detected macroscopically, often nearly incorporate the entire affected gland. A narrow rim of compressed parenchyma may be detected at one side of the gland, or the affected parathyroid may be completely incorporated by the adenoma. Chief cells in this rim often are compressed and atrophic due to pressure and the persistent hypercalcemia. Peripherally situated follicles in the adjacent thyroid lobe may be compressed to a limited

extent by larger parathyroid adenomas. The parathyroid glands that do not contain a functional adenoma also undergo trophic atrophy in response to the hypercalcemia and become smaller.

Influence of Age on Development of Parathyroid Tumors There are relatively few chemicals or experimental manipulations reported in the literature that significantly increase the incidence of parathyroid tumors. Long-standing renal failure with intense diffuse hyperplasia does not appear to increase the development of chief cell tumors in rats. The historical incidence of parathyroid adenomas in untreated control male F344 rats in studies conducted by the NTP was 4/1315 (0.3 percent); for female F344 rats, it was 2/1330 (0.15 percent). However, parathyroid adenomas are an example of a neoplasm in F344 rats whose incidence increases dramatically when life-span data are compared to 2-year studies. Solleveld and coworkers (1984) reported that the incidence of parathyroid adenomas increased in males from 0.1 percent at 2 years to 3.1 percent in lifetime studies. Corresponding data for female F344 rats was 0.1 percent at 2 years and 0.6 percent in lifetime studies. Hexachlorobenzene (40ppm) fed to Sprague-Dawley rats (F_0 rats for 3 months and until weaning of F_1 rats that subsequently were fed for the rest of their life of 130 weeks) has been reported to increase the incidence of parathyroid adenomas in the male rats (24.5 percent; 12 of 49 rats) (Arnold et al., 1985).

Influence of Gonadectomy Oslapas and colleagues (1982) reported an increased incidence of parathyroid adenomas in female (34 percent) and male (27 percent) rats of the Long-Evans strain administered 40 mCi sodium ^{131}I and saline at 8 weeks of age. There were no significant changes in serum calcium, phosphorus, and parathyroid hormone compared to controls. Gonadectomy performed at 7 weeks of age decreased the incidence of parathyroid adenomas in irradiated rats (7.4 percent in gonadectomy versus 27 percent in intact controls), but there was little change in the incidence of parathyroid adenomas in irradiated females. X-irradiation of the thyroid-parathyroid region also increased the incidence of parathyroid adenomas. When female Sprague-Dawley rats received a single absorbed dose of x-rays at 4 weeks of age, they subsequently developed a 24 percent incidence of parathyroid adenomas after 14 months (Oslapas et al., 1981).

Influence of Xenobiotic Chemicals Parathyroid adenomas have been encountered infrequently following the administration of a variety of chemicals in 2-year bioassay studies in Fischer rats. In a study with the pesticide rotenone in F344 rats, there appeared to be an increased incidence of parathyroid adenomas in high-dose (75 ppm) males (4 of 44 rats) compared to low-dose (38 ppm) males, control males (1 of 44 rats), or NTP historical controls (0.3 percent) (Abdo et al., 1988). It was uncertain whether the increased incidence of this uncommon tumor was a direct effect of rotenone feeding or the increased survival in high-dose males. Chief cell hyperplasia was not present in parathyroids that developed adenomas.

Influence of Irradiation and Hypercalcemia Induced by Vitamin D Wynford-Thomas and associates (1982) reported that irradiation significantly increases the incidence of parathyroid adenomas in inbred Wistar albino rats and that the incidence could be modified by feeding diets with variable amounts of vitamin D. Neonatal Wistar rats were given either 5 or 10 mCi radioiodine (^{131}I) within 24 h of birth. In rats 12 months of age and older, parathyroid adenomas were found in 33 percent of rats administered 5 mCi ^{131}I and in 37 percent of rats given 10 mCi ^{131}I compared to 0 percent in unirradiated controls. The incidence of parathyroid adenomas was highest (55 percent) in normocalcemic rats fed a low vitamin D diet and lowest (20 percent) in irradiated rats fed a diet high in vitamin D (40,000 IU/kg) that had a significant elevation in plasma calcium.

Age-Related Changes in Parathyroid Function

Serum immunoreactive parathyroid hormone (iPTH) [as well as calcitonin (iCT)] has been reported to be different in young compared to aged Fischer 344 (F344) rats; however, the serum calcium concentration does not change with age (Wongsurawat and Armbrecht, 1987). This suggests that the regulation of iPTH (and iCT) secretion may be affected by the process of aging. The decreased responsiveness of chief cells to calcium may be due to age-related changes in the regulation of the secretory pathway. This could include age-related changes in the effect of calcium on release of stored PTH, intracellular degradation of PTH, or modification of adenylate cyclase activity as observed in other tissues that utilize calcium as an intermediary signal (Brown, 1982). Therefore, the sensitivity of parathyroid chief cells to circulating calcium ion concentration appears not to be fixed but may change during development, aging, and in response to certain disease processes.

The increased secretion of iPTH with advancing age in rats could be due to several factors: *first,* an increased number of parathyroid secretory cells with age; or, *second,* an altered regulation of chief cells in response to calcium ion associated with the process of aging. For example, a decreased sensitivity of chief cells to negative feedback by calcium ion could result in the higher blood levels of iPTH in aged F344 rats. Wada et al. (1992) reported that the early age-related rise in plasma PTH in F344 rats was neither a consequence of low plasma calcium nor of renal insufficiency. Age-related changes in the responsiveness of chief cells to circulating levels of other factors that modulate iPTH secretion, particularly 1,25-dihydroxycholecalciferol and alpha- and beta-adrenergic catecholamines, also could contribute to the variations in blood levels of iPTH in rats of different ages. In addition, target cell responsiveness to PTH also decreases with advancing age in rats. PTH does not increase the renal production of 1,25-dihydroxyvitamin D in adult (13-month-old) male F344 rats compared to young (2-month-old) rats, where its production was increased 61 percent (Armbrecht et al., 1982). Older rats have a decreased calcemic response and decreased renal production of 1,25-dihydroxycholecalciferol compared to young rats (Armbrecht et al., 1982; Kalu et al., 1982).

TESTIS

Introduction

Leydig (interstitial) cell tumors are among the more frequently occurring endocrine tumors in rodents in chronic toxicity/carcinogenicity studies, and a great deal of research has been published investigating their pathogenesis and implications for safety assessment. Rodent testicular tumors are classified into five general categories, including tumors derived from cells of the gonadal stroma, neoplasms of germ cell origin, tumors derived from adnexal structures or serous membranes, and, last, a group of tumors derived from the supporting connective tissues and vessels of the testis.

Neoplasms of the gonadal stroma include benign and malignant tumors derived from Leydig (interstitial) cells, Sertoli cells of the seminiferous tubules, as well as a rare mixed tumor with an admixture of both cell types. The Leydig cell tumor is the most common tumor developing in the rodent testis and frequently presents a problem in separating between focal hyperplasia and early neoplastic growth (i.e., adenoma formation).

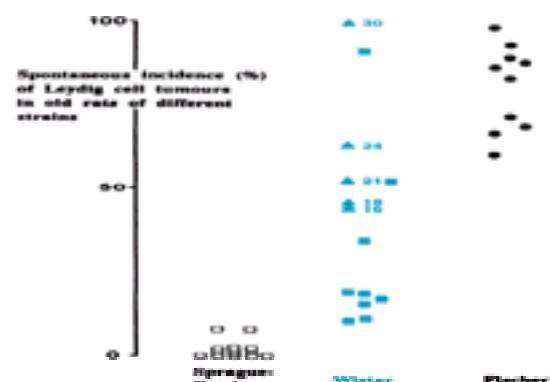
The incidence of Leydig cell tumors in old rats varies considerably depending upon the strain. In general, Sprague-Dawley, Osborne-Mendel, and Brown-Norway strains have a much lower incidence than other strains frequently used in chronic toxicity/carcinogenicity studies, including the Fischer 344 and Wistar strains. The spontaneous incidence of Leydig cell tumors in three different strains of rats is illustrated in Fig. 21-39 (Bär, 1992). The actual incidence of Leydig cell tumors in old rats is lowest in Sprague-Dawley, highly variable in Wistar rats, and highest in Fischer rats (in which the incidence at 2 years of age often approaches 100 percent). The specific numerical incidence of benign Leydig cell tumors in rats also will vary considerably depending upon the histologic criteria used by the pathologist in the separation of focal hyperplasia from adenomas.


Figure 21-39. Spontaneous incidence of Leydig cell tumors of the testis in Sprague-Dawley, Wistar, and Fischer rats. (From Bär, 1992, with permission.)

The incidence of Leydig cell tumors in human patients, in comparison to rodents, is extremely rare, something on the order of 1 in 5 million, with age peaks at approximately 30 and 60 years. Ninety or more percent of Leydig cell tumors in humans are benign and some appear to be endocrinologically active and associated

clinically with gynecomastia.

Structure and Endocrinologic Regulation of Leydig (Interstitial) Cells

Although the numbers of Leydig cells vary somewhat among different animal species and humans, the basic structural arrangement is similar. In the rat, there are small groups of Leydig cells clustered around blood vessels in the interstitium, between seminiferous tubules with an incomplete layer of endothelial cells around the groups of Leydig cells. In humans, the Leydig cells are present as small groups in the interstitium near blood vessels or in loose connective tissue but without the surrounding layer of endothelial cells. Leydig cells are much more numerous in some animal species, such as the domestic pig. Microscopic evaluation of the normal rat testis reveals the inconspicuous clusters of Leydig cells in the interstitium between the much larger seminiferous tubules composed of spermatogonia and Sertoli cells. The close anatomic association of Leydig cells and interstitial blood vessels permits the rapid exchange of materials between this endocrine cell population and the systemic circulation.

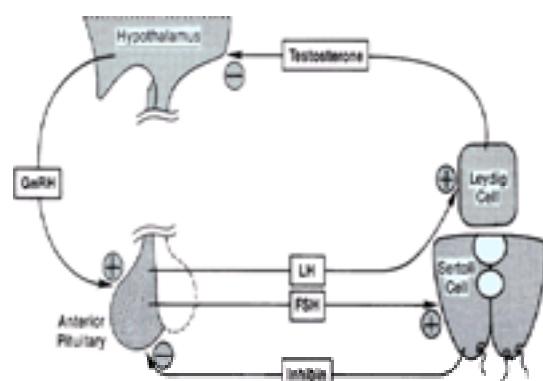
The endocrinologic regulation of Leydig cells involves the coordinated activity of the hypothalamus and adenohypophysis (anterior pituitary) with negative feedback control exerted by the blood concentration of gonadal steroids (Fig. 21-40). Hypothalamic gonadotrophin-releasing hormone (GnRH) stimulates the pulsatile release of both luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from gonadotrophs in the adenohypopthysis. Luteinizing hormone is the major trophic factor controlling the activity of Leydig cells and the synthesis of testosterone. The blood levels of testosterone exert negative feedback on the hypothalamus and, to a lesser extent, on the adenohypophysis. Follicle-stimulating hormone binds to receptors on Sertoli cells in the seminiferous tubules and, along with the local concentration of testosterone, plays a critical role in spermatogenesis. Testosterone, by controlling GnRH release, is one important regulator of FSH secretion by the pituitary gland. The seminiferous tubules also produce a glycopeptide, designated as inhibin, which exerts negative feedback on the release of FSH by the gonadotrophs.


Figure 21-40. Hypothalamus–anterior pituitary gland–gonad axis in the endocrine control of Leydig and Sertoli cells by luteinizing hormone (LH) and follicle stimulating hormone (FSH). (From Hedge et al. 1987, with permission.)

Leydig cells have a similar ultrastructural appearance as other endocrine cells that synthesize and release steroid hormones. The abundant cytoplasmic area contains numerous mitochondria, abundant profiles of smooth endoplasmic reticulum, prominent Golgi apparatuses associated with lysosomal bodies, and occa-sional lipofucsin inclusions. However, they lack the hormone-containing secretory granules that are found characteristically in peptide hormone–secreting endocrine cells.

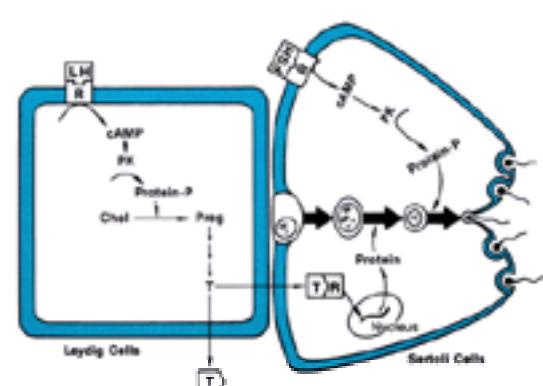
The hormonal control of testicular function is largely the result of the coordinated activities of LH and FSH from the pituitary gland. LH binds to high-affinity, low-capacity receptors on the surface of Leydig cells and activates adenylate cyclase in the plasma membrane resulting in the generation of an intracellular messenger, cyclic AMP (Fig. 21-41). The cyclic AMP binds to a protein kinase, resulting in the phosphorylation of a specific set of proteins in the cytosol, which increases the conversion of cholesterol to pregnenolone by making more substrate available and increasing the activity of an enzyme that cleaves the side chain of cholesterol. The pregnenolone in Leydig cells is rapidly converted to testosterone, which is released into interstitial blood vessels or taken up by adjacent Sertoli cells. Testosterone in the Sertoli cells binds to nuclear receptors, where it increases genomic expression and transcription of mRNAs that direct the synthesis of proteins (e.g., androgen-binding protein and others) involved in spermatogenesis. In the rat, the mitotic phase of gametogenesis can occur without hormonal stimulation but testosterone is necessary for meiosis of spermatocytes to spermatids. FSH is required for the la-ter stages for spermatid maturation to spermatazoa (Fig. 21-41). Once FSH and testosterone initiate spermatogenesis at puberty in the rat, testosterone alone is sufficient to maintain sperm production.


Figure 21-41. Hormonal control of testicular function.

Luteinizing hormone (LH) stimulates testosterone (T) release by binding to its receptor (R) and increasing the conversion of cholesterol (chol) to pregnenolone (preg) via a cAMP-protein kinase (PK) cascade. Spermatogenesis (*bold arrows*) is controlled by both FSH and testosterone acting via Sertoli cells. (From Hedge et al., 1987, with permission.)

Pathology of Leydig (Interstitial) Cell Tumors

Before discussing the pathology of focal proliferative lesions of Leydig cells, a few points should be made about the importance of standardized sectioning methods for the complete evaluation of the rodent testis. It is not unusual to have less than optimal sections to evaluate, due either to a lack of a consistent plane of section or to inadequate fixation. The goal should be to include the largest testicular area containing all anatomic features on a mid-sagittal section along the long axis of the testis, including spermatic vessels, attachment sites of the epididymis, the tubulus rectus, and the intratesticular rete testis. It is also important to emphasize the need to cut the thick outer covering (tunica albuginea) of the testis at several points prior to immersion in the fixative in order to permit more rapid penetration of the formalin or other fixing solution.

The major issue in the interpretation of focal proliferative lesions of Leydig cells in the rodent testis is the accurate and consistent separation of focal hyperplasia from benign tumors (adenomas) that possess autonomous growth. The separation of focal hyperplasia from adenomas derived from Leydig cells is arbitrary based upon current methods of evaluation and often is based primarily on the size of the focal lesion, since cytologic features usually are similar between focal hyperplastic and benign neoplastic lesions derived from Leydig cells.

In the multistage model of carcinogenesis, proliferative lesions are designated as beginning with hyperplasia, often progressing to benign tumors (adenomas); infrequently, a few assume malignant potential and form carcinomas ("cancer") (Fig. 21-42). Although this terminology often is applied to focal proliferative lesions in rodent endocrine tissues for convenience and standardization, it is essential to understand that the separation, especially between focal hyperplasia and adenoma, is

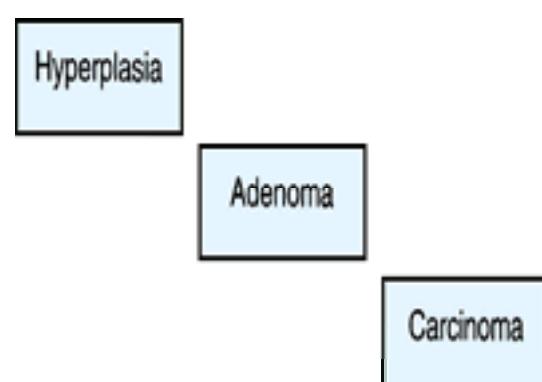
based primarily on size and morphologic changes in the proliferating Leydig cells. It is important to emphasize that focal proliferative lesions associated with hormonal imbalances in rodent endocrine tissues—also including Leydig cells, adrenal medullary cells, thyroid follicular cells, and C cells, among others—represent a morphologic continuum that begins with hyperplasia and progresses often but not always to the formation of adenomas that grow autonomously and only occasionally undergo a malignant transformation to form carcinomas ("cancer") (Fig. 21-43).


Figure 21-42. Multistage model of carcinogenesis of proliferative lesions in endocrine tissues of rodents.
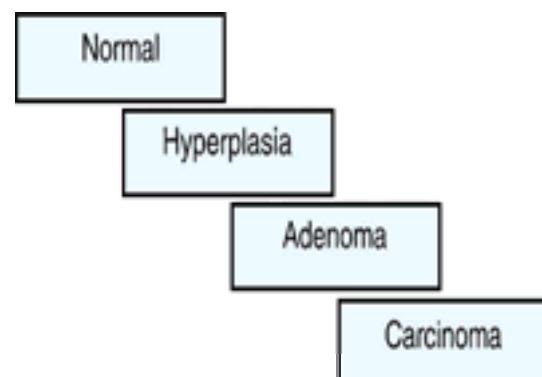

Figure 21-43. Morphologic continuum of proliferative lesions in endocrine tissues of rodents.

The National Toxicology Program (NTP), in an attempt to standardize the classification of focal proliferative lesions of Leydig cells between studies with different xenobiotic chemicals and different testing laboratories, established the following diagnostic criteria (Boorman, 1987): (1) Hyperplasia was defined as a focal collection of Leydig cells with little atypia and a diameter of less than 1 seminiferous tubule. (2) An adenoma was defined as a mass of Leydig cells larger in diameter than 1 seminiferous tubule with some cellular atypia and compression of adjacent tubules. (3) It was emphasized that the separation was arbitrary, since at that time little was known about the biological behavior of these lesions in rodents.

A more contemporary set of diagnostic criteria for focal proliferative lesions of Leydig cells has been published recently by the Society of Toxicologic Pathologists (STP) (McConnell et al., 1992). Recognizing that many small focal proliferative lesions of Leydig cells (i.e., between one and three tubule diameters) will regress following removal of the inciting stimulus, they recommend the diagnosis of Leydig cell adenoma be used for a mass of interstitial cells equal to or greater than the diameter of three adjacent seminiferous tubules plus one or more of the following criteria: symmetrical peripheral compression of adjacent tubules, evidence of cellular pleomorphism or an increase in the nuclear:cytoplasmic ratio, an endocrine sinusoidal vascular network, increased mitotic activity, or coalescence of adjacent cell masses.

Leydig cell neoplasms in laboratory rats associated with hormonal imbalances rarely undergo malignant transformation with progression to the development of carcinomas ("cancer"). Histologic features of malignancy include invasion into the epididymis, spermatic cord, or tunica albuginea. The most definitive criteria of malignancy is the demonstration of metastases in extratesticular sites. Leydig cell carinomas are large and often distort the overall contour of the affected testis, with extensive areas of both hemorrhage and necrosis. The cytology of Leydig cell carcinomas usually is more pleomorphic than with adenomas consisting of an admixture of poorly differentiated cells with an increased nuclear:cytoplasmic ratio and larger, more differentiated cells with an abundant vacuolated eosinophilic cytoplasmic area. The frequency of mitotic figures may be increased either in focal areas or throughout the Leydig cell carcinomas. The most convincing evidence of malignancy in carcinomas is the establishment of foci of growth outside of the testis, such as multiple foci of tumor cell emboli growing within and distending vessels of the lung.

Mechanisms of Leydig (Interstitial) Cell Tumor Development

Leydig (interstitial) cells of the testis frequently undergo proliferative changes with advancing age and following chronic exposure to large doses of xenobiotic chemicals. In addition, it should be emphasized that the "sensitivity" of rodent endocrine tissues, such as Leydig cells of the testis and other populations of endocrine cells, appears to be increasing over time particularly if one compares data generated in the 1970s to that gathered in the 1990s for the same compound (Table 21-3). This appears to be the result of several factors, including (1) animal husbandry practices, such as specific pathogen-free conditions, that result in a greater survival for 2 years, high body weight related to over feeding, and immobility; and (2) the genetic selection process for high productivity and rapid growth.

Table 21-3 Changes in Rodent Endocrine Sensitivity over Time (1970s–1990s)

Pathogenic mechanisms reported in the literature to be important in the development of proliferative lesions of Leydig cells include irradiation, the species and strain differences mentioned previously, and exposure to certain chemicals such as cadmium salts and 2-acetoaminofluorene (Prentice and Meikle, 1995) (Table 21-4). Other pathogenic mechanisms include physiologic perturbations such as cryptorchidism, a compromised blood supply to the testis, or heterotransplantation into the spleen. Hormonal imbalances also are important factors in the development of focal proliferative lesions of Leydig cells, including increased estrogenic steroids in mice and hamsters and elevated pituitary gonadotrophins resulting from the chronic administration of androgen receptor antagonists, 5a-reductase inhibitors, testosterone biosynthesis inhibitors, GnRH agonists, and aromatase inhibitors (Fig. 21-44) (Clegg et al., 1997; Cook et al., 1999). Many xenobiotic chemicals administered chronically to rats disrupt the hypothalamic-pituitary-testis axis at one of several possible sites, interfering with negative feedback control and resulting in

an overproduction of luteinizing hormone (LH), which causes the proliferative changes (hyperplasia, adenoma) in Leydig cells (Fig. 21-45). For example, chronic exposure to chemicals with antiandrogenic activity, such as procymidone due to binding to the androgen receptor, increases circulating levels of LH and results in stimulation of Leydig cells leading to an increased incidence of hyperplasia and adenomas in rats (Murakami et al., 1995).

Physiologic perturbations
   Cryptorchidism
   Compromised blood supply
   Heterotransplantation (spleen)
Hormonal imbalances
   Decreased testosterone
   Increased estrogens (mice, hamsters)
   Increased pituitary gonadotropins (e.g., LH)
Irradiation
Species/strain differences
Chemicals
   Cadmium salts
   2-Acetoaminofluorene

Data from several studies in the recent literature emphasize the importance of several of these pathogenetic factors in the frequent development of Leydig cell tumors in rats. Thurman and colleagues (1994) reported the effects of food restriction on the development of Leydig cell adenomas in the high incidence strain of Fischer 344 rats (Table 21-5). Beginning at 13 weeks of age, rats were either continued on an ad libitum feeding or were food-restricted 40 percent (NIH-31 diet with 1.673 fat-soluble and B vitamins) over their lifetime until they died or became moribund due to spontaneous disease. The incidence of Leydig cell adenomas was decreased to 19 percent in food-restricted rats compared to 49 percent in the ad libitum–fed group (Table 21-5). In another group from the food restriction study reported by Thurman and coworkers (1994), rats were periodically removed for serial sacrifice at 6-month intervals. Food restriction resulted in a similar marked reduction in Leydig cell adenomas (23 percent compared to 60 percent in ad libitum–fed rats) (Table 21-6). Examination of the serially sacrificed F344 rats in this study also demonstrated that feed restriction delayed the onset of development as well as decreasing the incidence of Leydig cell adenomas compared to the ad libitum–fed group (Table 21-7). For example, at the 30-month sacrifice, only 17 percent of feed-restricted F344 rats had developed Leydig cell adenomas, compared to 100 percent in the ad libitum group.

Table 21-7 Effects of Food Restriction on the Development of Interstitial (Leydig) Cell Adenoma (ICA) in F344 Rats at Different Ages

Investigations reported by Chatani and associated (1990) documented the importance of hormonal imbalances on the incidence of Leydig cell adenomas and hyperplasia in Fischer rats (Table 21-8). The incidence of adenomas was 70 percent and of hyperplasia 100 percent in control rats killed at 70 weeks of age. In rats administered testosterone for 28 weeks (by silastic tubes implanted subcutaneously at 42 weeks of age), the incidence of Leydig cell adenomas and hyperplasias was decreased to 0 percent for both at 70 weeks of age. This dramatic reduction in the incidence of focal proliferative lesions of Leydig cells was associated with a significant lowering in circulating levels of LH, through negative feedback exerted by testosterone on the pituitary gland.

TREATMENT (28 WEEKS)	TERMINAL AGE (WEEKS)	ICA %/No. TESTES	ICH % TESTES	ICH (NODULES/ TESTES)	SERUM LH (ng/mL)

The important studies reported by Chatani and coworkers (1990) also demonstrated that hormones other than testosterone could markedly decrease the development of Leydig cell adenomas in F344 rats (Table 21-9). The administration of estradiol-17b for 28 weeks (by silastic tubes implanted subcutaneously) decreased the incidence of Leydig cell adenomas to 0 percent (compared to 100 percent in controls) and significantly reduced serum LH, due to negative feedback control on the pituitary gland. An LH-releasing hormone agonist administered continuously for 28 weeks (injection of microcapsules every 4 weeks at a dose of 5 mg/2 mL/kg) also decreased the incidence of Leydig cell adenomas to 0 percent and significantly decreased circulating LH levels, most likely a result of the known-down regulation of LH-RH receptors on pituitary gonadotrophs (Table 21-9).

TREATMENT (28 WEEKS)	TERMINAL AGE (WEEKS)	ICA % (No./No. TESTES)	SERUM LH (ng/mL)

The studies of Bartke and colleagues (1985) demonstrated that hyperprolactinemia also markedly decreased the incidence of Leydig cell adenomas in Fischer rats (Table 21-10). Pituitaries transplanted beneath the renal capsule (four per rat) resulted in a chronic elevation of circulating prolactin levels, owing, most likely, to the lack of dopamine inhibition of prolactin secretion, which occurs when the pituitary gland is in its normal anatomic location in close proximity to the hypothalamus. In this interesting experiment, 83 percent of sham-operated rats developed Leydig cell adenomas at 21 to 24 months of age, whereas 0 percent of rats developed tumors in animals with ectopic pituitaries and elevated serum prolactin levels.

Table 21-10 Effect of Hyperprolactinemia from Ectopic Pituitary Transplants on the Incidence of Interstitial Cell Adenoma (ICA) and Testicular/Seminal Vesicle Weights in Fischer 344 Rats

The administration of a calcium-channel blocker (SVZ 200-110) at high doses (62.5 mg/kg/day for 2 years) significantly increased the incidence of Leydig cell adenomas in Sprague-Dawley rats. Endocrinologic studies demonstrated that increased serum levels of LH and FSH were present only after 52 and 66 weeks, respectively, and persisted to week 104 for LH. This compound is unusual in that most xenobiotic chemicals that cause hormonal imbalances result in earlier significant changes in circulating hormone levels.

Another important mechanism by which xenobiotics increase the incidence of Leydig cell tumors in rats is by inhibition of testosterone synthesis by cells in the testis. For example, lansoprazole is a substituted benzimidazole, which inhibits the hydrogen-potassium ATPase (proton pump) responsible for acid secretion by the parietal cells in the fundic mucosa of the stomach (Fort et al., 1995). The presence of the imidazole moiety in lansoprazole was suggestive of an effect on testosterone synthesis, since several imidazole compounds (e.g., ketoconazole and miconazole) are known to inhibit testosterone synthesis. Lansoprazole resulted in decreased circulating levels of testosterone, increased levels of LH, and an increased incidence of Leydig cell hyperplasia and benign neoplasia (adenomas) in chronic studies in rats (Fort et al., 1995). The most sensitive site for inhibition of testosterone synthesis by lansoprazole was the transport of cholesterol to the cholesterol side chain cleavage enzyme.

Although several hormonal imbalances result in an increased incidence of Leydig cell tumors in rodents, several disease conditions associated with chronic elevations in serum LH (including Klinefelter's syndrome and gonadotroph adenomas of the pituitary gland) in human patients have not been associated with an increased development of this type of rare testicular tumor.

There are a number of reports in the literature of xenobiotic chemicals (many of which are marketed drugs) that increase the incidence of proliferative lesions of Leydig cells in chronic toxicology/carcinogenicity in rats. These include indomethacin, lactitol, muselergine, cimetidine, gemfibrozil, and flutamide, among many others (Table 21-11).

Table 21-11 Selected Examples of Drugs that Increase the Incidence of Proliferative Lesions of Leydig Cells in Chronic Exposure Studies in Rats or Mice

Flutamide is a potent nonsteroidal, antiandrogen compound that displaces testosterone from specific receptors in target cells and decreases negative feedback on the hypothalamus-pituitary gland, resulting in elevated circulating levels of LH and FSH. The chronic administration of flutamide is known to result in a striking increase in the incidence of Leydig cell adenomas in rats. The Schering-Plough Research Institute's Department of Drug Safety and Metabolism completed an important reversibility study in which Sprague-Dawley rats were administered flutamide daily either for 1 year, 1 year followed by a 1-year recovery period, or continuously for 2 years (Table 21-12). This important study emphasizes the lack of autonomy of many focal proliferative lesions of Leydig cells in rats and their continued dependence upon compound administration for stimulation of growth. There was a reduction in the incidence of Leydig cell adenomas (using the conservative NTP criteria of greater than 1 tubule diameter) in rats administered three dose levels of flutamide daily for 1 year followed by a 1-year recovery prior to termination compared to rats given flutamide for 1 year and immediately evaluated (Table 21-12). Conversely, in rats administered flutamide for 2 years the numbers of adenomas continued to increase until 95 percent of animals in the mid- and high-dose groups (30 and 50 mg/kg, respectively) had developed Leydig cell tumors. There also was a marked reduction in the incidence of focal hyperplasia (focus less than 1 tubule diameter) after 1 year of recovery, compared to rats terminated immediately following 1 year of flutamide administration, a finding that emphasizes the frequent reversibility of these small proliferative lesions of Leydig cells.

	1-Year Dosing				1-Year Dosing, 2-Year Recovery				2-Year Dosing

Table 21-12 Flutamide: Incidence of Interstitial Cell (IC) Adenoma in Sprague-Dawley Rats after Various Dosing Intervals

Although a number of xenobiotics have been reported to increase the incidence of Leydig cell adenomas in chronic studies in rats, similar compounds such as cimetidine, ketoconazole, and certain calcium channel blocking agents have not resulted in an increased incidence of Leydig cell neoplasia in humans. In summary, Leydig cell tumors are a frequently occurring tumor in rats, often associated mechanistically with hormonal imbalances; however, they are not an appropriate model for assessing the potential risk to human males of developing this rare testicular tumor.

OVARY

Introduction

Ovarian tumors in rodents can be subdivided into five broad categories, including epithelial tumors, sex cord–stromal tumors, germ cell tumors, tumors derived from nonspecialized soft tissues of the ovary, and tumors metastatic to the ovary from distant sites. The epithelial tumors of the ovary include cystadenomas and cystadenocarcinomas, tubulostromal adenomas, and mesothelioma. The tubular (or tubulostromal) adenomas are the most important of the ovarian tumors in mice, and they are the tumors whose incidence often is increased by various endocrine perturbations associated with exposure to xenobiotics, senescence, or inherited genic deletion (Murphy and Beamer, 1973). Tubular adenomas are a unique lesion that develops frequently in the mouse ovary, accounting for approximately 25 percent of naturally occurring ovarian tumors in this species (Alison and Morgan, 1987; Rehm et al., 1984). They are uncommon in rats, rare in other animal species, and not recognized in the ovaries of women. In some ovarian tumors of this type in mice, there is an intense proliferation of stromal (interstitial) cells of sex cord origin. These tumors often are designated tubulostromal adenomas or carcinomas to reflect the bimorphic appearance.

The tubulostromal adenomas in mice are composed of numerous tubular profiles derived from the surface epithelium, plus abundant large luteinized stromal cells from the ovarian interstitium. The differences in histologic appearance of this type of unique ovarian tumor in mice are interpreted to represent a morphologic spectrum with variable contributions from the surface epithelium and sex cord–derived ovarian interstitium rather than being two distinct types of ovarian tumors. The histogenic origin of this unique ovarian tumor in mice has been a controversial topic in the literature, but most investigators currently agree that it is derived from the ovarian

surface epithelium, with varying contributions from stromal cells of the ovarian interstitium. However, some early reports suggested an origin from the rete ovarii or thecal/granulosal cells of the ovary.

Another important group of ovarian tumors are those derived from the sex cords and/or ovarian stroma. These include the granulosal cell tumors, luteoma, thecoma, Sertoli cell tumor, tubular adenoma (with contributions from ovarian stroma), and undifferentiated sex cord–stromal tumors. The granulosal cell tumor is the most common of this group which, according to Alison and Morgan (1987), accounts for 27 percent of naturally occurring ovarian tumors in mice. Granulosal cell tumors may develop within certain tubular or tubulostromal adenomas following a long-term perturbation of endocrine function associated with genic deletion, irradiation, oocytotoxic chemicals, and neonatal thymectomy (Frith et al., 1981; Li and Gardner, 1949; Hummel, 1954).

Mechanisms of Ovarian Tumorigenesis in Rodents

Five model systems of ovarian tumorigenesis in mice have been reported in the literature. The first model system identified was the production of ovarian neoplasms by radiation (Furth and Boon, 1947; Gardner, 1950). After acute radiation exposure, the initial change was a rapid loss of oocytes and a destruction of graafian follicles. There was proliferation and down-growth of the ovarian epithelium into the stroma within 10 weeks after radiation exposure. The first ovarian tumors developed approximately 1 year after exposure. The tubular adenomas that develop following radiation often were bilateral, endocrinologically inactive, and not lethal unless they reached a very large size. Some irradiated mice also developed endocrinologically active granulosal cell tumors, which transplantation experiments have shown to be different from the tubular adenomas. Granulosal cell tumors were transplantable into the spleen and often grew rapidly, whereas tubular adenomas grew slowly after transplantation, most successfully in castrated animals.

The second model of ovarian tumorigenesis arose out of the work published by Biskind and Biskind (1944). They transplanted ovaries into the spleen of castrated rats to prevent negative feedback by circulating sex hormones on the hypothalamus and pituitary gland because estrogen is degraded as it circulates through the liver. Transplantation resulted in a rapid loss of ovarian follicles as well as an interference with estrogen feedback on the hypothalamus. Following the loss of graafian follicles, the epithelial covering of the ovary began to proliferate and invaginate into the ovary, with an accompanying increase in stromal tissue, which ultimately resulted in the formation of tubular adenomas and, occasionally, granulosal cell tumors (Guthrie, 1957). The presence of a single functioning gonad prevented the development of the proliferative lesions in the ovary, suggesting that the lack of negative feedback from estrogen was necessary for the changes to develop. Administration of exogenous estrogen or testosterone after transplantation completely suppressed development of the proliferative changes in the ovarian cortex.

The third model of ovarian tumorigenesis was described by Marchant (1957, 1960), who reported that ovarian tumors developed in mice exposed to dimethylbenzanthracene. This chemical is a reproductive toxicant that is cytotoxic to oocytes, resulting in the loss of graafian follicles from the ovary. This was followed by a proliferation of the interstitial (stromal) tissue, invaginations of the surface epithelium, and subsequent development of tubular adenomas and occasionally granulosal cell tumors of the ovary (Taguchi et al., 1988). Support for an endocrinologic mechanism of hormonal imbalance included the observation that the xenobiotic chemical first must cause sterility, because the presence of a single normal gonad prevented the development of the hyperplastic lesions and tumors of the ovary. The administration of estrogen prevented tumor formation even in sterile mice, and hypophysectomy also prevented the development of ovarian tumors.

The fourth model of ovarian tumorigenesis was described by Nishizuki and associates (1979). They reported that removal of the thymus from neonatal mice resulted in ovarian dysgenesis and the development of ovarian tumors. Thymectomy prior to 7 days of age resulted in an immune-mediated destruction of follicles in the ovary. Because estrogen was not produced by the follicles, these mice also developed hormone-mediated proliferative lesions and ovarian tumors identical to those in the previously described models. After the immune-mediated destruction of follicles, there was a proliferation of the interstitial (stromal) and surface epithelial cells of the ovary, resulting in the formation of tubular adenomas. If the mice survived for longer periods, some animals developed granulosal cell tumors and luteomas in the ovary. Because this model also did not involve exposure to any carcinogen, it is another indication that the prerequisite for ovarian tumor response in mice is the production of sterility, which results in hormonal imbalances that lead to stimulation of the sensitive populations of target cells (Michael et al., 1981).

Case Study: Ovarian Tumors Associated with Xenobiotic Chemicals

Nitrofurantoin Nitrofurantoin is an example of a chemical that, when fed at high doses to mice for 2 years in a NTP study, increased the incidence of ovarian tumors of the tubular or tubulostromal type (Table 21-13). Nitrofurantoin fed at both low (1300 ppm) and high (2500 ppm) doses to $B_6C_3F_1$ mice caused sterility due to the destruction of ovarian follicles, leading to hormonal imbalances, which resulted in the development of an increased incidence of this unique type of ovarian tumor.

Table 21-13 NTP Nitrofurantoin Study of Treatment-Related Ovarian Lesions in $B_6C_3F_1$ Mice (50/Group Exposed for 2 Years in Feed)

Mice administered nitrofurantoin had a consistent change in the ovarian cortex, termed *ovarian atrophy.* This lesion was characterized by an absence of graafian follicles, developing ova, and corpora lutea; by focal or diffuse hyperplasia with localized or diffuse down-growth of surface epithelium into the ovary; and by varying numbers of polygonal, often vacuolated, sex cord–derived stromal (interstitial) cells between the tubular profiles. The ovaries were small, had irregular surfaces due to the tubular down-growths into the cortex, and had scattered eosinophilic stromal cells between tubular profiles. In addition, there was a lack of graafian follicles and corpora lutea throughout the ovarian cortex.

The benign ovarian tumors in this study were classified either as tubular adenomas (5 of 50 mice) or as tubulostromal tumors (4 of 50 mice) (Table 21-13). In tubulostromal adenomas, the proliferating stromal (interstitial) cells between the tubules were considered to represent a significant component of the lesion. However, the separation between these two types of proliferating ovarian lesions in mice was not distinct and both appeared to be part of a continuous morphologic spectrum. Because all treated mice in the NTP nitrofurantoin feeding study were sterile due to ovarian atrophy, an indirect mechanism secondary to a disruption of endocrine function leading to hormonal imbalances was suggested to explain the development of the ovarian tubular adenomas.

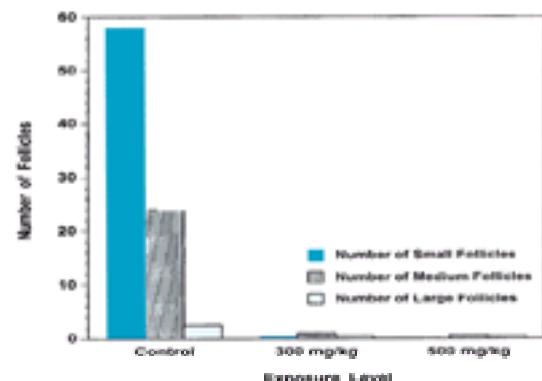
The results of an investigative study demonstrated that nitrofurantoin had an effect on graafian follicles in the ovary of $B_6C_3F_1$ mice. Female mice of the same strain were fed 350 or 500 mg/kg/day of nitrofurantoin beginning at 7 weeks of age. These levels approximate the low (1300 ppm) and high (2500 ppm) doses used in the NTP study with nitrofurantoin. Ten female mice per group were sacrificed at 4, 8, 13, 17, 43, and 64 weeks of feeding nitrofurantoin. The numbers of follicles were quantified from nitrofurantoin-treated and control mice on serial sections of the ovary. The morphometric data revealed that the numbers of small, medium, and large follicles in nitrofurantoin-treated mice were numerically decreased at 17 weeks compared with controls and were significantly decreased in rats fed 350 and 500 mg/kg/day nitrofurantoin after 43 and 64 weeks (Fig. 21-46). All mice in the treated groups were sterile by 43 weeks of feeding nitrofurantoin.


Figure 21-46. Morphometric evaluation of ovaries of mice following the administration of 350 and 500 mg/kg/day of nitrofurantoin.

The numbers of small, medium, and large ovarian follicles were decreased after 17 weeks and significantly decreased after 43 and 64 weeks due to a direct action of the nitrofurantoin.

Selective Estrogen Receptor Modulators Selective estrogen receptor modulators (SERMs) are compounds that have estrogen agonist effects on some tissues and estrogen antagonist actions on other tissues (Cohen et al., 2000). The triphenylethylene SERMs tamoxifen and toremifene have estrogen antagonist effects in the breast and currently are used in the medical management of breast cancer. The benzothiophene SERM raloxifene has estrogen agonist effects on bone and serum lipids but estrogen antagonist actions on the uterus and breast. This is in contrast to tamoxifen, which has an estrogen agonist effect on bone and also may stimulate the uterine endometrium. These SERMs (e.g., tamoxifen, toremifene, and raloxifene) all have been reported to increase the incidence of ovarian tumors when administered chronically to mice. For example, CD_1 mice administered raloxifene (9, 50, 225 mg/kg) per day for 21 months developed an increased incidence of granulosa/theca cell tumors (benign and malignant) and tubular/papillary adenomas of the ovary. However, there is no evidence of an increased risk for ovarian cancer in women administered SERMs, since tamoxifen has been used clinically since 1978 (Fisher et al., 1994; Cook et al., 1995).

Raloxifene binds to the estrogen receptor (Yang et al., 1996) and appears to block the negative feedback of circulating levels of estrogen on the hypothalamus, resulting in a sustained increase in circulating levels of LH. Mice (CD_1) administered raloxifene (233 or 236 mg/kg) daily for 2 and 4 weeks had a dose-dependent significant elevation of serum LH levels (4- to 7-fold and 4.4-fold compared to controls, respectively) (Cohen et al., 2000). Raloxifene-treated mice had sustained elevations in serum LH over a 24-h period and did not have the preovulatory LH surge present in many control mice. Histomorphologic changes in the ovary were indicative of arrested follicular maturation including anovulatory hemorrhagic follicles, some developing follicles, and few corpora lutea. Following a recovery period of 3 weeks during which no raloxifene was administered, serum LH concentrations were indistinguishable from controls and follicular maturation and corpora lutea distribution were normal (Long et al., 2001). Raloxifene binding to the estrogen receptor resulted in an elevation of serum LH and ovarian tumor development similar to those in estrogen receptor-a knockout mice with genetic deletion of the estrogen receptor (Korach, 1994), suggesting that the tumors in both instances develop secondary to the hormonal imbalances.

Ovarian Tumors in Mutant Strains of Mice

W^x/W^v Strain with Genetic Deletion of Germ Cells in Ovarian Cortex In an attempt to arrive at further mechanistic explanations for the development of tubular adenomas in $B_6C_3F_1$ mice fed high doses of nitrofurantoin, ovaries were evaluated from several mutant mouse strains not exposed to any xenobiotic chemicals but known to develop ovarian tumors. In this mutant mouse strain, referred to as W^x/W^v, few germ cells migrate into the ovary during development. Murphy (1972) reported that less than 1 percent of the normal complement of oocytes were present in the ovary at 1 day of age and the numbers of graafian follicles decrease progressively until none were present at 13 weeks of age. In this mutant mouse strain (W^x/W^v), a mutant allele at the C-kit locus encodes for a defective protein kinase receptor, resulting in an inability to respond to stem cell growth factor encoded by the Steel locus (Witte, 1990; Majumder et al., 1988). A failure of proliferation of primordial germ cells during gonadogenesis leads to the marked reduction of graafian follicles in the ovarian cortex.

Ovaries from mutant mice at age 13 weeks were small, had an irregular surface, were devoid of graafian follicles, and had numerous hyperplastic tubules growing into the cortex. These tubules were lined by a hyperplastic cuboidal epithelium similar to that on the surface of the ovary. Interspersed between the tubular profiles were luteinized stromal cells of the ovarian interstitium with a lightly eosinophilic, often vacuolated, cytoplasm. The proliferative changes observed in the ovary of these mutant (W^x/W^v) mice at 13 weeks of age were similar morphologically to the ovarian atrophy lesions in the NTP nitrofurantoin study.

The ovaries of heterozygous controls (1/1) of this strain were larger than in the mutant mice and had a histologic appearance similar to normal mouse ovaries. The ovarian cortex in control mice had plentiful graafian follicles with developing ova. The surface epithelium covering the ovary consisted of a single layer of cuboidal cells without the down-growth of tubules into the underlying cortex.

The ovaries of mutant (W^x/W^v) mice at 22 weeks of age had a more intense proliferation of surface epithelium, either with extensive down-growths of hyperplastic tubules into the cortex or the formation of small tubular adenomas. The tubular adenomas in the mutant (W^x/W^v) mice with genetic deletion of graafian follicles but without any exposure to xenobiotic chemicals were composed of proliferating tubules of surface epithelium that replaced much of the ovary. They were similar microscopically to the smaller tubular adenomas in the $B_6C_3F_1$ mice fed the high dose (2500 ppm) of nitrofurantoin in the 2-year NTP feeding study. Interspersed between the hyperplastic profiles of surface epithelium in the tubular adenomas were scattered luteinized stromal cells with varying degrees of vacuolation of the eosinophilic cytoplasm. In mutant (W^x/W^v) mice, age 22 weeks, whose ovaries had been under long-term intense gonadotrophin stimulation, there appeared to be a morphologic continuum between ovarian atrophy and tubular adenomas.

At age 20 months, ovaries of the mutant (W^x/W^v) mice without any exposure to xenobiotic chemicals consistently had large tubular adenomas that incorporated all of the ovarian parenchyma and greatly enlarged the ovary. These neoplasms were similar histologically to the larger tubular adenomas in the high-dose (2500 ppm) mice of the NTP study. Several of the larger ovarian neoplasms of the 20-month-old mutant mice had evidence of malignancy with invasion of tumor cells through the ovarian capsule into the periovarian tissues, often accompanied by a localized desmoplastic response. Histopathologic evidence of malignancy was not observed in the ovarian tubular adenomas from the high-dose (2500 ppm) female mice in the NTP study. An occasional mutant mouse at 20 months of age also had developed focal areas of hyperplasia of granulosal cells or small granulosa cell tumors.

Hypogonadal (hpg/hpg) Mice Unable to Synthesize Hypothalamic Gonadotrophin-Releasing Hormone (GnRH) Mutant hypogonadal mice, designated hpg/hpg, are unable to synthesize normal amounts of hypothalamic GnRH (Tennent and Beamer, 1986). They have low circulating levels of pituitary gonadotrophins (both FSH and LH); however, hypogonadal mice have a normal complement of ovarian follicles (Cattanach et al., 1977).

In the studies of Tennent and Beamer (1986), both genetically normal littermates and hypogonadal (hpg/hpg) mice were irradiated at age 30 days to destroy the oocytes. The irradiated control mice of this strain produced normal amounts of pituitary gonadotrophic hormones and developed ovarian tubular adenomas at age 10 to 15 months. The tumors that developed in the absence of any exposure to xenobiotic chemicals had similar histological characteristics as tubular adenomas in the high-dose (2500 ppm) females of the nitrofurantoin study. They either were small nodules involving only a portion of the ovary or large masses that completely incorporated the affected gonad. They were composed predominantly of tubular profiles, some of which were dilated, with interspersed stromal cells.

The irradiated hypogonadal (hpg/hpg) mice failed to develop tubular adenomas or to have intense hyperplasia of the ovarian surface epithelium and interstitial (stromal) cells in the absence of GnRH and with low circulating levels of pituitary gonadotrophins. The ovaries of irradiated hypogonadal mice were small and had single- or multiple-layered follicles, without oocytes, scattered throughout the ovary. There also was an absence of stromal cell hypertrophy and hyperplasia, a change frequently observed in ovaries of the irradiated normal littermates.

The experiments reported by Tennent and Beamer (1986) demonstrated that a normal secretion of hypothalamic GnRH and pituitary gonadotrophins was necessary for the intense proliferation of ovarian surface epithelium and stromal cells, leading to the formation of tubular adenomas in mice, which develop subsequent to

irradiation-induced loss of ovarian follicles and decreased ability to produce gonadal steroids (especially estradiol-17b).

Genetically Engineered Mouse Models of Ovarian Tumors Transgenic mice expressing a chimeric lutenizing hormone (LH) b submit (LHb) in pituitary gonadotrophs have increased pituitary expression of LH mRNA and elevated circulating levels of LH (as well as estradiol and testosterone) but are infertile (Risma et al. 1995 and 1997). They ovulate infrequently, maintain a prolonged luteal phase, and develop a variety of ovarian lesions including cyst (blood and fluid filled) formation and ovarian tumors. A subset of LHb transgenic mice developed ovarian granulosa and theca–interstitial cell tumors by 4 to 8 months of age as a result of the chronic stimulation by the elevated gonadotropin (LH) levels. The findings of granulosa and stromal cell tumors in transgenic mice whose only genetic alteration is the addition of a gene encoding a chimeric gonadotropin suggest that abnormal gonadotropin stimulation is tumorigenic to the ovary in mice. In addition, genetically altered mice deficient in inhibin (hormone which suppresses the secretion of follicle stimulating hormone [FSH]) have elevated blood concentrations of FSH (two- to threefold) and develop granulosa cell tumors and mixed or incompletely differentiated gonadal stromal tumors of the ovary (Matzuk et al., 1992).

Another example of hormonal dysregulation leading to the induction of ovarian tumors are the estrogen receptor knockout (ERKO) mice that lack the alpha estrogen receptors and are unable to regulate gonadotropin secretion due to a lack of negative feedback control by the blood estrogen level (Lubahan et al., 1993; Korach, 1994). Female mice are infertile with hypoplastic uteri and hyperemic ovaries with no detectable corpora lutea. There was no uterine stimulation (uterotropic response) when these animals were treated with tamoxifen (an estrogen agonist in mice). ERKO mice also develop ovarian granulosa cell tumors in response to the chronic elevations in circulating gonadotropin levels.

Summary: Ovarian Tumorigenesis in Rodents

A review of studies on mutant mice and the NTP study of nitrofurantoin support an interpretation that the unique intense hyperplasia of ovarian surface epithelium and stromal cells, leading eventually to an increased incidence of tubular adenomas and occasionally granulosa cell tumors, develops secondary to chronic pituitary gonadotrophic hormone stimulation. Factors that destroy or greatly diminish the numbers of ovarian follicles—such as senescence, genetic deletion of follicles, x-irradiation, drugs, and chemicals such as nitrofurantoin, and early thymectomy with the development of autoantibodies to oocytes—are known to diminish sex steroid hormone secretion by the ovary. This results in elevated circulating levels of gonadotrophins, especially LH, due to decreased negative feedback on the hypothalamic-pituitary axis by estrogens and possibly other humoral factors produced by the graafian follicles (Carson et al., 1989). The long-term stimulation of stromal (interstitial) cells, which have receptors for LH (Beamer and Tennent, 1986), and, indirectly, the ovarian surface epithelium appears to place the mouse ovary at increased risk for developing the unique tubular or tubulostromal adenomas.

The finding of similar tubular adenomas in the ovaries of the xenobiotic-treated and genetically sterile mice not exposed to exogenous chemicals supports the concept of a secondary (hormonally mediated) mechanism of ovarian oncogenesis associated with hormonal imbalances (Fig. 21-47). The ovarian tumors developed only in sterile mice in which the pituitary-hypothalamic axis was intact; administration of exogenous estrogen early in the course will prevent ovarian tumor development. The intense proliferation of ovarian surface epithelium and stromal (interstitial) cells with the development of unique tubular adenomas in response to sterility does not appear to have a counterpart in the ovaries of human adult females.

- TUMORS DEVELOP ONLY IN STERILE MICE

- REQUIRES AN INTACT HYPOTHALAMUS-
  PITUITARY-OVARIAN AXIS

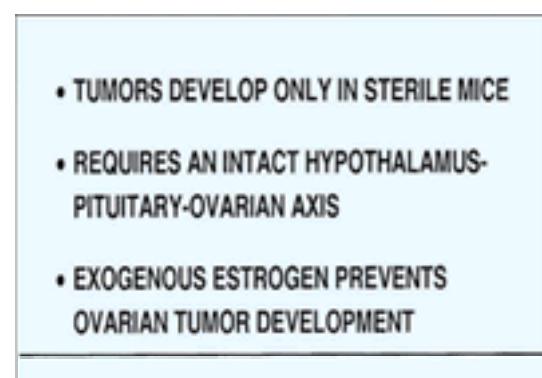
- EXOGENOUS ESTROGEN PREVENTS
  OVARIAN TUMOR DEVELOPMENT


Figure 21-47. Secondary mechanisms of ovarian oncogenesis in mice.

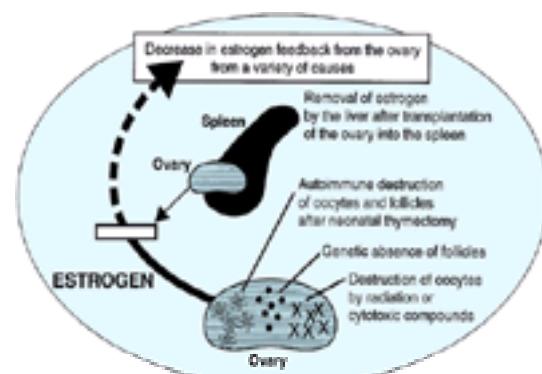
Experimental ovarian carcinogenesis has been investigated in inbred and hybrid strains of mice and induced by a diversity of mechanisms, including x-irradiation, oocytotoxic xenobiotic chemicals, ovarian grafting to ectopic or orthotopic sites, neonatal thymectomy, mutant genes reducing germ cell populations, and aging (Fig. 21-48). Disruptions in the function of graafian follicles by a variety of mechanisms results in a spectrum of ovarian proliferative lesions, including tumors. The findings in mutant mice support the concept of a secondary (hormonally mediated) mechanism of ovarian carcinogenesis in mice associated with sterility. Multiple pathogenetic factors that either destroy or diminish the numbers of graafian follicles in the ovary result in decreased sex hormone secretion (especially estradiol-17b), leading to a compensatory overproduction of pituitary gonadotrophins (particularly LH) (Fig. 21-48), which places the mouse ovary at an increased risk for developing tumors (Fig. 21-49). The intense proliferation of ovarian surface epithelium and stromal (interstitial) cells with the development of unique tubular adenomas in response to sterility does not appear to have a counterpart in the ovaries of human adult females.


Figure 21-48. Multiple pathogenic mechanisms in ovarian tumorigenesis of mice resulting in decreased negative feedback by diminished levels of gonadal steroids, particularly estrogen.
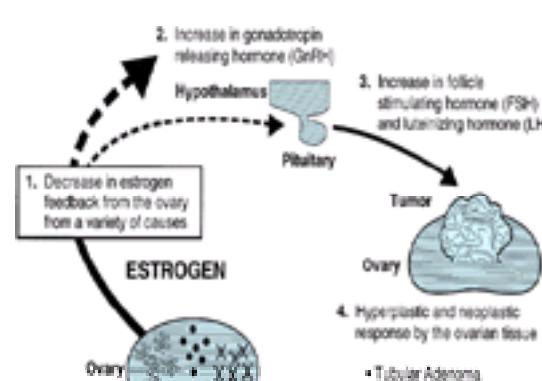

Figure 21-49. Decreased circulating estrogens release the hypothalamus-pituitary gland from negative feedback inhibition.

The increased gonadotrophin levels (LH and FSH) result in the mouse ovary being at greater risk of developing tubular adenomas in chronic studies.

CHAPTER 22

TOXIC EFFECTS OF PESTICIDES

Donald J. Ecobichon

INTRODUCTION

The U.S. Environmental Protection Agency (U.S. EPA) defines a pesticide as any substance or mixture of substances intended for preventing, destroying, repelling, or mitigating any pest. A pesticide may also be described as any physical, chemical, or biological agent that will kill an undesirable plant or animal pest. The term *pest* includes harmful, destructive, or troublesome animals, plants, or microorganisms. *Pesticide* is a generic name for a variety of agents that are classified more specifically on the basis of the pattern of use and organism killed. In addition to the major agricultural classes that encompass insecticides, herbicides, and fungicides, one finds pest-control agents grouped as acaricides, larvacides, miticides, molluscides, pediculicides, rodenticides, scabicides, plus attractants (pheromones), defoliants, desiccants, plant growth regulators, and repellants.

HISTORICAL DEVELOPMENT

Over the centuries, humans have developed many ingenious methods in their attempts to control the invertebrates, vertebrates, and microorganisms that constantly threatened the supply of food and fiber as well as posing a threat to health. The historical literature is replete with descriptions of plant diseases and insect plagues and the measures taken to control them. Sulfur was used as a fumigant by the Chinese before 1000 B.C. and as a fungicide in the 1800s in Europe against powdery mildew on fruit; it is still the major pesticide used in California today. In sixteenth-century Japan, poor-quality rendered whale oil was mixed with vinegar and sprayed on paddies and fields to prevent the development of insect larvae by weakening the cuticle. The Chinese applied moderate amounts of arsenic-containing compounds as insecticides in the sixteenth century. As early as 1690, water extracts of tobacco leaves (*Nicotiana tabacum*) were sprayed on plants as insecticides, and nux vomica, the seed of *Strychnos nux-vomica* (strychnine), was introduced to kill rodents. In the mid-1800s, the pulverized root of *Derris eliptica,* containing rotenone, was used as an insecticide, as was pyrethrum extracted from the flowers of the chrysanthemum (*Chrysanthemum cineariaefolum*). In the late 1800s, arsenic trioxide was used as a weed killer, particularly for dandelions. Bordeaux mixture—copper sulfate, lime [Ca(OH) $_2$], and water—was introduced in 1882 to combat vine downy mildew (*Plasmopara viticola*), a disease introduced into France from the United States when phylloxera-resistant vine rootstocks were imported. Sulfuric acid, at a concentration of 10% v/v, was used in the early 1900s to destroy dicotyledonous weeds that would absorb the acid, whereas cereal grains and substitute plants, having a smooth and waxy monocotyledon, were protected. Paris Green (copper arsenite) was introduced to control the Colorado beetle in the late 1800s; calcium arsenate replaced Paris Green and lead arsenate was a major cornerstone in the agriculturalist's armamentarium against insect pests in the early 1900s. By the 1900s, the widespread use of arsenical pesticides caused considerable public concern because some treated fruits and vegetables were found to have toxic residues. Although some of these early pesticides caused only minimal harm to the humans exposed, other agents were exceedingly toxic, and the medical literature of the era is sprinkled with anecdotal reports of poisonings. Looking back over the early years of pesticide development, before the 1930s, it is somewhat surprising to realize just how few pesticides were available (Cremlyn, 1978).

The 1930s ushered in the era of modern synthetic chemistry, including the development of a variety of agents such as alkyl thiocyanate insecticides, dithiiocarbamate fungicides, ethylene dibromide, methyl bromide, and ethylene oxide (Cremlyn, 1978). By the beginning of World War II, there were a number of pesticides, including dichlorodiphenyltrichloroethane (DDT), dinitrocresol, 4-chloro-2-methyloxyacetic acid (MCPA), and 2.4-dichlorophenoxyacetic acid (2,4-D) under experimental investigation, much of this activity being kept under wraps during the war (Kirby, 1980). In the postwar era, there was rapid development in the agrochemical field, with a plethora of insecticides, fungicides, herbicides, and other chemical agents being introduced. In no other field of chemistry has there been such a diversity of structures arising from the application of the principles of chemistry to the mechanism(s) of action in pests to develop selectivity and specificity in agents toward certain species while reducing toxicity to other forms of life.

Despite the modern-day development of second- and third-generation derivatives of the early chemical pesticides, all pesticides possess an inherent degree of toxicity to some living organism, otherwise they would be of no practical use. Unfortunately, the target-species selectivity of pesticides is not as well developed as might be hoped for, and nontarget species frequently are affected because they have physiologic and/or biochemical systems similar to those of the target organisms. There is no such thing as a completely safe pesticide. There are, however, pesticides that can be used safely and/or that present a low level of risk to human health when applied with proper attention to the label's instructions. Despite the current controversy over pesticide use and the presence of low levels of residues in food, groundwater, and air, these agents are integral components of our crop- and health-protection programs. As long as pesticides continue to be used, accidental and/or intentional poisoning of wildlife, domestic stock, and humans can be anticipated and will require treatment.

On a worldwide basis, intoxications attributed to pesticides have been estimated to be as high 3 million cases of acute, severe poisoning annually, with as many or more unreported cases and some 220,000 deaths (WHO, 1990). These estimates suffer from inadequate reporting of data for developing countries, but they may not be too far off the mark. From estimations based on California data, a total of some 25,000 cases of pesticide-related illness occur annually among agricultural workers in that state, with national estimate for the United States as a whole being on the order 80,000 cases per year (Coye et al., 1986). Results from California, a state that uses a vast amount of chemical pesticides, revealed that 1087 occupationally related exposures occurred in 1978. A breakdown of these poisonings by job category,

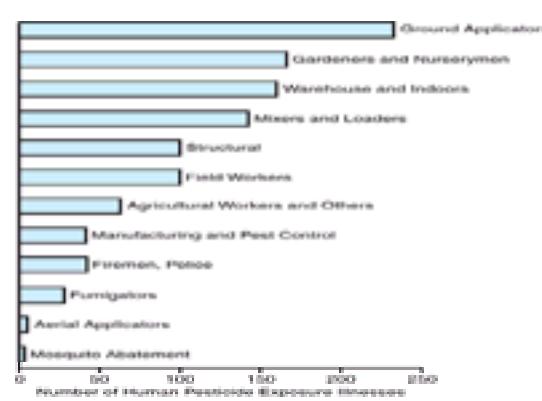
as shown in Fig. 22-1, revealed that ground applicators were at greatest risk, whereas aerial applicators and workers involved in mosquito-abatement programs had the least pesticide-related illness (Kilgore, 1980, 1988). Of 1211 cases of pesticide-related illness reported to California physicians in 1986, a total of 1065 were occupational in nature (Edmiston and Maddy, 1987). However, in other countries, the incidence of poisoning is very low; for example, in the United Kingdom, fewer than 20 agricultural incidents with organophosphates are reported each year (Weir et al., 1992). Such data are not representative of the rest of the agricultural world.


Figure 22-1. Frequency of pesticide poisoning related to occupation and potential for exposure. [From the records of the California Department of Public Health (Kilgore, 1988)].

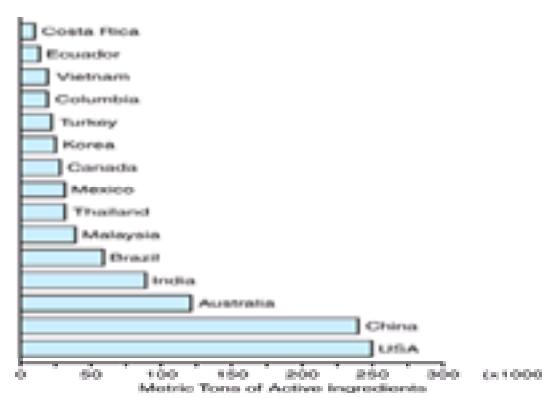
The incidence of poisoning is 13-fold higher in developing countries than in highly industrialized nations, which consume 85 percent of world's pesticide production (Forget, 1989). A recently published proceedings gives a good overview of the situation in developing nations, where there are few regulations controlling the importation, registration, and sale of pesticides (Forget, 1993). Many countries in Central and South America, Africa, and Southeast Asia are becoming "breadbaskets" for countries of more temperate climate, being sources of fresh fruits, vegetables, cut flowers, and so on in the off-season, since they are capable of growing two or three crops of export produce each year. Figure 22-2 shows the quantities of pesticidal active ingredients used in a number of countries in 1994 (UN FAO, 1994). A more complete listing can be found in O'Malley (1997). In developed countries, more herbicides are used than any other class of pesticides, whereas in tropical, developing nations, there is a predominant use of insecticides. As other developing nations explore the global export produce market, pesticide consumption—now around 3000 to 10,000 metric tons—will increase dramatically. Most developing nations have yet to develop stringent "philosophies" concerning pesticide control and usage (Mbiapo and Youovop, 1993).


Figure 22-2. Quantities of pesticides (active ingredients) used in representative countries around the world in 1994. (From O'Malley, 1997, with permission.)

Most pesticide-related poisonings in developing nations can be attributed to inexperience with such chemicals, negligible training in their use, and the absence of appropriate personal protective equipment. In 1983 in Thailand, 117 incidents per 100,000 agricultural workers were reported for compensation claims by companies having more than 20 employees; by comparison, hospital admissions/deaths due to pesticide poisonings totaled 8268 per 100,000 individual farmers, cooperative members, and workers for small companies (Boon-Long et al., 1986). In 1981 in Sri Lanka, approximately 10,000 to 13,000 persons were admitted to hospitals for acute poisoning annually, with almost 1000 deaths (Jeyaratnam, 1993; Jeyaratnam et al., 1982). In Taiwan, for the years 1985 to 1993, some 7386 out of a total of 23,436 chemical-related poisonings involved pesticides (Yang et al., 1996). In Costa Rica in 1996, some 920 out of a total of 1274 pesticide-related poisonings were due to occupational or accidental exposure (Leveridge, 1998). Poisonings by organophosphorus and carbamate insecticides represented 38.5 percent of the total (438 out of 1274), while only 8 intoxications were associated with organochlorine insecticides (Leveridge, 1998). None of the above values included affected individuals who either did not seek medical attention or could not afford the time away from work to do so.

No one can doubt the efficacy of pesticides for the protection of crops in the field, thereby providing us with abundant, inexpensive, wholesome, and attractive fruits and vegetables. It has been estimated that in 1830 it took 58 person-hours to tend and harvest an acre of grain, whereas today it takes approximately 2 person-hours (Kirby, 1980). Over this time period, the price of cereal grain has not risen proportionally to the costs of the labor to produce it. Along with improved strains of crops, an important role in crop improvements and yields has been played by insecticides, fungicides, and herbicides. Even with such advances, it is estimated that up to 50 percent of harvested crops can be damaged by postharvest infestation by insects, fungi, rodents, and the like (Table 22-1).

	POTENTIAL HARVEST (1000 TONS)	HARVEST 1978 (1000 TONS)	Losses Through		
CROP			WEEDS %	DISEASES %	INSECTS %
Rice	715,900	376,645	10.6	9.0	27.5
Maize	563,016	362,382	13.0	9.6	13.0
Wheat	576,400	437,236	9.8	9.5	5.1
Sugarcane	1,603,200	737,483	15.1	19.4	19.5

Table 22-1 Worldwide Harvest Losses in Five Important Crops

The medical miracles accomplished by pesticides have been documented: the suppression of a typhus epidemic in Naples, Italy, by DDT in the winter of 1943–1944 (Brooks, 1974); the control of river blindness (onchocerciasis) in West Africa by killing of the insect vector (black fly) carrying the filariae for this disease (WHO, 1977; Calamari et al., 1988); and the control of malaria in Africa, the Middle East, and Asia by elimination of the plasmodium-bearing mosquito populations with a variety of insecticides (Matsumura, 1985). There is still a great need for advancement in the control of disease vector with pesticides: 600 million people are at risk from schistosomiasis in the Middle East and Asia; 200 million suffer from filariasis in tropical Africa, Asia, Indonesia, and the Caribbean region; 20 million people in tropical Africa, the Middle East, Mexico, and Guatemala are infected by the filarium causing onchocerciasis; and 1000 million people worldwide harbor pathologic intestinal worm infestations (Albert, 1987). Although the benefits of pesticides are recognized by those who require them, certain parts of the world are experiencing an

environmentalist- and media-evoked backlash toward all pesticide use because of the carelessness, misuse, and/or abuse of some agents by a relatively few individuals in a limited number of well-publicized incidents. Without bearing any direct responsibility for planning or involvement in health care or food or fiber production, some environmental and consumer advocacy groups propose a total ban on pesticide use. Between the two extremes of overwhelming use and total ban lies a position advocating the careful and rational use of the beneficial chemicals.

REGULATORY MANDATE

The widespread use and misuse of the early, toxic pesticides created an awareness of the potential health hazards posed by them and the need to protect the consumer from residues in foods. It was not until 1906 that the Wiley or Sherman Act was passed, creating the first Federal Food and Drugs Act. This was replaced by the Federal Food, Drug and Cosmetic Act (FDCA) in 1938, with specific pesticide amendments being passed in 1954 and 1958; these required that pesticide tolerances be established for all agricultural commodities. The 1958 amendment contained the famous Delaney clause (Section 409), which states that "no additive shall be deemed safe if it is found to induce cancer when ingested by man or animal or, if it is found, after tests which are appropriate for the evaluation of the safely of food additives, to induce cancer in man or animals" (National Academy of Sciences, 1987). It should be noted that the Delaney clause does not require proof of carcinogenicity in humans. Pesticides fall under this "additive" legislation.

The Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) was originally passed by Congress in 1947 as a labeling statute that would group all pest control products—initially only insecticides, fungicides, rodenticides, and herbicides—under one law to be administered by the U.S. Department of Agriculture (USDA). Amendments in 1959 and 1961 added nematicides, plant growth regulators, defoliants, and desiccants to FIFRA jurisdiction, plus the authorizations to deny, suspend, or cancel registrations of products, although it assured the registrant's right to appeal. In 1972, FIFRA was reorganized and administrative authority was turned over to the newly formed Environmental Protection Agency (EPA). The new law, along with subsequent amendments in 1975, 1978, 1980, and 1984, defines the registration requirements and appropriate chemical, toxicologic, and environmental impact studies, label specifications, use restrictions, tolerances for pesticide residues on raw agricultural products, and the responsibility to monitor pesticide residue levels in foods. FIFRA is not all-encompassing because the Food and Drug Administration (FDA) retains the basic responsibility for both monitoring residue levels and for seizure of foods not in compliance with the regulations; what is more, the USDA continues to be the authority responsible for the monitoring of meat and poultry for pesticides as well as for other chemicals. The Food Quality Protection Act (FQPA), passed by the U.S. Congress in 1996, amended federal laws regarding pesticides to give special consideration for children by (1) providing additional protection when allowable levels of pesticides for foods are set (data providing children's food consumption patterns, recognition of all possible routes of exposure in risk assessment); and (2) considering whether infants and children are disproportionally susceptible to pesticides. Where data on the pesticides are not adequate, pesticide tolerances for children must incorporate an additional 10-fold safety factor.

FIFRA regulations set out the requirements essential before EPA-Office of Programs review of any pesticide and/or formulated product can occur for registration purposes. This information base includes product and residue chemistry, environmental fate, toxicology, biotransformation/degradation, occupational exposure and reentry protection, spray drift, environmental impact on nontarget species, and product performance and efficacy. Depending on the proposed use pattern of the pesticide, results from different "groups" or toxicologic studies are required to support the registration. The typical spectrum of basic pesticide toxicity data required under FIFRA regulations is summarized in Table 22-2. Extensive ancillary studies of environmental impact on birds, mammals, aquatic organisms, plants, soils, environmental persistence, and bioaccumulation are also required. A schematic diagram showing the "information package" required in support of a registration and the appropriate time span required to develop this database—from the point of patenting the newly synthesized chemical until its registration, production, marketing, and user acceptability—is shown in Fig. 22-3. Although the ultimate uses of the particular chemical will govern the extent of the information base required prior to registration, estimates of average development costs on the order of $30 to $80 million are not unrealistic.

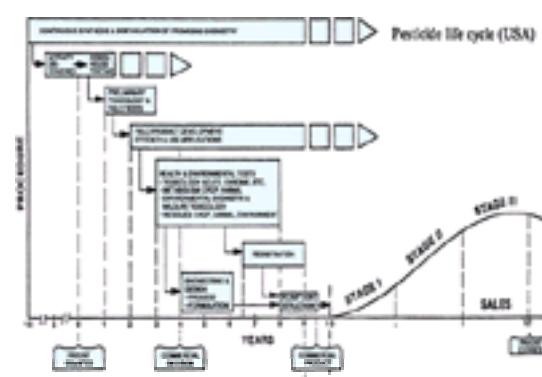
Table 22-2 Basic Requirements Regarding Toxicity Data for New Pesticide Registrations


Figure 22-3. A schematic diagram depicting the generation of an appropriate toxicity database, the time frame for data acquisition and the significant milestones in the life cycle of a pesticide in the United States. Stages I to III represent the sales of the pesticide once the commercial product enters the marketplace. (GIFAP Bulletin, Sept. 1983, with permission.)

Other nations including Canada, the United Kingdom, Japan, and, more recently, the European Economic Community (EEC) have promulgated harmonizing legislation similar to that of the United States as safeguards in human exposure to pesticides in food commodities. Some developing nations, with a shortage of trained technical, scientific, and legal professionals to develop their own legislation, have adopted the regulatory framework of one or another of the industrialized nations, permitting the sale and use of pesticides registered under the legislation of that country but prohibiting the use of agents unable to meet the stringent requirements. In still other countries, almost any pesticide ever manufactured is available, no legislation having been introduced to curb adverse effects to the environment and human health.

Exposure

The evaluation of the hazards of pesticides to human health begins with the development of a dose-effect relationship based on documented and anecdotal information on human exposure (Fig. 22-4). Several populations of individuals may be identified as having exposure to a range of concentrations of a particular agent, including: (1) accidental and/or suicidal poisonings that no amount of legislation or study can prevent; (2) occupational (manufacturing, mixing/loading, application, harvesting, and handling of crops) exposure (Albertson and Cross, 1993; Edmiston and Maddy, 1987); (3) bystander exposure to off-target drift from spraying operations with, in some cases, the development of hypersensitivity (Bartle, 1991); (4) the general public who consume food items containing pesticide residues as a consequence of the illegal use of an agent (e.g., aldicarb on melons and cucumbers) or its misuse, in terms of an incorrect application rate or picking and shipping a crop too soon after pesticide application, resulting in residue concentrations above established tolerance levels. The media are replete with documented incidents of environmental contamination by pesticides: (1) of surface and/or groundwater essential as sources of potable drinking water; (2) of commercial fish stock as well as

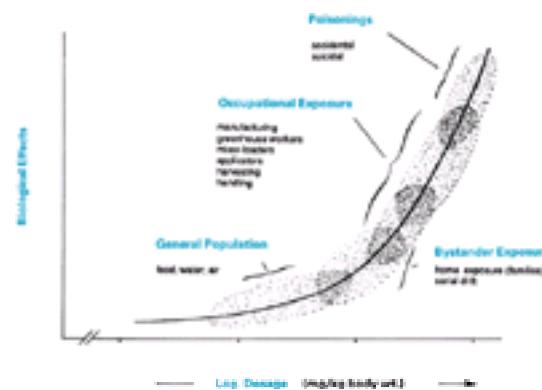
sporting fish; (3) of wildlife upon which native peoples depend as a major source of dietary protein; and (4) of long-distance aerial transport of undeposited and/or revolatilized pesticide.


Figure 22-4. A theoretical dose – effect relationship for acute toxicity, comparing the potential for exposure in terms of occupation, level of exposure and possible biological effects.

The shape of the dose-effect curve is dependent on a detailed knowledge of the amount of exposure received by each of these groups. Within each group, variability will be considerable. Frequently, exposure evaluations begin at the top of the relationship where exposure is greatest, more easily estimated, and, in most cases, the acute biological effects are clearly observed and may be associated with a specific agent or a class of chemicals over a relatively narrow dosage range. If no discernible adverse health effects are seen at high levels of exposure, it is unlikely that anything will be observed at lower levels of exposure. Although this hypothesis may be true for acute systemic effects, it is not applicable to chronic effects (changes in organ function, mutagenicity, teratogenicity, carcinogenicity) that may develop after some latent period following either a single high-level exposure, repeated moderate or high-level exposure, or annual exposure to low levels of the agents for decades.

There is sufficiently detailed documentation on many pesticidal poisonings to permit an estimation of exposure (Hayes, 1982). In some 48 suicide attempts by ingestion of the herbicide glyphosate, the average volume of product (concentrate containing active ingredient and a surfactant) ingested was 120 mL [range of 104 mL (nonfatal) to 206 mL (fatal)] (Swada et al., 1988). In other cases, such as one involving the insecticide fenitrothion, where the individual experienced dermal exposure to a 7.5% solution of the agent in corn oil wiped up with facial tissues by a bare hand, exposure was more difficult to assess (Ecobichon et al., 1977). It is imperative that forensic and clinical toxicologists and emergency service personnel attempt to ascertain how much of the material was involved in the poisoning.

Worker exposure can be estimated within reason by considering the various job functions performed (e.g., diluting concentrated formulations, loading diluted end-use formulations into tanks, spray application, harvesting sprayed crops, postharvest handling of sprayed crops, etc.). The potential level(s) of pesticide encountered in each job category and the route(s) of exposure can be estimated. The majority of occupational illnesses arising from pesticides involve dermal exposure enhanced, in certain job categories, by acquisition of a portion of the dosage by the inhalation of the aerosolized spray. Many exposures appear to be entirely dermal in character (Vercruysse et al., 1999). The surface areas of the unclothed parts of the body of an unprotected worker are shown in Table 22-3, being derived from the U.S. EPA (1987). Data for the entire surface area of a "50 percentile man," as determined by Spear and coworkers (1977), are shown in Table 22-4. With surface patch (gauze, fabric) testing on various parts of the body, accurate estimates of dermal exposure can be obtained. The reader is referred to the following studies for details: Wolfe and colleagues (1967, 1972), Wojeck and coworkers (1981), and Franklin and coworkers (1981). Where inhalation can be considered to contribute significantly to the total exposure, as in greenhouse and other structural spraying operations in enclosed environments, drivers in tractor cabs, operators of rotary fan mist sprayers, and other operations, measurements of aerial concentrations in the working environment can be made and related to respiratory rates and length of time spent in that environment. Assessment of the inhalation component of an exposure can be obtained with personal air sampling monitors worn during the day (Trumbull et al., 1985; Grover et al., 1986).

UNCLOTHED SURFACE	SURFACE AREA (SQ FT)	PERCENT OF TOTAL
Face	0.70	22.0
Hands	0.87	27.6
Forearms	1.30	41.3
Back of neck	0.12	3.8
Front of neck and "v" of chest	0.16	5.1

Table 22-4 Percent of Total Body Surface Area Represented by Body Regions4

In the past, direct exposure was estimated by measuring deposition (on skin, clothing, or surrogate patch) or by ambient air concentrations of the potentially toxic agent (Durham and Wolfe, 1962). In reality, direct exposure should be attributed only to pesticide residues gaining entry into the body by systemic absorption following ingestion, inhalation, and/or transdermal penetration. Total exposure can be estimated by measuring excretory products (the parent chemical, degradation products) in urine and feces over a suitable postexposure time interval (Durham et al., 1972; Kolmodin-Hedmann et al., 1983; Frank et al., 1985; Grover et al., 1986; Takamiya, 1994; Azaroff, 1999). Potential biological effects of exposure can be monitored, including plasma and erythrocytic cholinesterase measurements, d-aminolevulinic dehydratase (ALAD), superoxide dismutase (SOD) activities, cytogenic analysis of lymphocytic micronuclei, semen quality, fertility, etc. (Lopez-Carillo and Lopez-Cervantes, 1993; Ciesielski et al., 1994; Davies et al., 1998; Panemangalore et al., 1998; Venegas et al., 1998; Larsen et al., 1999). A more complete discussion of the topic of occupational exposure can be found in Ecobichon (1998a).

Minimal protection of certain parts of the body can markedly reduce exposure to an agent. Protection of the hands (5.6 percent of the body surface) by appropriate

chemical-resistant gloves may reduce contamination by 33 percent (in forest spraying with a knapsack sprayer having a single-nozzle lance), by 66 percent (in weed control using tractor-mounted booms equipped with hydraulic nozzles), or by 86 percent (involving filling tanks on tractor-powered sprayers) (Bdonsall, 1985). Studies monitoring the absorption of pesticides applied to the skin of different areas of the human body have revealed marked regional variations in per cutaneous absorption, with the greatest uptake being in the scrotal region, followed by the axilla, forehead, face, scalp, the dorsal aspect of the hand, the palm of the hand, and the forearm in decreasing order (Feldman and Maiback, 1974).

The exposure of a bystander, where an individual is accidentally sprayed directly or exposed to aerial off-target drifting aerosol, is considerably more difficult to assess. The levels encountered may be severalfold lower than those in the occupational setting, making the analysis of residue and the detection of meaningful biological changes more difficult. Greater variation in exposure estimates and biological effects can be anticipated. The adverse health effects may be subtle in appearance and nonspecific, reflecting a slow deterioration of physiologic function clouded by the individual's adjustment or adaptation to the changes, taking many years to develop to the point of detection. The identification of pesticide-related adverse health effects in the general population, who inadvertently acquire low levels of pesticides daily via food and water, is extremely difficult. The residue levels in these media are often orders of magnitude lower than those encountered in occupational or bystander exposure and are at or near the limits of analytical detection by sophisticated techniques. Any biological effects resulting from such low-level exposure are unlikely to be distinctive and any causal association with a particular chemical or class of agents is likely to be tenuous and confounded by many other factors of a given lifestyle.

Many of the public concerns about pesticides are related to "older" chemicals, these having entered the market in the 1950s and 1960s without the benefit of the extensive toxicity and environmental impact studies demanded prior to the registration of chemicals today. It must also be pointed out that many of these older pesticides have received little reassessment using the more definitive techniques and protocols required today. Although government agencies and industry have been slow in their reevaluation of a vast array of pesticides in use, reassessment often comes in the wake of or concomitant with some recently disclosed adverse environmental or health effect. Given the above-mentioned costs of conducting a full range of studies (introductory section, this chapter), the time frame required, and the limited market for some of these chemicals in North America or even worldwide, the registration of many of these pesticides will be withdrawn voluntarily by industry, and the answers to some of the public's concerns will never be obtained. Hazardous chemicals will be removed from use but, unfortunately, it is possible that some very beneficial and essential pesticides will be lost. The problems of today's situation, created by the last generation and inherited by the present one, still must be dealt with.

INSECTICIDES

The literature pertaining to the chemistry and development of the various classes of insecticides over the past 45 years is extensive and the reader is referred to the monographs of O'Brien (1960, 1967), Melnikov (1971), Fest and Schmidt (1973), Brooks (1974), Eto (1974), Hayes (1982), Kuhr and Dorough (1976), Buchel (1983), Leahey (1985), Chambers and Levi (1992), and Ecobichon and Joy (1994) for detailed discussions of the chemistry, nomenclature (chemical, common, and trade names), biotransformation and degradation, and environmental effects as well as target and nontarget species toxicity. Compilations of LD $_{50}$ values in the laboratory rat may be found in Gaines (1969), Frear (1969), and Worthing (1987). Acute toxicity data for laboratory animals, fish, and wildlife are recorded in a number of reports (Pickering et al., 1962; Tucker and Crabtree, 1970; Worthing, 1987). Several compilations of pesticide monographs exist, giving brief but succinct profiles of the physical and chemical properties of various pesticides as well as their environmental persistence and toxicity to wildlife, domestic animals, and humans (Kamrin, 1997; Montgomery, 1997; Tomlin, 1997). Only selected examples of the classes of insecticides are discussed in this chapter, with emphasis on their toxicity to humans.
